The second edition of *Bergey's Manual of Systematic Bacteriology* reflects the enormous progress that has been made in microbial taxonomy since the first edition was published. This is particularly true of the molecular approaches to phylogenetic analysis. Whereas microbial classification in the first edition was phenetic (based on phenotypic characterization), classification in the second edition of *Bergey's Manual* is largely phylogenetic. Although Gram-staining properties are generally considered phenetic characteristics, they also play a role in the phylogenetic classification of microbes.

In addition to the reorganization based on phylogeny, the second edition has more ecological information about individual taxa. It does not group all the clinically important bacteria together as the first edition did. Instead, pathogenic species are placed phylogenetically and thus scattered throughout the five volumes:

Volume 1, *The Archaea and the Deeply Branching and Phototrophic Bacteria*
Volume 2, *The Proteobacteria*
Volume 3, *The Firmicutes*
Volume 4, *The Bacteroidetes, Spirochaetes, Tenericutes (Mollicutes), Acidobacteria, Fibrobacteres, Fusobacteria, Dictyoglomi, Gemmatimonadetes, Lentisphaerae, Verrucomicrobia, Chlamydiae, and Planctomycetes*
Volume 5, *The Actinobacteria*

Figure 19.13 illustrates most of the groups covered in *Bergey's Manual* and in chapters 20–24.

Retrieve, Infer, Apply

1. Why is the second edition of *Bergey's Manual* no longer based on phenetic classification?
2. Describe two different situations in which it would be essential to identify the genus and species of a bacterium or archaeon.

Key Concepts

19.1 Microbial Taxonomy Is Based on the Evolution of Multiple Traits

- Taxonomy, the science of biological classification, is composed of three parts: classification, nomenclature, and identification.
- A polyphasic approach is used to classify microbes. This incorporates information gleaned from genetic, phenotypic, and phylogenetic analysis (**Table 19.1**).

19.2 Taxonomic Ranks Provide an Organizational Framework

- Taxonomic ranks are arranged in a nonoverlapping hierarchy (**figure 19.1**).
- A bacterial or archaeal species is a collection of strains that have many stable properties in common and differ significantly from other groups of strains.
- Microorganisms are named according to the binomial system.

19.3 Microbial Taxonomy and Phylogeny Are Largely Based on Molecular Characterization

- Historically, microbial taxonomic and phylogenic analysis used morphological, physiological, and ecological characteristics. These remain important in building a complete picture that also includes molecular information.
- The G + C content of DNA is taxonomically valuable because it is an indirect reflection of the base sequence.
- Nucleic acid hybridization studies are used to compare DNA or RNA sequences and thus determine genetic relatedness.
- Nucleic acid sequencing is the most powerful and direct method for comparing genomes. The sequences of SSU rRNA are used most often in phylogenetic studies of microbes (**figure 19.3**). Alternatively, SSU rRNA genes can be analyzed by phylotyping, which does not require nucleotide sequencing (**figure 19.4**).
- Additional techniques must be applied to identify a microbe at the species or strain level. They include restriction fragment length polymorphism (RFLP) analysis, multilocus sequence typing (MLST), the study of repetitive sequences, and single nucleotide polymorphism analysis (**figures 19.5** and **19.6**).

19.4 Phylogenetic Trees Illustrate Evolutionary Relationships

- Phylogenetic relationships often are shown in the form of branched diagrams called phylogenetic trees. Trees are based on pairwise comparison of amino acid or nucleotide sequences, followed by computer analysis (**figure 19.7**).
- Trees may be either rooted or unrooted and are created in several different ways. Unrooted trees can be rooted by including an outgroup when the tree is constructed (**figure 19.8**).
- Microbes have a long history of horizontal gene transfer, which confuses taxonomic analysis. Complete genome analysis has revealed a set of core genes found in all members of a given taxon and a pan-genome, which is the sum of all genes outside the core genome of that taxon. The pan-genome is the result of horizontal gene transfer (**figure 19.9**).

19.5 Evolutionary Processes and the Concept of a Microbial Species Inspire Debate

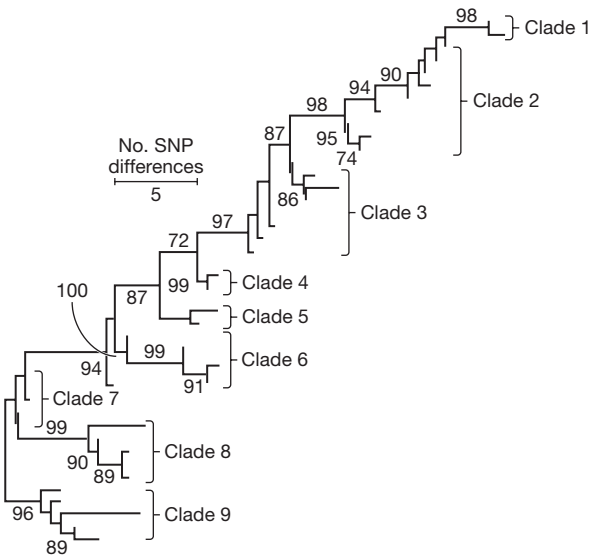
- There are several hypotheses regarding the origin of eukaryotic cells. Most biologists agree that endosymbioses of a bacterium and a cyanobacterium gave rise to mitochondria and chloroplasts, respectively (**figure 19.10**).
- The operational definition of a microbial species is based on criteria approved by the International Committee on the Systematics of Prokaryotes. This includes at least 70% whole genome similarity as determined by DNA-DNA hybridization, at least 97% 16S rRNA homology, no more than a 5°C difference in % G + C, and physiological, morphological, and ecological similarity.
- The concept of a microbial species is based on evolution. The ecotype model describes the outcome of a periodic natural selection on a genetically homogeneous microbial population. Individuals that acquire adaptive mutations are the source of microbial diversity (**figure 19.11**).
- Horizontal gene transfer is also important in microbial evolution. However, speciation is thought to be the outcome of mutation, while rapid adaptation to new niches is mediated by horizontal gene transfer (**figure 19.12**).

19.6 *Bergey's Manual of Systematic Bacteriology*

- *Bergey's Manual of Systematic Bacteriology* is based on the accepted system of prokaryotic taxonomy.
- The second edition of *Bergey's Manual* provides phylogenetic classifications. Bacteria are classified among 26 phyla and archaea are divided between two phyla. Comparisons of nucleic acid sequences, particularly 16S rRNA sequences, are the foundation of this classification.

Compare, Hypothesize, Invent

1. Consider the fact that the use of 16S rRNA sequencing as a taxonomic and phylogenetic tool has resulted in tripling the number of bacterial phyla. Why has the advent of this genetic technique expanded the currently accepted number of microbial phyla?
2. *Bacteria* and *Archaea* were classified phenetically in the first edition of *Bergey's Manual of Systematic Bacteriology*. What are the advantages and disadvantages of the phylogenetic classification used in the second edition?
3. You have recently established a pure culture of a new archaeon from soil. Describe the approaches you would use to identify your new microbe to the species level.
4. Discuss the problems in developing an accurate phylogenetic tree. Do you think it is possible to create a completely accurate universal phylogenetic tree? Explain your answer.
5. Why is the current classification system for *Bacteria* and *Archaea* likely to change considerably? How would one select the best features to use in the identification of unknown microbes and determination of relatedness?
6. In 2007 a severe food-borne outbreak of enterohemorrhagic *E. coli* (EHEC) O157:H7 occurred in the United States. The strain that caused this outbreak seemed to be more virulent, causing more severe illness, than previous outbreaks. To test if new, more virulent strains of EHEC might be evolving, SNP analysis was performed on 500 clinical isolates of the bacterium that were collected before, during, and after the 2007 outbreak. SNPs were detected in 96 loci, and 39 discrete SNP genotypes were identified. These could be separated into nine different clades, as shown in this phylogenetic tree. The amount of toxin produced and the severity of disease differed among clades. It was discovered that members of clade 8 caused the 2007 outbreak and this clade was associated with high levels of toxin production. Discuss the evolution of this pathogen. Specifically consider each of these mechanisms of genetic variation: horizontal gene transfer, mutation, gene amplification, gene deletion, and intragenic recombination. Which do you think is (or are) the most important? Explain your answer.



Read the original paper: Manning, S. D., et al. 2008. Variation in virulence among clades of *Escherichia coli* O157:H7 associated with disease outbreaks. *Proc. Natl. Acad. Sci. USA*. 105:4868.

7. The enzymes responsible for DNA replication in archaea are often considered simplified versions of eukaryotic replication machinery. However, archaea also possess replication enzymes that are unique to this domain, and some archaeal replication proteins have eukaryotic homologs that are not involved in replication. It is thought that genes involved in "information processing" (i.e., replication, transcription, and translation) are typically part of the core genome, but replication proteins vary greatly among archaeal lineages. These observations prompted a group of French microbiologists to survey 22 genes that encode DNA replication-related proteins in 142 archaeal genomes. Suggest a means by which the authors were able to assign these genes to the core genome or the pan-genome for each archaeal phylum and genus analyzed. How do you think the authors used these data to infer the last common archaeal ancestor with respect to the replication apparatus? What would you predict regarding the presence of eukaryotic replication genes in archaea if the last common eukaryotic ancestor arose from an archaeon?

Archaea

The recovery of natural gas (methane, produced by archaea) is a boon to the U.S. energy economy, but the method by which it is extracted—hydraulic fracturing—is not without controversy.

Methanogenic Archaea Fuel Domestic Energy Debate

Long before gas prices surged and politicians began to argue about energy security, archaea were busy generating methane, otherwise known as natural gas. Although methane deposits are billions of years old, only recently have geologists recognized that at least 2,000 trillion cubic feet (Tcf) of natural gas could be recovered within the United States. This upward revision is largely due to the inclusion of 750 Tcf of methane trapped in underground shale. This domestic source of gas, much of it under Appalachian and Rocky Mountain states, could provide over 20% of the total U.S. gas supply by 2020. This should be good news as the United States consumes about 25 Tcf annually. But there is a hitch. The methane has to be extracted from the earth.

Before we tackle the extraction problem, let's discuss how all that natural gas got there in the first place. There are two sources of methane: abiotic and biotic. Abiotic methane results principally from thermal decomposition of sedimentary rocks and is almost negligible compared to that produced by microbes. All biologically produced methane is generated by methanogenic archaea from either $CO_2 + H_2$ or acetate (section 20.4). Evidently, shale beneath the United States has been home to a vast and productive archaeal community for eons.

Although the abundance of natural gas in shale has been known for a long time, only recently has methane recovery become financially worthwhile. The price of extracting the gas trapped within the soft, porous shale far exceeded any later profits. But the recent development of horizontal drilling and hydraulic fracturing ("fracking") technologies changed the economic equation. Now a typical well can be drilled vertically about 3,000 meters and then extended just as far horizontally. Fracking involves high-pressure pumping of up to 9 million liters of water, sand, and chemicals into the well. This cracks the shale, while a "propping agent" keeps the pores open so the gas can be recovered.

However, some citizens in communities where fracking takes place are concerned about groundwater contamination, fracking-induced earthquakes, the escape of contaminated drilling fluids at the well surface, and methane leaking from the wells, thereby increasing the carbon footprint of natural gas usage. Federal regulations mandate that recovered drilling fluids be treated before they are discharged back into the environment. In some cases, drillers have used municipal wastewater treatment facilities for this, creating a tremendous burden on local infrastructure. Escaping methane is considered problematic because methane is a harmful greenhouse gas (*see section 28.2*). If the United States is to continue to use this tremendous natural resource, these concerns must be addressed to the satisfaction of producers and consumers.

In this chapter, we review archaea, which were once considered almost exclusively extremophiles—organisms that thrive in extreme conditions, where they do unusual things, such as make methane. However, we know now that they are physiologically and ecologically diverse, found in both mundane and challenging environments. Indeed, the third domain of life deserves our respect, especially if they are to provide us with energy to fuel our power grid.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Draw the basic structure of the phylogenetic tree of life based on SSU rRNA sequences and explain the placement of *Archaea* (section 1.2)
- ✔ Describe an archaeal cell wall and membrane, including component parts (section 4.2)
- ✔ List environmental factors that influence microbial growth, including oxygen (section 7.4)
- ✔ Describe the difference between heterotrophy and autotrophy (section 11.1)
- ✔ Define chemolithotrophy and identify an example of an electron donor and an acceptor (section 11.10)
- ✔ Review archaeal DNA replication, gene transcription, and protein synthesis and secretion (chapter 15)
- ✔ Describe the use of metagenomics in the discovery of new microbial taxa (section 18.3)

20.1 Overview of *Archaea*

After reading this section, you should be able to:

- List some common habitats in which archaea reside
- Describe the debate that surrounds archaeal taxonomy
- Compare at least three key metabolic pathways that are central to archaeal physiology with those used by bacteria

Archaea have many features in common with eukaryotes, others in common with bacteria, and still other elements that are uniquely archaeal. In general, archaeal genes that encode proteins involved in DNA replication, transcription, and translation, often called information genes, share homology with those of eukaryotes, whereas genes involved in metabolism are similar to bacterial genes. Some unique archaeal features include their tRNA structure and the production of methane. Like bacteria, archaea are quite diverse, both in morphology and physiology. They may be spherical, rod-shaped, spiral, lobed, cuboidal, triangular, plate-shaped, irregularly shaped, or pleomorphic. Some are single cells, whereas others form filaments or aggregates. They range in diameter from 0.3 to over 15 μm, and some filaments can grow up to 200 μm in length. Although they stain either Gram positive or Gram negative, they have unique cell walls—different from that of bacteria. Multiplication is usually by binary fission but may be by budding, fragmentation, or other mechanisms. Archaea are just as diverse physiologically. They can be aerobic, facultatively anaerobic, or strictly anaerobic. Nutritionally, they range from chemolithoautotrophs to organotrophs. They include psychrophiles, mesophiles, and hyperthermophiles that can grow above 100°C.

Archaea inhabit a wide variety of habitats, but for many years they were considered microbes of extreme environments, or extremophiles. Indeed, many, but by no means all, archaea inhabit niches that have very high or low temperatures or pH, concentrated salts, or are completely anoxic. For instance, in some hypersaline environments, their populations become so dense that the brine is red with archaeal pigments. By contrast, archaea also make up about 20% of the prokaryotic biomass of marine plankton and are important members of some soil communities—environments that cannot be considered extreme. In addition, some are symbionts in the digestive tracts of animals, but to date, no pathogenic archaea have been confirmed. Thus the notion that archaea are exclusively extremophiles is no longer valid as archaea are known to inhabit temperate and tropical soils and waters as well as the human body.

Archaeal Taxonomy

As shown in **table 20.1**, well-characterized archaea can be divided into six major groups based on physiological and morphological differences. However, we use a taxonomic organization to discuss archaea. Published in 2001, the first volume of *Bergey's Manual of Systematic Bacteriology* divides *Archaea* into the phyla *Euryarchaeota* (Greek *eurus,* wide, and *archaios,* ancient or primitive) and *Crenarchaeota* (Greek *crene,* spring or fount, and *archaios*) (**figure 20.1**). The euryarchaeotes are given this name because they occupy a wide variety of ecological niches and are therefore metabolically diverse. Methanogens, extreme halophiles, sulfate reducers, and many extreme thermophiles with sulfur-dependent metabolism are placed in *Euryarchaeota*. Crenarchaeotes are thought to resemble the ancestral archaea, and all are thermophiles or hyperthermophiles found in unusual environments such as acidic hot springs and submarine hydrothermal vents.

Crenarchaeota phylogeny has been the subject of considerable debate over the last decade or so. Metagenomic sequences suggested the presence of what were dubbed "mesophilic crenarchaeota," distinguishing them from thermophilic crenarchaeotes in pure culture. More recently, many of these organisms have been placed in the phylum *Thaumarchaeota* (Greek *thaumas,* wonder) (**figure 20.2**). The phylum was initially proposed based on 16S rRNA data from uncultured archaea and the genomic sequence of *Cenarchaeum symbiosum,* a marine sponge symbiont. More recently the genomes of *Nitrosopumilus maritimus* and *Candidatus* (*Ca.*) Nitrososphaera gargensis have been analyzed. In addition, there is now an abundance of metagenomic and single-cell genome studies that demonstrate the presence of these organisms in both marine and soil environments. Thaumarchaea are aerobic ammonia-oxidizing archaea; all such nitrifying archaea belong to this lineage.

Three additional phyla have been proposed. The phylum *Korarchaeota* (from the Greek word for "young man") was suggested over a decade ago, based solely on the SSU rRNA data of uncultured microbes. Since that time, there have been many metagenomic and single-cell genomic analyses, but as yet no members of this candidate phylum have been grown in pure culture. Perhaps this is because members of this lineage are hyperthermophilic anaerobes, residing in marine and terrestrial geothermal habitats. Recent genome analysis of (*Ca.*) Korarchaeum cryptofilum reveals tRNA maturation proteins that resemble those of euryarchaeotes. It is argued that this helps support the notion that *Korarchaeota* represents a unique lineage, separate from *Crenarchaeota,* where *Bergey's* places these microbes (figure 20.2). K. cryptofilum also lacks genes for many biosynthetic pathways, which may also help explain why it has not yet been grown in pure culture. Because this archaeon has not been grown axenically, it has candidate (*Candidatus*) species status and its name is not italicized.

The proposed phylum, *Aigarchaeota,* is more tenuous. It is based largely on the genome sequence of the archaeon *Ca.* Caldiarchaeum subterraneum, which was found in a subsurface geothermal stream. This is very controversial, with some taxonomists arguing that C. subterraneum and related taxa are members of *Thaumarchaeota,* while others feel that these microbes belong in *Crenarchaeota.* ⏮ *Comparative genomics (section 18.7); Phylogenetic trees illustrate evolutionary relationships (section 19.4)*

The third proposed phylum is also based solely on genomic sequences recovered from the environment. The discovery of *Lokiarchaeota* is particularly exciting because these sequences encode "eukaryotic signature proteins." If further evidence continues to support this lineage, the lokiarchaeaotes may represent the closest extant relatives of the first eukaryotic cell, lending support to the hypothesis that eukaryotes arose from an archaeal ancestor. ⏮ *Evolution of the the three domains of life (section 19.5)*

Table 20.1 Characteristics of the Major Archaeal Physiological Groups

Group	General Characteristics	Representative Genera
Methanogenic archaea	Strict anaerobes. Methane is the major metabolic end product. S^0 may be reduced to H_2S without yielding energy. Cells possess coenzyme M, factors 420 and 430, and methanopterin.	*Methanobacterium (E)*[1] *Methanococcus (E)* *Methanomicrobium (E)* *Methanosarcina (E)*
Archaeal sulfate reducers	Regular and irregular cocci. H_2S formed from thiosulfate and sulfate. Autotrophic growth with thiosulfate and H_2. Can grow heterotrophically. Traces of methane also formed. Extremely thermophilic and strictly anaerobic. Possess factor 420 and methanopterin but not coenzyme M or factor 430.	*Archaeoglobus (E)*
Extremely halophilic archaea	Rods, cocci, or irregular shaped cells that may include pyramids or cubes. Primarily chemoorganoheterotrophs. Most species require sodium chloride ≥1.5 M, but some survive in as little as 0.5 M. Most produce characteristic bright-red colonies; some are unpigmented. Neutrophilic to alkalophilic. Generally mesophilic; however, at least one species is known to grow at 55°C. Possess either archaerhodopsin or halorhodopsin and can use light energy to produce ATP.	*Halobacterium (E)* *Halococcus (E)* *Natronobacterium (E)*
Cell wall-less archaea	Pleomorphic cells. Thermoacidophilic and chemoorganotrophic. Facultatively anaerobic. Plasma membrane contains mannose-rich glycoproteins and lipoglycans.	*Thermoplasma (E)*
Extremely thermophilic S^0-metabolizers	Rods, filaments or cocci. Obligately thermophilic (optimum growth temperature between 70–100°C). Usually strict anaerobes but may be aerobic or facultative. Acidophilic or neutrophilic. Autotrophic or heterotrophic. Most are sulfur metabolizers. S^0 reduced to H_2S anaerobically; H_2S or S^0 oxidized to H_2SO_4 aerobically.	*Desulfurococcus (C)* *Pyrodictium (C)* *Pyrococcus (E)* *Sulfolobus (C)* *Thermococcus (E)* *Thermoproteus (C)*
Mesophilic aerobic ammonia-oxidizers	Globally distributed in marine and soil environments, chemolithoautotrophic, using ammonia as electron donor and oxygen as terminal electron acceptor. Use HP/HB[2] pathway for carbon fixation. Evidence that some deep-ocean thaumarchaea may use urea as carbon and nitrogen source.	*Cenarchaeum symbiosum (T)* *Nitrosopumilus maritimus (T)*

1 Indicates phylum; *E, Euryarchaeota, C, Crenarchaeota, T, Thaumarchaeota*
2 HP/HB, 3-Hydroxypropionate/4-Hydroxybutyrate Cycle

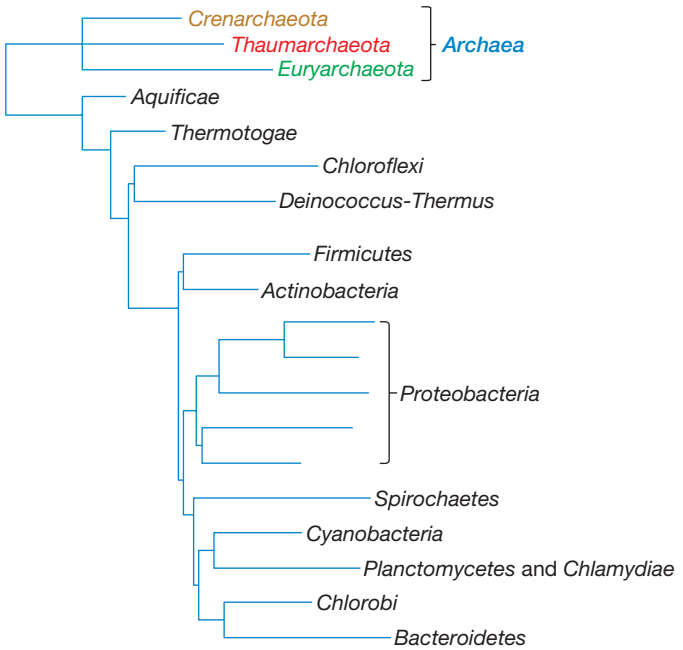

Figure 20.1 Phylogenetic Relationships Among Members of *Bacteria* and *Archaea*. Recognized archaeal lineages are highlighted.

Thus although *Bergey's* currently accepts only two archaeal phyla, one new phylum has been accepted, and *Korarchaeota* is fairly likely to gain full standing within the next 5 years. This state of flux in archaeal phylogeny demonstrates how dynamic microbial taxonomy can be. The use of molecular probes to dissect microbial communities, combined with innovative culture techniques, ensures that phylogenetic analysis will continue to evolve.

Metabolism

In view of the diversity of archaeal lifestyles, it is not surprising that archaeal metabolism varies greatly among members of different groups. Some archaea are heterotrophs; others are autotrophic. Here we review the pathways by which archaea fix carbon and catabolize carbohydrates.

CO_2-Fixation Pathways

Like all anabolic processes, carbon fixation requires reducing power and energy. Because inorganic carbon (CO_2 or HCO_3^-) has an oxidation state of +4, it requires four reducing equivalents for its assimilation into cellular carbon (oxidation state of 0). Most known autotrophic archaea are either anaerobic or live in low oxygen conditions. These microbes tend to use ferredoxin

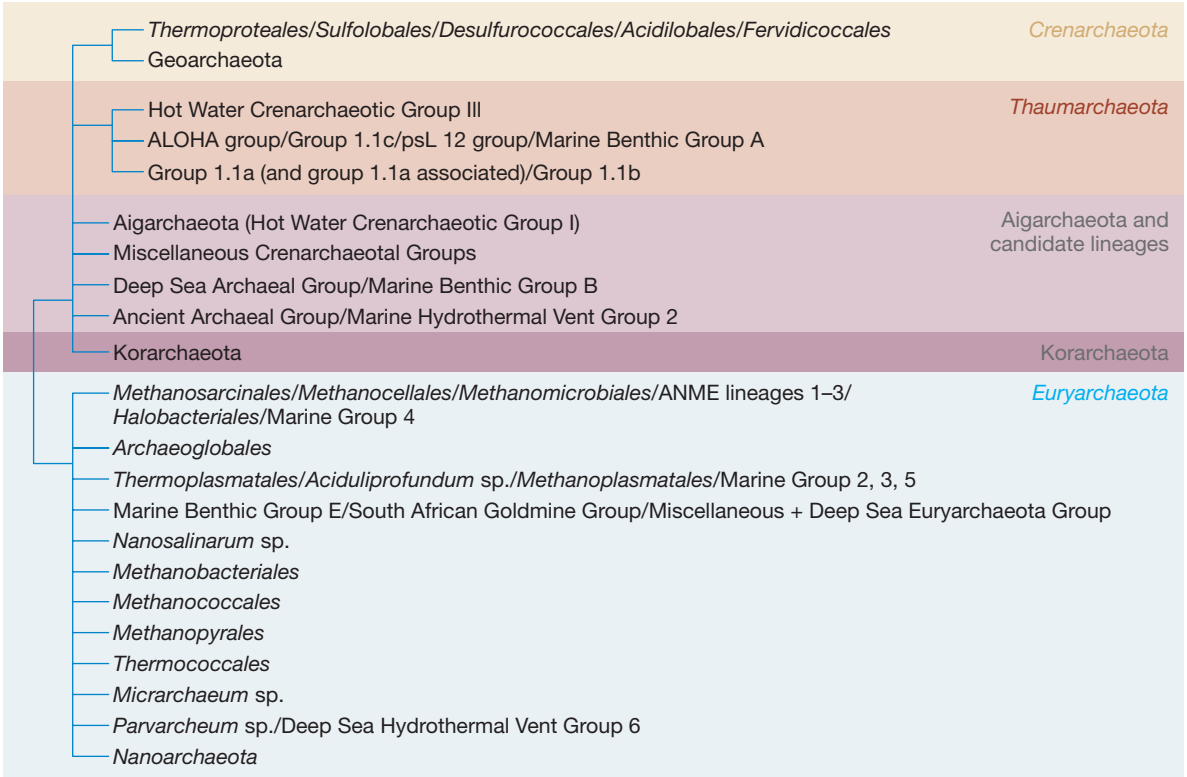

Figure 20.2 Phylogenetic Tree of *Archaea*. This schematic representation shows the phylogenetic diversity of archaea but also illustrates the dynamic nature of archaeal systematics. Phyla in gray font have not been accepted as valid. *Lokiarchaeaota* sequences were not available for consideration.

(Fd) instead of NADPH as their source of electrons. Because reduced Fd has a standard reduction potential (E_0') of −400 mV, it bears more energy than NADPH (E_0' of −320 mV), and most anaerobic pathways require less ATP per CO_2 fixed than aerobic carbon fixation pathways (e.g., the Calvin cycle). This is important as some autotrophic archaea, particularly methanogens, live close to their thermodynamic limit and therefore have very little (if any) ATP to spare. ⏮ *Redox reactions (section 10.3); CO_2 fixation (section 12.3)*

Three different carbon fixation pathways have been characterized in archaea: the reductive acetyl-CoA pathway, the 3-hydroxyproprionate/4-hydroxybutyrate (HP/HB) cycle, and the dicarboxylate/4-hydroxybutyrate (DC/HB) cycle (**table 20.2**). Recently it has been shown that the euryarchaeotes *Archaeoglobus* and *Ferroglobus* spp. use the reductive acetyl-CoA pathway (**figure 20.3**). By contrast, it has long been known that methanogens (also euryarchaeotes) use this pathway, as it is the most energetically favorable route. It requires only about one ATP per pyruvate synthesized, compared to seven for the Calvin cycle. As the pathway's name reflects, two CO_2 molecules are reduced and incorporated into one acetyl-CoA. One CO_2 is reduced to carbon monoxide (CO) by a CO dehydrogenase that also functions as an acetyl-CoA synthase. Another CO_2 is reduced to the level of CH_3 and bound to a tetrahydropterin coenzyme. Methanogens withdraw this from the pathway and reduce it to methane, as discussed in section 20.3. Thus methanogens use the acetyl-CoA pathway for both carbon assimilation and energy conservation. *Archaeoglobus* and *Ferroglobus* spp. capture energy using anaerobic respiration with sulfate as the terminal electron acceptor, so this pathway is used only for carbon fixation. Likewise, several anaerobic bacteria, including some planctomycetes, proteobacteria, and spirochetes, use the reductive acetyl-CoA pathway to fix CO_2.

The HP/HB cycle is found in members of the crenarchaeote order *Sulfolobales* and in *Thaumarchaeota* (**figure 20.4**). It

Table 20.2 Comparison of Archaeal CO_2-Fixation Pathways to the Calvin-Benson Cycle

CO_2-Fixation Pathway	Figure	Oxygen Tolerance	ATP Consumed per Pyruvate Produced	Archaeal Phyla Known to Use Pathway
Reductive Acetyl-CoA	20.3	Anaerobic	1	*Euryarchaeota*
3-Hydroxpropionate/ 4-Hydroxybutyrate	20.4	Aerobic	9	*Crenarchaeota* *Thaumarchaeota*
Dicarboxylate/ 4-Hydroxybutyrate	20.4	Anaerobic	5	*Crenarchaeota*
Calvin-Benson	12.4	Aerobic	7	None

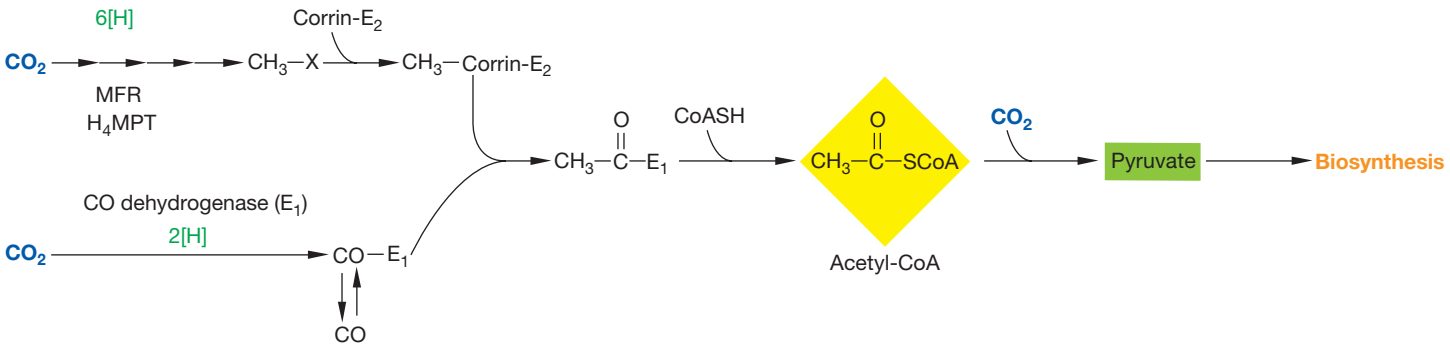

Figure 20.3 The Reductive Acetyl-CoA Pathway. Methanogens reduce two molecules of CO_2, each by a different mechanism, and combine them to form acetyl and then acetyl-CoA.

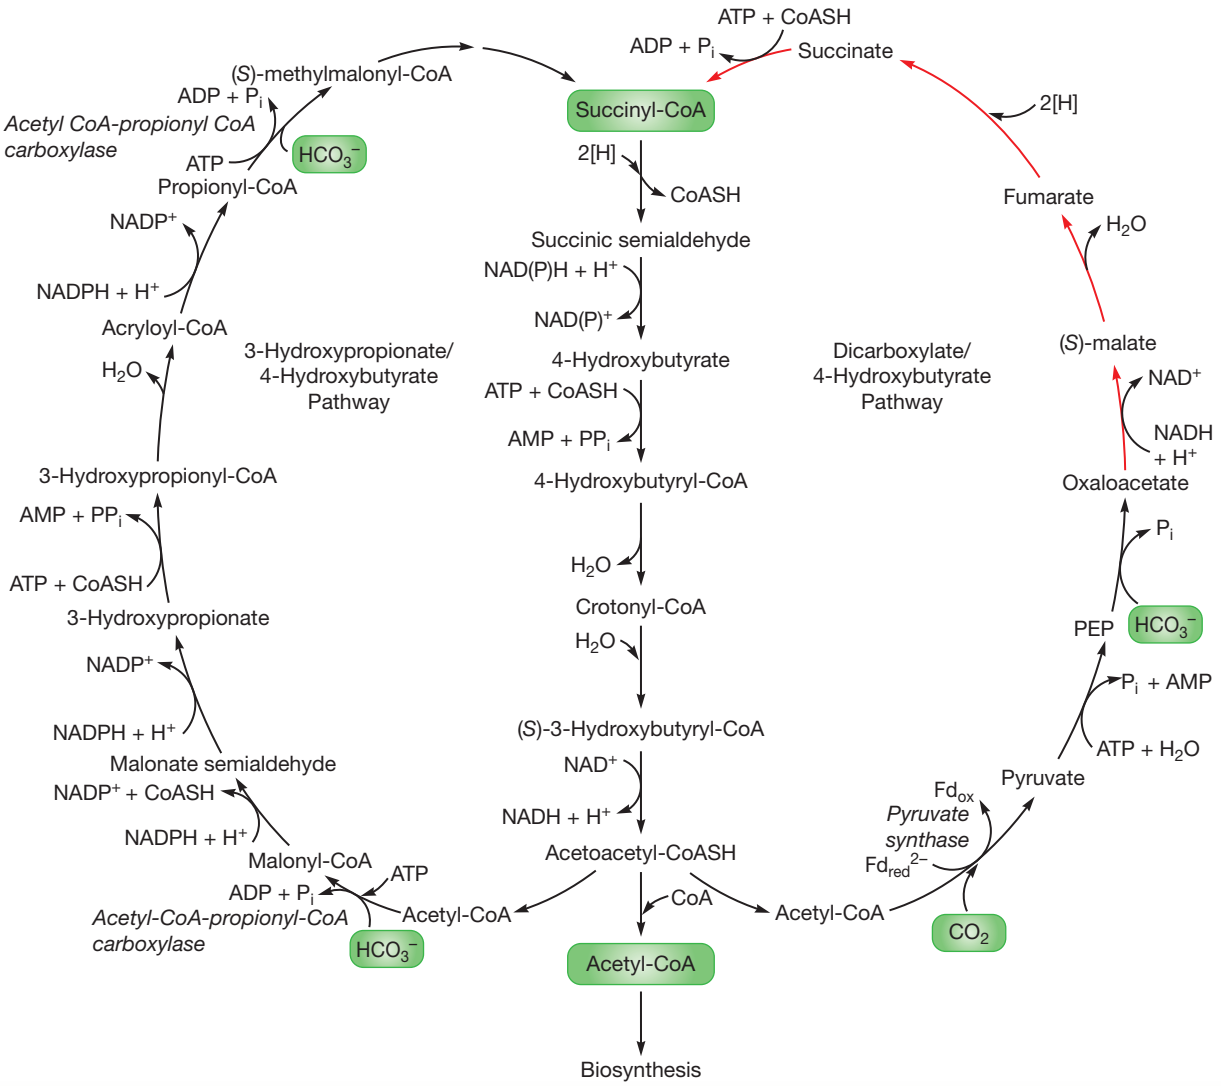

Figure 20.4 The 3-Hydroxypropionate/4-Hydroxybutyrate (HP/HB) and Dicarboxylate/4-Hydroxybutyrate (DC/HB) Cycles. Aerobic crenarchaea such as *Sulfolobus* and some thaumarchaea use the HP/HB pathway (left) to convert two bicarbonate ions into acetyl-CoA. Some crenarchaea fix one molecule of CO_2 and one HCO_3^- using the anaerobic DC/HB pathway (right). The reactions shown with red arrows are also used in the reductive tricarboxylic acid cycle.

MICRO INQUIRY *Given that the DC/HB pathway uses far less ATP per pyruvate synthesized than the HP/HB pathway, why do some archaea use the HP/HB pathway instead?*

requires more energy than any other CO_2 fixation pathway (9 ATP/pyruvate synthesized) but has other advantages. It has a low demand for metal cofactors, and unlike either the acetyl-CoA pathway or the DC/HB cycle, it can operate under aerobic conditions (table 20.2). The key carboxylase enzyme, a biotin-dependent acetyl-CoA/propionyl-CoA carboxylase, accepts two bicarbonate ions (HCO_3^-) in a series of steps that yields succinyl-CoA and net synthesis of one acetyl-CoA. Interestingly, bacteria and eukaryotes use acetyl-CoA carboxylase as the first step in fatty acid biosynthesis, but because archaea do not make fatty acids, this enzyme can be dedicated to carbon assimilation.

The last autotrophic pathway known to occur in archaea is the anaerobic DC/HB pathway (figure 20.4). It is found in the anaerobic and microaerobic members of two crenarchaeote families, *Thermoproteales* and *Desulfurococcales*. The DC/HB pathway starts when an acetyl-CoA and a CO_2 molecule are condensed to form pyruvate, which is then converted to phosphoenolpyruvate (PEP). PEP carboxylase then adds HCO_3^- to PEP to form oxaloacetate (OAA). Through a series of reductive tricarboxylic acid cycle steps (i.e., backward TCA cycle steps), OAA is converted to succinyl-CoA, which is transformed through 4-hydroxybutyrate into two molecules of acetyl-CoA. As in the HP/HB pathway, one acetyl-CoA is then used for biosynthesis, and the other is used as a CO_2 acceptor in the next round of the cycle. The DC/HB cycle uses only five ATP per pyruvate made, but some of its enzymes are oxygen sensitive. Thus while the conversion of succinyl-CoA to acetyl-CoA is the same in both the HP/HB and DC/HB pathways, aerobes must perform the more expensive HP/HB pathway.

Inspection of figures 20.3 and 20.4 reveals that autotrophic pathways used by archaea result in the production of the 2-carbon compound (C2) acetyl-CoA that must be converted to the central metabolite pyruvate (C3) for anabolic purposes. The most common means by which this is accomplished is through the glyoxylate cycle (**figure 20.5**). Here the enzyme isocitrate lyase splits isocitrate (C6) into glyoxylate (C2) and succinate (C4); glyoxylate is then condensed with acetyl-CoA (C2) to form malate (C4). While autotrophic archaea and haloarchaea such as *Haloferax volcanii* use the glyoxylate cycle, other haloarchaea that must assimilate acetyl-CoA do not. These microbes use the methylaspartate pathway. This pathway also yields malate and succinate but requires many more steps. In the methylaspartate pathway (figure 20.5), α-ketoglutarate (C5) is converted to the amino acid glutamate, which is then rearranged to form the nonstandard amino acid methylaspartate. The ammonia is next removed, and several steps are required before the cleavage of a C5 intermediate into propionyl-CoA (C3) and glyoxylate (C2). Just as in the glyoxylate pathway, acetyl-CoA condenses with glyoxylate to form malate, which is used for biosynthesis. Unlike the glyoxylate pathway, another CO_2 (as HCO_3^-) is accepted by propionyl-CoA to form succinate, which is also converted to malate. All this begs the question, why use a more complicated (and therefore costly) mechanism? The answer may be linked to the fact that so far, the methylaspartate pathway is found only among haloarchaea. These microbes are

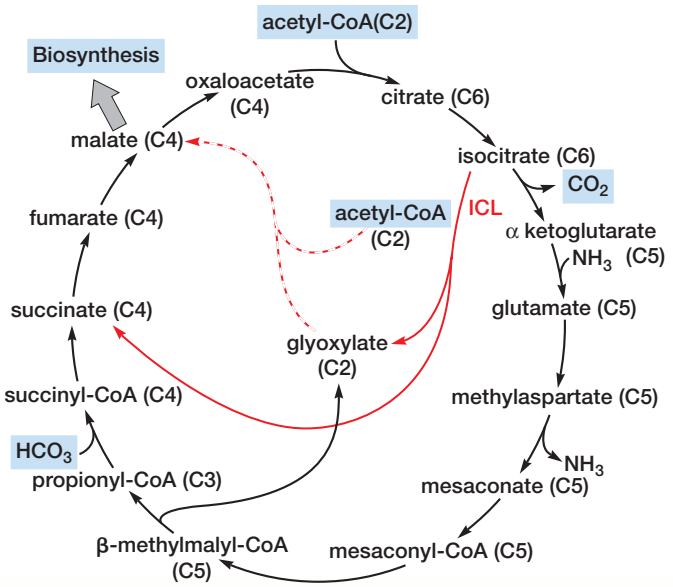

Figure 20.5 Glyoxylate and Methylaspartate Pathways Are Used for Acetyl-CoA Assimilation. Autotrophic archaea and some haloarchaea use the glyoxylate pathway (red and dashed arrows) to incorporate acetyl-CoA. Other haloarchaea lack the key enzyme isocitrate lyase (ICL) and assimilate acetyl-CoA via the longer methylaspartate pathway instead (black and dashed arrows).

MICRO INQUIRY *Why might the production of glutamate as an intermediate be beneficial for some haloarchaea?*

under constant osmotic stress in the high-salt environments they inhabit. Glutamate is used as an osmoprotectant, so it is hypothesized that haloarchaea may use the accumulation of intracellular glutamate as a signal to activate the methylaspartate pathway when growing on acetate or compounds that produce acetate as an intermediate. ◀◀ *Solutes affect osmosis and water activity (section 7.4)*

Very few details are known about other archaeal biosynthetic pathways. Evidence suggests that pathways for amino acid, purine, and pyrimidine biosynthesis are similar to those in other organisms. Some methanogens can fix atmospheric dinitrogen, and this pathway also seems to be well conserved among bacteria and archaea. ◀◀ *Anabolism: the use of energy in biosynthesis (chapter 12)*

Chemoorganotrophic Pathways

Among chemoorganotrophic archaea, a least three novel carbohydrate catabolic pathways have been identified: a modified Embden-Meyerhof (EM) pathway and two variations of the Entner-Doudoroff pathway. The modified EM pathway used by hyperthermophilic euryarchaeotes involves several novel enzymes, including an ADP-dependent glucokinase and phosphofructokinase (**figure 20.6**). These kinases each result in the production of AMP; in fact, unlike the classical EM pathway, there is no net ATP produced. Another unique step in

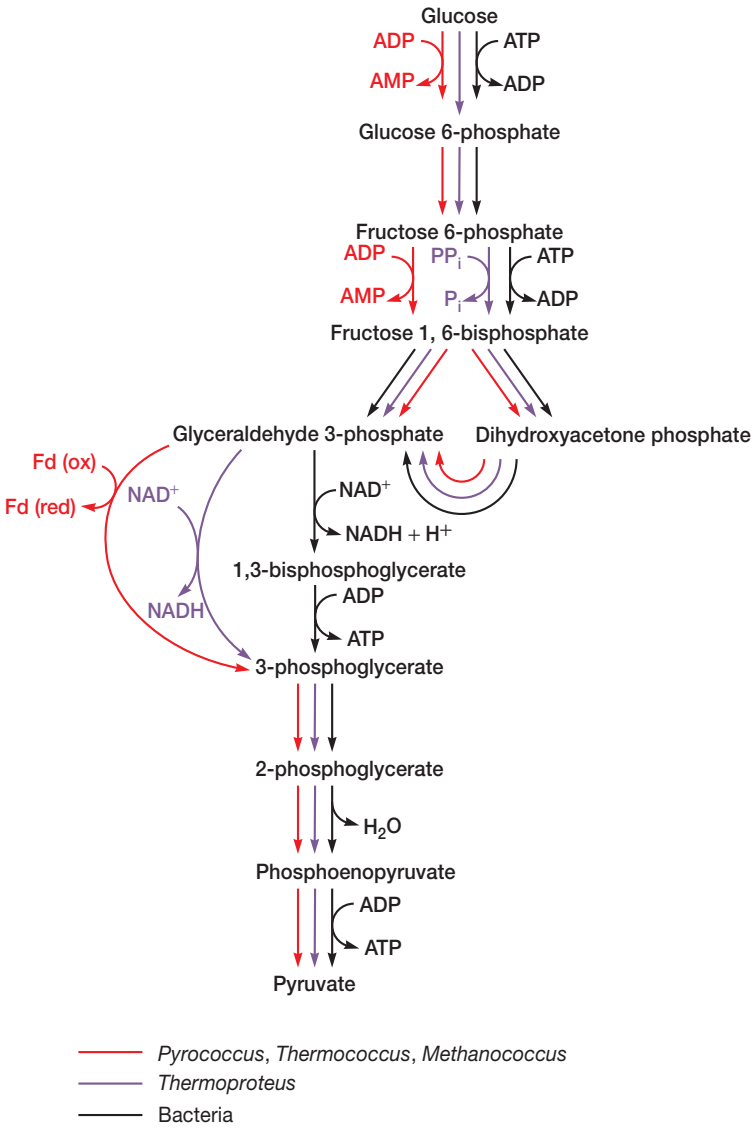

Figure 20.6 **Modified Embden-Meyerhof Pathway.** The pathway used by some archaea compared to that of bacteria. The only difference between the pathway used by *Thermoproteus* spp. and the other archaea shown is the use of NAD^+ as the electron acceptor rather than ferredoxin when glyceraldehyde 3-phosphate is oxidized to 3-phosphoglycerate. There is no net ATP produced in the archaeal pathway.

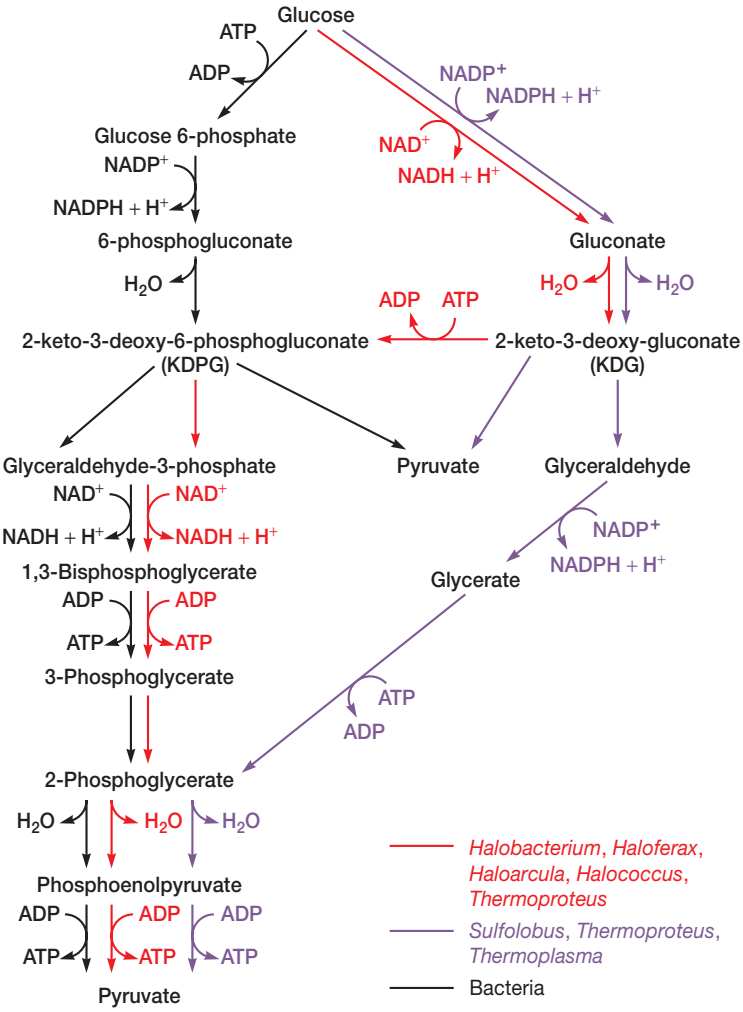

Figure 20.7 **Two Alternate Versions of the Entner-Doudoroff Pathway.** The phosphorylative pathway (red) used by halophilic archaea involves the ATP-dependent phosphorylation of KDG to KDPG; the remainder of the pathway is like that of bacteria and an ATP is gained. The nonphosphorylative pathway (purple) used by *Sulfolobus* spp. and others joins the bacterial ED pathway when glycerate is converted to 2-phosphoglycerate, so no net ATP is produced.

this modified EM pathway is the conversion of glyceraldehyde 3-phosphate directly to 3-phosphoglycerate, with the use of ferredoxin as the electron acceptor, rather than NAD^+. By contrast, members of the thermophilic crenarchaeote genus *Thermoproteus* employs NAD^+ as the electron acceptor in the modified EM pathway.

The two Entner-Douderoff pathways include one called the phosphorylative pathway and another dubbed the nonphosphorylative pathway. Extreme halophiles and *Thermoproteus* spp. catabolize glucose using the phosphorylative Entner-Doudoroff (ED) pathway. As shown in **figure 20.7**, glucose is oxidized to gluconate and then dehydrated to 2-keto-3-deoxy-gluconate (KDG). KDG is phosphorylated at the expense of ATP to KDPG, and the remainder of the ED pathway is like that of bacteria. This results in a net yield of one ATP. The nonphosphorylative ED pathway is found in *Sulfolobus, Thermoplasma,* and *Thermoproteus* spp. (note that thermoprotei can utilize all three archaeal-specific pathways). This pathway begins like that of the halophiles, but KDG is cleaved by KDG aldolase to pyruvate and glyceraldehyde. Glyceraldehyde is oxidized to glycerate, which is then phosphorylated to 2-phosphoglycerate. Pyruvate is then generated as in the classical and halophilic ED pathway. Because these microbes bypass the energy-conserving step in which 1,3-bisphosphoglycerate is converted to 3-phosphoglycerate, there is no net yield of ATP. ◀◀ *Glucose to pyruvate (section 11.4)*

All archaea that have been studied can oxidize pyruvate to acetyl-CoA. However, they lack the pyruvate dehydrogenase complex present in eukaryotes and respiratory bacteria, and use the enzyme pyruvate ferridoxin oxidoreductase instead. Halophiles and the extreme thermophiles *Thermoplasma* spp. appear

to have a functional tricarboxylic acid cycle. Methanogens do not catabolize glucose to any significant extent, so it is not surprising that they lack a complete tricarboxylic acid cycle. However, some store glycogen, which is catabolized via a modified EM pathway (figure 20.6). ⏮ *Pyruvate to carbon dioxide (step 2) is accomplished by the tricarboxylic acid cycle (section 11.5)*

Retrieve, Infer, Apply

1. How are euryarchaeotes, crenarchaeotes, and thaumarchaeotes distinguished?
2. Why do methanogens use the reductive acetyl-CoA pathway for carbon fixation?
3. Why do haloarchaea use the methylaspartate rather than the glyoxylate cycle for the incorporation of acetate?
4. Compare the ATP and NADH yield of each of the archaeal glycolytic pathways with that used by bacteria.

20.2 Phylum *Crenarchaeota*: Metabolically Diverse Thermophiles

After reading this section, you should be able to:

- List the major physiological types among crenarchaea
- Discuss hyperthermophilic and thermoacidophilic growth

Bergey's Manual lists only the well-characterized members of the phylum *Crenarchaeota,* all of which are thermophilic. They belong to a single class, *Thermoprotei,* which is divided into four orders. **Table 20.3** shows the further division of these orders and summarizes some of the characteristics of each family.

Figure 20.8 Habitat for Thermophilic Archaea. The Sulfur Cauldron in Yellowstone National Park. The water is at its boiling point and very rich in sulfur. *Sulfolobus* spp. grow well in such habitats.

Many crenarchaeotes are sulfur dependent. The sulfur may be used either as an electron acceptor in anaerobic respiration or as an electron donor by lithotrophs. They are often found in geothermally heated water or soils that contain elemental sulfur. These environments are sometimes called solfatara and are scattered all over the world. Familiar terrestrial examples are the sulfur-rich hot springs in Yellowstone National Park (**figure 20.8**).

Table 20.3 Phylum *Crenarchaeota*; Class *Thermoprotei*

Order	Family or Families	Typical Morphology	Optimal Growth Temp Range	Growth Characteristics	Representative Genera
Thermoproteales	*Thermoproteaceae*	Cocci, clubs, rods	75 to >100°C	Facultatively anaerobic or anaerobic, chemolithoautotropic reduction of S^0 with H_2 or chemoorganotrophic	*Thermoproteus* *Pyrobaculum* *Thermocladium*
	Thermofilaceae	Thin rods, filamentous	80 to 90°C	Obligately anaerobic, acidophilic, sulfur respiration	*Thermofilum*
Desulfurococcales	*Desulfurococcaceae*	Cocci, disc-shaped	85 to 95°C	Most anaerobic, few aerobic; chemolithoautotrophic or heterotrophic growth with sulfur reduction or fermentation	*Desulfurococcus* *Ignicoccus* *Thermodiscus* *Staphylothermus*
	Pyrodictiaceae	Cocci, disc-shaped	108 to 113°C	Facultatively anaerobic, or anaerobic; chemolithoautotrophic reduction of S^0 or fermentative	*Pyrodictium* *Pyrolobus* *Hyperthermus*
Sulfolabales	*Sulfolobaceae*	Cocci, irregular	75 to 85°C	Aerobic, facultatively anaerobic, or anaerobic; Chemolithoautotrophic or chemoorganotrophic; Acidiphilic	*Sulfolobus,* *Metallosphaera* *Acidianus* *Sulfurisphaera* *Sulfurococcus*
Caldisphaerales	*Caldisphaeraceae*	Cocci	70 to 75°C	Anaerobic, chemoorganotrophic, acidophilic	*Caldisphaera*

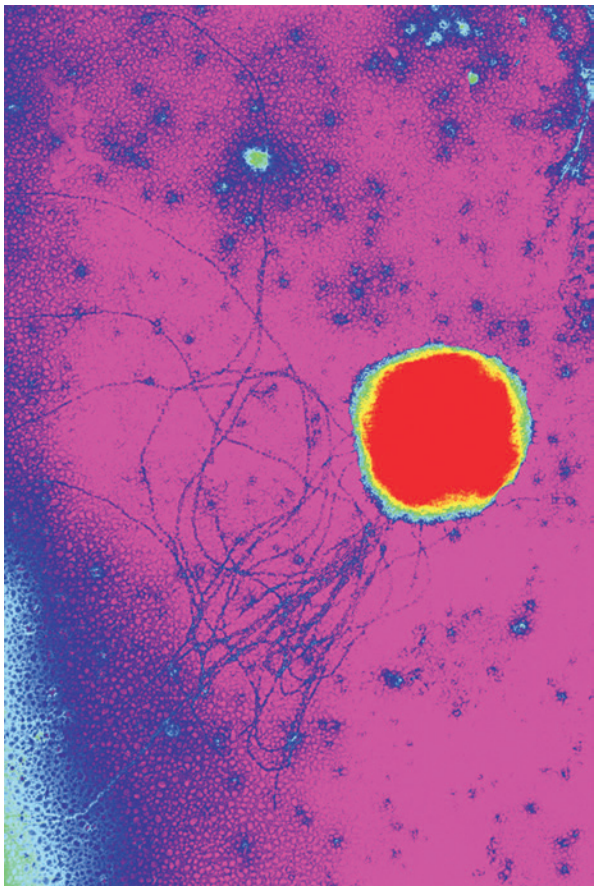

Figure 20.9 An Extremely Hyperthermophilic Crenarchaeote. A member of the family *Pyrodictiaceae,* this archaeon grows following autoclaving at 121°C, and so was dubbed "strain 121." It reduces Fe(III) to magnetite when incubated anaerobically; colorized electron micrograph.

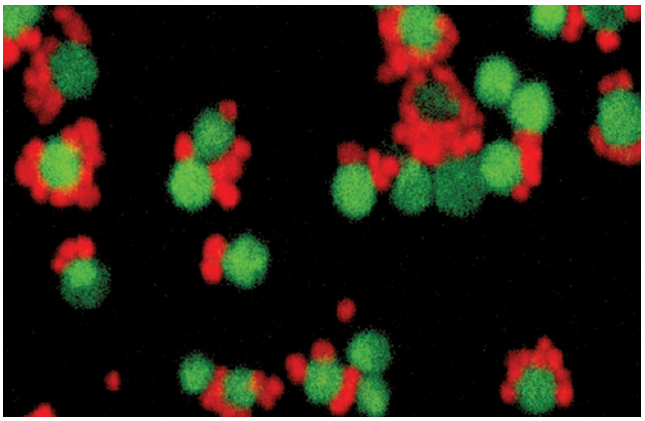

Figure 20.10 Parasitic Cells of *Nanoarchaeum equitans* Attached to the Surface of Its Host, *Ignicoccus hospitalis*. The crenarchaeote *I. hospitalis* is the only archaeon known to have an outer membrane, which may be important for *N. equitans* attachment. In this confocal laser scanning micrograph, *I. hospitalis* is stained green and *N. equitans* is red.

Many hyperthermophiles have also been isolated from the waters surrounding submarine volcanoes (*see figure 32.4*). These archaea are classified as **hyperthermophiles** if their optimum growth temperature exceeds 85°C. The most extreme example is *Pyrolobus fumarii,* which was isolated from an active hydrothermal vent in the northeast Pacific Ocean. This member of the *Pyrodictiaceae* family grows best at about 105°C, but it can survive autoclaving at 121°C for 1 hour. It is strictly anaerobic, using Fe(III) as a terminal electron acceptor and H_2 or formate as electron donors and energy sources (**figure 20.9**).

Hydrothermal vents are also home to the only parasitic archaeon, *Nanoarchaeum equitans* (a euryarchaeote), which relies on its crenarchaeal host, *Ignicoccus hospitalis,* for replication (**figure 20.10**). *I. hospitalis* is an anaerobic, chemolithoautotrophic hyperthermophilic member of *Desulfurococcaceae* that uses H_2 as an electron donor and elemental sulfur as its electron acceptor. It uses the DC/HB pathway for carbon fixation (figure 20.4). Its cell envelope is unique as it lacks an S layer and is the only archaeon to possess a double membrane. The plasma membrane is composed of di- and tetraethers that frequently give rise to small, bleblike vesicles. The outermost membrane surrounds a wide periplasm-like compartment between the two membranes. These lipids, which should not be confused with fatty acids, are called caldarchaeol lipids. They are extremely thermostable tetraethers found in many hyperthermophilic archaea. They consist of two C40 isoprenoid units linked to glycerol at both ends (i.e., it has four ether bonds), thus generating a monolayer rather than the more familiar lipid bilayer seen in bacteria and eukaryotes (*see figures 4.4* and *4.6*). The outermost membrane of *I. hospitalis* houses H_2:sulfur oxidoreductase and ATP synthase complexes, and is thereby energized. Its parasitic partner *N. equitans* is also quite interesting. It cannot be grown without its host and forms tiny cells of only 350 to 500 nm that attach to the *I. hospitalis* outermost membrane. Very little is known about the physiology of *N. equitans,* although genome analysis reveals that it lacks the capacity to synthesize most lipids, amino acids, nucleotides, and cofactors. At 490,000 bp, it seems *N. equitans* has taken genome reduction to the extreme. ⏮ *Comparative genomics (section 18.7)*

Two of the best-studied members of *Crenarchaeota* belong to the genera *Sulfolobus* and *Thermoproteus* (table 20.3). Members of *Sulfolobus* are aerobic, and spherical, with a temperature optimum around 80°C and a pH optimum of only 2 to 3. For this reason, they are **thermoacidophiles.** Their cell walls contain carbohydrate and archaeal-specific lipoproteins. They grow chemoorganotrophically under oxic conditions, but they can also grow chemolithoautotrophically, using H_2, H_2S, and FeS_2 as electron donors and with oxygen as the terminal electron acceptor, although the use of ferric iron has been reported. When growing chemolithoautotrophically, they use the HP/HB cycle, and when growing chemoorganotrophically, they employ the nonphosphorylative version of the Entner-Doudoroff pathway (figure 20.7) and a complete TCA cycle. Unlike most organisms, *S. solfataricus* rarely uses NAD^+ as an electron acceptor; instead, it uses $NADP^+$ and ferredoxin-dependent oxidoreductases. In fact, archaea in general seem to lack NADH dehydrogenase, whereas it is integral to the

function of bacterial and mitochondrial electron transport chains. The genomes of *Sulfolobus* spp. show a high level of plasticity; indeed, the *S. solfataricus* genome has 200 integrated insertion sequences, indicating a history of horizontal gene transfer. Although *S. solfataricus* grows at pH 2 to 4, it maintains a cytoplasmic pH of about 6.5, thereby generating a large pH gradient across the plasma membrane. This energy is conserved in the formation of ATP by membrane-bound ATP synthases and at least 15 secondary transport systems that couple the transport of organic solutes (e.g., sugars, amino acids) with the movement of protons (**figure 20.11**). The ABC transporters also used for nutrient uptake have high substrate affinity, an important adaptation in low nutrient environments. ⏮ *Electron transport and oxidative phosphorylation (step 3) generate the most ATP (section 11.6)*

Thermoproteus spp. are long, thin rods that can be bent or branched, with cell walls composed of glycoprotein. Thermoprotei are anaerobic and grow at temperatures from 75 to 100°C. Some are acidophiles, with optimum pH values between 3 and 4, while others are neutrophiles. They are found in hot springs and other hot aquatic habitats rich in sulfur. *Thermoproteus* spp. can grow organotrophically and oxidize glucose, amino acids, alcohols, and organic acids with elemental sulfur as the electron acceptor during anaerobic respiration. Like *Sulfolobus* spp., they use the nonphosphorylative Entner-Doudoroff pathway to catabolize sugars. They also grow chemolithotrophically, oxidizing H_2 with S^0 as the electron acceptor. CO_2 is incorporated through the DC/HB cycle (figure 20.4).

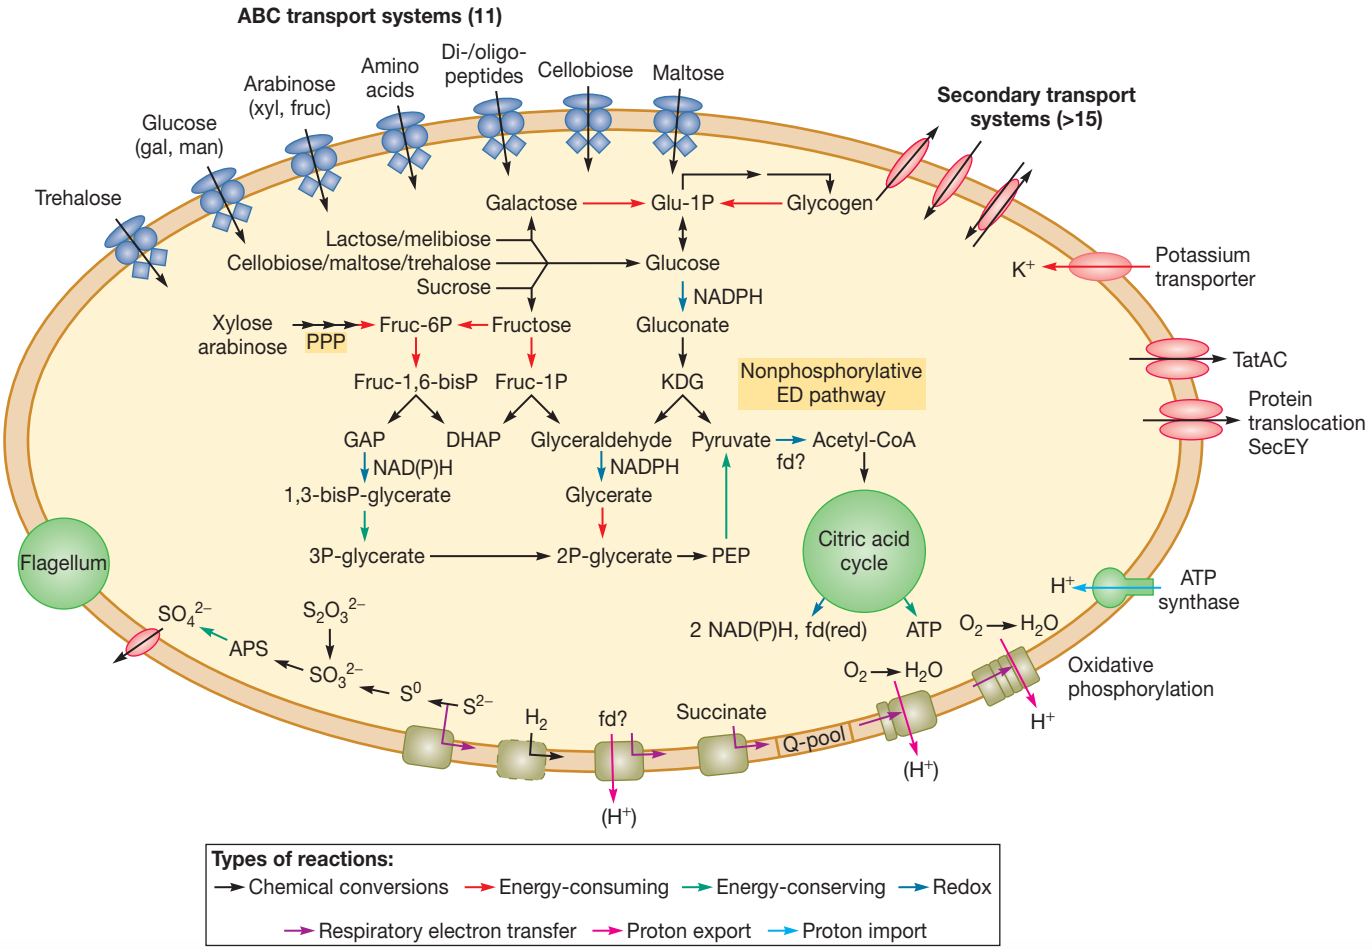

Figure 20.11 **Genomic Reconstruction of *Sulfolobus solfataricus*.** Each type of reaction is denoted by a different color arrow, as shown in the key. Components of the aerobic respiratory network include the reduction of a quinone (Q) pool, a putative ferredoxin dehydrogenase (Fd?), and succinate dehydrogenase. Alternative electron donors include hydrogen and sulfide, which reduce the quinone pool through hydrogenase and sulfide reductase, respectively. Elemental sulfur and thiosulfate are converted to sulfate. The ABC transport systems import xylose (xyl), fructose (fruc), glucose (glu), galactose (gal), and mannose (man). The flagellar apparatus more closely resembles type IV pili, as is the case with other archaea, and a gene encoding a methyl-accepting chemotaxis protein is present.

MICRO INQUIRY *Identify the potential electron donors to the electron transport chain. What is the source of energy for the potassium transporter shown on the right-hand side of the cell? Hint: Examine the arrow color code box.*

20.3 Phylum Thaumarchaeota: Mesophilic Ammonia Oxidizers

After reading this section, you should be able to:

- Describe the importance of archaeal-specific lipids in the discovery of thaumarchaeoetes
- Explain, in basic terms, the metabolism of thaumarchaeotes
- Predict where you might find members of this phylum

The first evidence for what would become the phylum *Thaumarchaeota* was the discovery of an archaeal-specific lipid called, at that time, crenarchaeol (**figure 20.12**). The detection of this lipid, coupled with metagenomic data, showed what appeared to be mesophilic crenarchaeotes in marine plankton from polar, temperate, and tropical waters. These organisms were also found in rice paddies, soils, and freshwater lake sediments, and at least two symbiotic species have been isolated, one from a cold-water sea cucumber and the other from a marine sponge. Collectively, these microbes were for many years called the group I archaea or mesophilic *Crenarchaeota*, but as discussed in section 20.1, these archaea are now placed in the phylum *Thaumarchaeota,* and crenarchaeol is now called **thaumarchaeol** (figure 20.2). ⏮ *Metagenomics provides access to uncultured microbes (section 18.3)*

The purification and growth of the marine sponge symbiont *Cenarchaeum symbiosum* and the free-living thaumarchaeote *Nitrosopumilus maritimus* confirmed that archaea are capable of nitrification. Indeed, ammonia oxidation is the metabolic feature that defines *Thaumarchaeota*. *N. maritimus* grows chemolithoautotrophically, fixing carbon via the HP/HB cycle. However, some thaumarchaeotes use organic carbon rather than CO_2 as their carbon source, as demonstrated by two recently purified coastal strains. These archaea are considered mixotrophic rather than heterotropic because they capture energy through the oxidation of ammonia to nitrite using oxygen as the terminal electron acceptor while using organic carbon for anabolic purposes. The first step in ammonia oxidation is its conversion to hydroxylamine (NH_2OH), a reaction catalyzed by ammonia monooxygenase (AMO; *see figure 22.15*). AMO is composed of three subunits, AmoA, AmoB, and AmoC; the archaeal versions of the genes encoding these proteins are phylogenetically distinct from bacterial *amo* genes. This has made it possible to assess the presence and, through reverse transcription PCR studies, the activity of archaeal nitrification in soils and waters. While it had long been thought that α- and β-proteobacteria were solely responsible for nitrification, many metagenomic studies have shown that ammonia oxidation by thaumarchaeotes is very important. This is particularly true of marine environments. ⏭ *Nitrifying bacteria oxidize ammonium or nitrate to gain energy and electrons (section 22.1)*

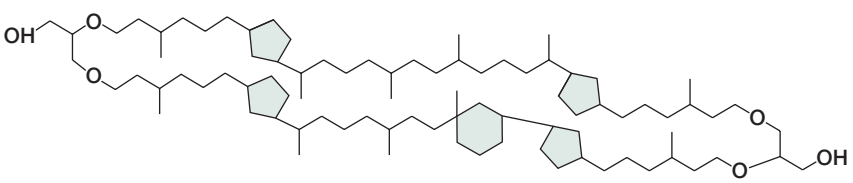

Figure 20.12 Thaumarchaeol. This membrane lipid is composed of dicyclic biphytane and a tricyclic biphytane.

5. You have discovered a new microorganism that oxidizes ammonia. How will you determine if this microbe is a thaumarchaeote or a bacterium?

20.4 Phylum *Euryarchaeota:* Methanogens, Haloarchaea, and Others

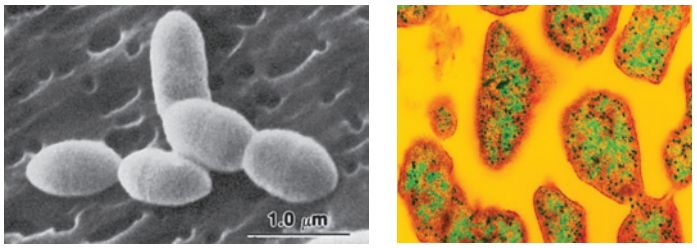
After reading this section, you should be able to:

- Outline the process of methanogenesis and discuss its importance in the flow of carbon through the biosphere as well as in the production of energy
- Discuss the physiology and ecology of anaerobic methane oxidation
- Explain the strategies halophiles have evolved to cope with osmotic stress and why these strategies are needed
- Outline rhodopsin-based phototrophy as used by halophiles
- Describe the habitats in which methanogens and halophiles reside
- List one unique feature of *Thermoplasma, Pyrococcus,* and *Archaeoglobus* spp.

Euryarchaeota is a very diverse phylum with many genera (figure 20.2). We discuss five major physiologic groups within the euryarchaeotes.

Methanogens and Methanotrophs

Late in the eighteenth century, Italian physicist Alessandra Volta discovered that he could ignite gas released from anoxic marshes. In this way, Volta discovered the biological production of methane and demonstrated the industrial importance of natural gas. The production of methane—**methanogenesis**—is the last step in the anaerobic degradation of organic compounds. Because the ΔG of methanogenesis compares unfavorably to other forms of respiration, methanogenesis occurs only when O_2 and most other electron acceptors are unavailable, making it a strictly anaerobic process (*see figure 28.1*). All methanogenic microbes belong to *Euryarchaeota* and are called **methanogens.** They



(a) (b)

Figure 20.13 Methanogens. (a) *Methanobrevibacter smithii;* SEM. (b) *Methanococcoides burtonii;* TEM

generate methane from H_2 and CO_2 or from short-chain organic compounds, such as formate, acetate, and methanol. These compounds are usually the fermentation products of other microbes that live in the same community. When using H_2 and CO_2, their growth is autotrophic. As discussed in section 20.1, these archaea use the reductive acetyl-CoA pathway to incorporate CO_2 (figure 20.3).

Methanogens are the largest group of cultured archaea. There are five orders (*Methanobacteriales, Methanococcales, Methanomicrobiales, Methanosarcinales,* and *Methanopyrales*) that differ greatly in overall shape, 16S rRNA sequence, cell wall chemistry and structure, membrane lipids, and other features. For example, methanogens construct three different types of cell walls. Several genera have walls with pseudomurein; other walls contain either proteins or heteropolysaccharides (*see figure 4.6*). The morphology of two representative methanogens is shown in **figure 20.13**, and selected properties are presented in **table 20.4**.

Methanogenesis

Methanogenesis, or the production of methane, is a complex process that requires several unique cofactors. As pictured in **figure 20.14**, these include *m*ethano*fur*a*n* (MFR), tetrahydro*m*ethano*pt*erin (H_4MPT), coenzyme F_{420}, *co*enzyme *M* (CoM; 2-mercaptoethanesulfonic acid), and coenzyme F_{430}. These are used in the following series of reactions (**figure 20.15**): (1) Gaseous CO_2 is bound to MFR, and as such, is now activated and part of a formyl group (—HC═O). (2) The formyl group is transferred to H_4MPT and dehydrated. (3) Using F_{420} as the electron donor, the dehydrated formyl group (═HC—) is reduced to the methyl level (—CH_3) in a two-step process. (4) The methyl group is transferred to CoM. This reaction releases energy. (5) The methyl group is now ready for final reduction to methane (CH_4). This is catalyzed by the F_{430}-containing *m*ethyl-*c*oenzyme M *r*eductase (MCR). H_2 is the electron donor and protons are released.

It appears that ATP synthesis is linked with methanogenesis by electron transport, proton pumping, and a chemiosmotic mechanism. The precise means by which a proton motive force is generated is debated but may involve the oxidation of H_2 on the outer surface of the membrane (figure 20.15, step 5). In addition, the transfer of the methyl groups from methyl-H_4MPT to HS-CoM releases sufficient energy for the uptake of sodium ions (step 4). This results in a sodium motive force that could also drive ATP synthesis. This may explain why methanogens require about 1 mM Na^+ for growth. ◀◀ *Electron transport and oxidative phosphorylation (step 3) generate the most ATP (section 11.6)*

It can be useful to compare methanogens that possess cytochromes with those that lack them. Among the five orders of methanogens, only members of the youngest order,

Table 20.4 Selected Characteristics of Representative Methanogens

Order and Genera	Morphology	Wall Composition	Motility	Methanogenic Substrates Used	Capable of N_2 Fixation
Order *Methanobacteriales*					Yes
Methanobacterium	Long rods or filaments	Pseudomurein	–	$H_2 + CO_2$, formate	
Methanothermus	Straight to slightly curved rods	Pseudomurein with an outer protein S-layer	+	$H_2 + CO_2$	No
Order *Methanococcales*					Yes
Methanococcus	Irregular cocci	Protein	+	$H_2 + CO_2$, formate	
Order *Methanomicrobiales*					No
Methanomicrobium	Short curved rods	Protein	+	$H_2 + CO_2$, formate	
Methanogenium	Irregular cocci	Protein or glycoprotein	–	$H_2 + CO_2$, formate	No
Methanospirillum	Curved rods or spirilla	Protein	+	$H_2 + CO_2$, formate	Yes
Order *Methanosarcinales*					Yes
Methanosarcina	Irregular cocci, packets	Protein sometimes with polysaccharide	–	$H_2 + CO_2$, methanol, methylamines, acetate	

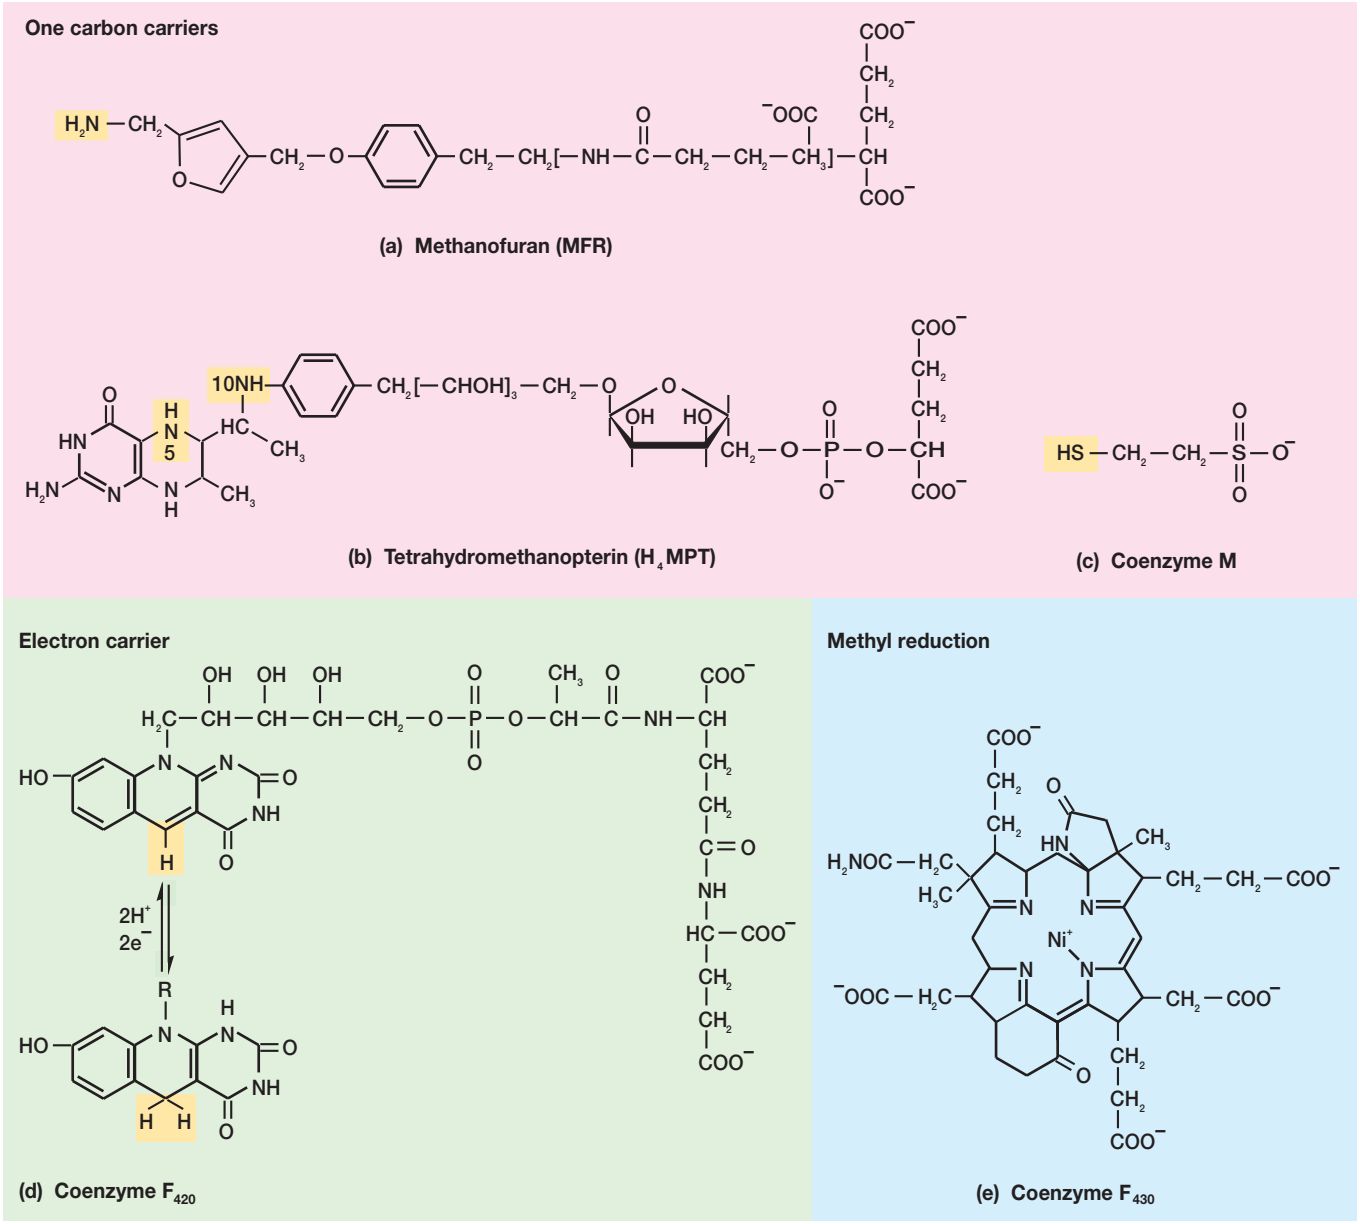


Figure 20.14 **Methanogen Coenzymes.** (a) Coenzyme MFR, (b) H_4MPT, and (c) coenzyme M are used to carry 1-carbon units during methanogenesis. MFR and a simpler form of H_4MPT called methanopterin (MPT; not shown) also participate in the synthesis of acetyl-CoA. The portions of the coenzymes that carry the 1-carbon units are highlighted. H_4MPT carries carbon units on nitrogens 5 and 10, like the more common enzyme tetrahydrofolate. (d) Coenzyme F_{420} participates in redox reactions. The part of the molecule that is reversibly oxidized and reduced is highlighted. (e) Coenzyme F_{430} participates in reactions catalyzed by the enzyme methyl-CoM methylreductase.

Methanosarcinales, have cytochromes and methanophenazine, a menaquinone-like, redox active molecule. These are the only methanogens with the capacity to grow on acetate, methanol, and methylamines, with a few species of *Methanosarcina* also growing on H_2 and CO_2. These archaea tend to have relatively high growth yields of around 7 grams of dried cellular material per mole of CH_4 produced. By contrast, most members of the other four orders convert H_2 and CO_2 to methane; a few can also use formate as a methanogenic substrate. These autotrophic methanogens have growth yields of between 1.5 to 3 grams per mole CH_4. Given these better growth yields, it is not surprising that members of *Methanosarcinales* account for about two-thirds of archaeal methanogenesis.

Methanogenic archaea are potentially of great practical importance, as discussed in the chapter opening story. Anaerobic digesters use fermentative bacteria to degrade particulate wastes such as sewage sludge to H_2, CO_2, and acetate (*see figure 43.7*). CO_2-reducing methanogens then form CH_4 from CO_2 and H_2, while acetoclastic methanogens cleave acetate to CO_2 and CH_4. The tight thermodynamic relationship between the H_2-producing

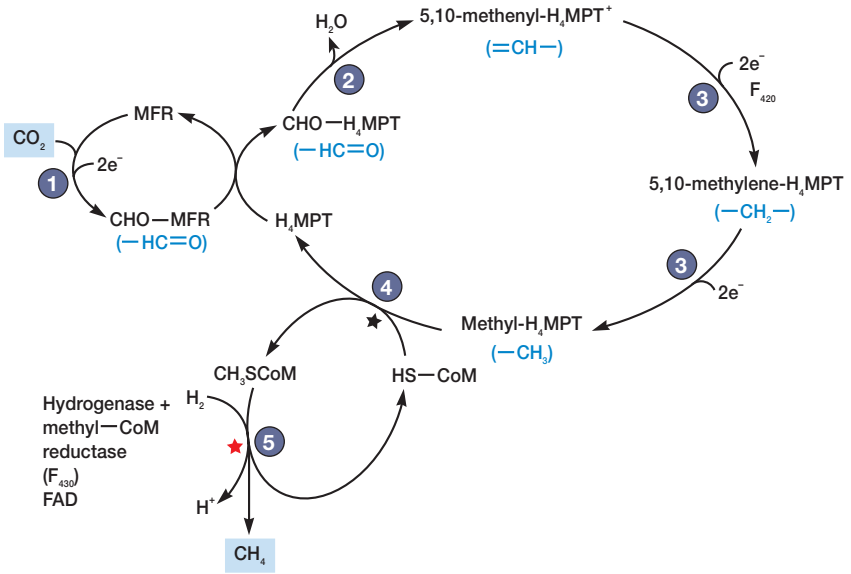

Figure 20.15 Methane Synthesis. Pathway for CH_4 synthesis from CO_2 in *M. thermoautotrophicus*. Cofactor abbreviations: methanopterin (MPT), methanofuran (MFR), and 2-mercaptoethanesulfonic acid or coenzyme M (CoM). The nature of the carbon-containing intermediates leading from CO_2 to CH_4 is indicated in parentheses. Stars indicate sites of energy conservation. The circled numbers correspond to steps described in text.

MICRO INQUIRY *What are the mechanisms by which methanogens are thought to couple CO_2 reduction to ATP generation? Why do you think this has been so hard to demonstrate?*

fermenting bacteria and methanogens is called interspecies hydrogen transfer and is discussed on page 693. A kilogram of organic matter can yield up to 600 liters of methane. It is quite likely that future innovation will greatly increase the efficiency of industrial methane production and make methanogenesis from organic waste an important source of energy. ▶▶| *Biofuel production is a dynamic field (section 42.2)*

Methanogenic archaea are estimated to produce about 1 billion tons of methane annually. In freshwater ecosystems, rates of methane production can be so great that bubbles of methane sometimes rise to the surface of lakes and ponds. Rumen methanogens are so active that a cow can belch 200 to 400 liters of methane a day. Methanogenesis is also an environmental problem. Methane absorbs infrared radiation and is a more potent greenhouse gas than CO_2. Atmospheric methane concentrations have been rising over the last 200 years. Methane production significantly promotes global warming; this subject is discussed in chapter 28. ▶▶| *The rumen ecosystem (section 32.1); Global climate change (section 28.2)*

Methanotrophy

No doubt the levels of archaeal-generated methane would render this planet uninhabitable were it not for the oxidation of methane by microbes capable of methanotrophy. For many decades, it was thought that this process—the capacity to oxidize methane and use it as a carbon source—was restricted only to obligate aerobic proteobacteria. However, it is now recognized that about 90% of methane produced in marine sediments is oxidized anaerobically by archaea. The use of fluorescent probes for specific DNA sequences has revealed assemblages of archaea and sulfate-reducing bacteria inhabiting anoxic, methane-rich sediments. The best-studied assemblage is characterized by clusters of about 100 cells from the order *Methanosarcinales* surrounded by a layer of bacteria related to the proteobacterial genus *Desulfosarcina* (**figure 20.16**). Although no anaerobic methane-oxidizing archaeon has yet been grown in pure culture, additional assemblages have since been identified and grouped into three distinct lineages called anaerobic methanotrophic archaea (ANME)-1, ANME-2, and ANME-3. Those in ANME-1 are related to members in the order *Methanomicrobiales,* while those in ANME-2 and ANME-3 are related to *Methanosarcinales.* These microbes are most often found in regions of the seafloor where methane seeps into the surrounding cold water. They have also been detected in hydrothermal vents, anoxic seawater columns, soils, and freshwater habitats.

Because none of the ANME archaea have been cultivated, the mechanism of methane oxidation has been deciphered by metagenomic analysis. The ANME archaea appear to possess all the genes needed for methanogenesis, implying that anaerobic methane oxidation is accomplished by running methanogenesis backward. The demonstration that purified enzyme methyl-coenzyme M reductase can catalyze the energetically unfavorable conversion of methane to methyl-coenzyme M (denoted with a red star in figure 20.15) supports the notion that methane is the electron

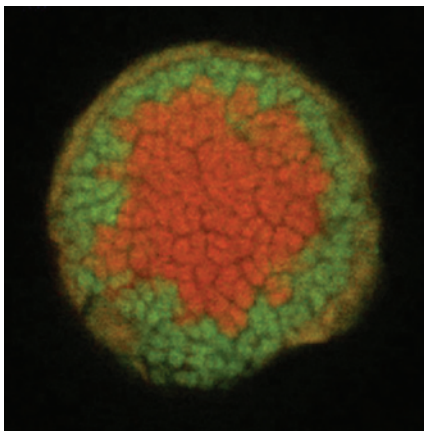

Figure 20.16 Methanotrophic Archaea Grow in Association with Sulfate-Reducing Bacteria. A cluster of methanotrophic archaea, stained red by an archaeal fluorescent 16S rRNA probe, surrounded by a layer of sulfate-reducing bacteria labeled by a green bacterial 16S rRNA fluorescent probe.

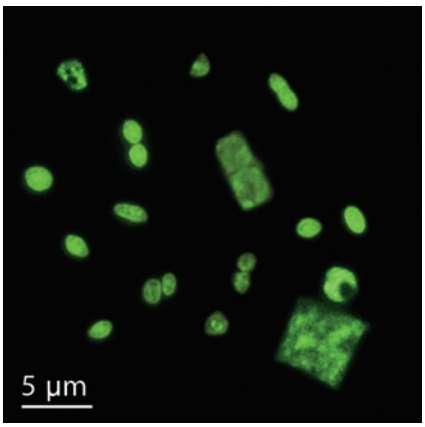

(a)

(b)

Figure 20.17 Halophilic Archaea. (a) A sample taken from a saltern in Australia viewed by fluorescence microscopy. Note the range of cell shapes includes cocci, rods, and cubes. (b) A solar evaporation pond is extremely high in salt and mineral content. The archaea that dominate this hot, saline habitat produce brilliant red pigments.

donor. In the ANME consortia with sulfate-reducing bacteria, sulfate is the terminal electron acceptor:

$$CH_4 + SO_4^{2-} \rightarrow HCO_3^- + HS^- + H_2O \ (\Delta G'^o = -17 \text{ kJ/mol})$$

It is not clear how electrons are transferred from the archaeon to the bacterium. The archaea provide the bacteria with much of their organic carbon. In addition, ANME archaea also fix N_2 gas and provide the bacteria with organic nitrogen.

The transfer of electrons from ANME archeae to sulfate-reducing *Deltaproteobacteria* appears to be the most common means by which methane is oxidized anaerobically. However, there have been some exceptions, including a freshwater ANME archaeon that couples the anaerobic oxidation of methane with bacterial denitrification—the reduction of nitrate to N_2 during anaerobic respiration. In addition, there have been at least two reports of ANME capable of anaerobic oxidation of methane without a bacterial partner. One involves an ANME-2 archaeon capable of independent methane oxidation because it possesses the genes for dissimilatory sulfate reduction. The other is also an ANME-2 archeaon, but it is capable of using nitrate as the terminal electron acceptor. It appears to have acquired the genes needed for nitrate reduction by horizontal gene transfer from bacteria.

Haloarchaea

The **extreme halophiles** include some bacteria, eukaryotic microorganisms, and **haloarchaea,** which belong to the order *Halobacteriales.* This euryarchaeal group currently has 17 genera in one family, *Halobacteriaceae*. These microbes received this unfortunate name before *Archaea* and *Bacteria* were recognized as different taxa. Most are aerobic chemoorganotrophs with respiratory metabolism. Extreme halophiles demonstrate a wide variety of nutritional capabilities. When grown in defined media, these archaea use carbohydrates or simple compounds such as glycerol, acetate, or pyruvate as their carbon source. Halophiles are found in a variety of cell shapes, including cubes and pyramids in addition to rods and cocci (**figure 20.17*a***). Some are motile.

The most obvious distinguishing trait of this family is its absolute dependence on a high concentration of NaCl, requiring at least 1.5 M NaCl (about 8%, wt/vol). Growth optima are usually 3 to 4 M NaCl (17 to 23%), but some will grow at salt concentrations approaching saturation (about 36%). The cell walls of most halophiles are so dependent on the presence of NaCl that they disintegrate when the NaCl concentration drops below 1.5 M. Thus they only grow in high-salinity habitats such as marine salterns and salt lakes such as the Dead Sea between Israel and Jordan, and the Great Salt Lake in Utah. Haloarchaea often have red-to-yellow pigmentation from carotenoids that are probably used as protection against strong sunlight. They can reach such high population levels that salt lakes, called salterns turn red (figure 20.17*b*).

Halophiles use two strategies to cope with osmotic stress. The first approach is to increase cytoplasmic osmolarity by accumulating small organic molecules called **compatible solutes.** These include glycine, betaine, polyols, ectoine, and amino acids. When this strategy is used, salt adaptation of cytoplasmic proteins is not necessary. Compatible solutes are found in extremely halophilic methanogenic archaea, as well as halophilic bacteria. By contrast, members of the orders *Halobacteriales, Haloanaerobiales,* and *Salinibacter* employ a "salt-in" approach. These archaea use Na^+/H^+ antiporters and K^+ symporters to concentrate KCl and NaCl to levels equivalent to the external environment. Thus proteins need to be protected from salt denaturation and dehydration. Proteins from these microbes have evolved to possess a limited number of hydrophobic amino acids and a greater number of acidic residues. The acidic amino acids tend to be located on the surface of the folded protein, where they attract cations, which form a hydrated shell around the protein, thereby maintaining its solubility.

Probably the best-studied member of the family is *Halobacterium salinarum*. This archaeon is unusual because it produces a protein called **archaerhodopsin** (originally termed bacteriorhodopsin) that can harvest light energy without the presence of chlorophyll. Structurally similar to the rhodopsin found in the mammalian eye, archaerhodopsin functions as a light-driven proton pump. Like all members of the rhodopsin family, archaerhodopsin has two distinct features: (1) a chromophore that is a derivative of retinal (an aldehyde of vitamin A), which is covalently

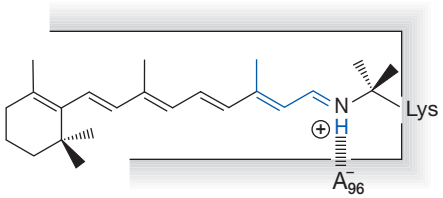

Figure 20.18 The Chromophore of Archaerhodopsin Is a Retinal Schiff Base.

attached to the protein by a Schiff base with the amino group of lysine (**figure 20.18**); and (2) seven membrane-spanning domains connected by loops on either side of the membrane with the retinal resting within the membrane. Archaerhodopsin molecules form aggregates in a modified region of the plasma membrane called the **purple membrane.** As shown in **figure 20.19**, this light-driven proton pump generates a pH gradient without an electron transport chain. Nonetheless, this gradient can be used to power the synthesis of ATP by a chemiosmotic mechanism. ◀◀ *Oxidative phosphorylation (section 11.6); Rhodopsin-based phototrophy (section 11.11)*

H. salinarum has three additional rhodopsins, each with a different function. Halorhodopsin uses light energy to transport chloride ions into the cell and maintain a 4 to 5 M intracellular KCl concentration. The two additional rhodopsins are called sensory rhodopsin I (SRI) and SRII. **Sensory rhodopsins** act as photoreceptors; in this case, one for red light and one for blue. They control flagellar activity to position the organism optimally in the water column. *Halobacterium* cells move to a location of high light intensity that optimizes archaerhodopsin proton pumping but limits the lethal effects of ultraviolet light.

Rhodopsin is widely distributed among bacteria as well as archaea. DNA sequence analysis of uncultivated marine bacterioplankton reveals the presence of rhodopsin genes among some α- and β-proteobacteria and bacteroidetes. This rhodopsin is called **proteorhodopsin.** Cyanobacteria also have sensory rhodopsin proteins, which like SRI and SRII of the haloarchaea, sense the spectral quality of light. All these bacterial and archaeal rhodopsins conserve the seven transmembrane helices through the cell membrane and the lysine residue that forms the Schiff base linkage with retinal. ▶▶ *Microorganisms in the open ocean are adapted to nutrient limitation (section 30.2)*

Genomic analysis of *Halobacterium* NRC-1 illustrates many of these physiologic strategies (figure 20.19). The use of both archaerhodopsin-mediated proton motive force and oxidative phosphorylation to drive ATP synthesis is shown, as is the import of cations to increase cytoplasmic osmolarity. The signals from sensory rhodopsins converge on the flagellar apparatus, along with input from 17 methyl-accepting chemotactic proteins. *Halobacterium* NRC-1 uses a variety of ATP transporters for the uptake of cationic amino acids, peptides, and sugars. Carbohydrates are oxidized via the phosphorylative variant of the Entner-Doudoroff pathway (figure 20.7) and the TCA cycle. Interestingly, genes for exporting the toxic heavy metals arsenite and cadmium are present, as well as genes homologous to nonspecific multidrug-resistance exporters.

Thermoplasms

Archaea in the class *Thermoplasmata* are thermoacidophiles that lack cell walls. At present, three genera—*Thermoplasma, Picrophilus,* and *Ferroplasma*—are known. They are sufficiently different from one another to be placed in separate families: *Thermoplasmataceae, Picrophilaceae,* and *Ferroplasmataceae.*

Members of the genus *Thermoplasma* grow in refuse piles of coal mines. These piles contain large amounts of pyrite (FeS), which is oxidized to sulfuric acid by chemolithotrophic bacteria. As a result, the piles become very hot and acidic. This is an ideal habitat for these archaea because they grow best at 55 to 59°C and pH 1 to 2. Although they lack cell walls, their plasma membranes are strengthened by large quantities of caldarchaeol, lipid-containing polysaccharides, and glycoproteins. At 59°C, *Thermoplasma* spp. take the form of irregular filaments, whereas at lower temperatures, they are spherical. The cells may be flagellated and motile.

Picrophilus spp. are even more unusual than *Thermoplasma.* They have an S-layer outside the plasma membrane. The cells grow as irregularly shaped cocci, around 1 to 1.5 μm in diameter, and have large cytoplasmic cavities that are not surrounded by a membrane. They are aerobic and grow between 47 and 65°C with an optimum of 60°C. They have remarkable pH requirements, growing only below pH 3.5 with a growth optimum at pH 0.7. Growth even occurs at about pH 0.

Extremely Thermophilic S^0-Reducers

This physiological group contains the class *Thermococci,* with one order, *Thermococcales.* These archaea are strictly anaerobic chemoorganoheterotrophs that use a variety of carbon substrates (e.g., peptides and carbohydrates) and reduce sulfur to sulfide. They are motile by flagella and have optimum growth temperatures around 88 to 100°C. The order contains one family and three genera, *Thermococcus, Paleococcus,* and *Pyrococcus.*

Sulfate-Reducing *Euryarchaeota*

Although many euryarchaea reduce sulfur during anaerobic respiration, only a few can use sulfate as a terminal electron acceptor. The sulfate reducers are found in the class *Archaeoglobi* and the order *Archaeoglobales.* This order has only one family and three genera. *Archaeoglobus* spp. are irregular coccoid cells with cell walls consisting of glycoprotein subunits. They can extract electrons from a variety of electron donors (e.g., H_2, lactate, glucose) and reduce sulfate, sulfite, or thiosulfate to sulfide. Elemental sulfur is not used as an acceptor. They are thermophilic (optimum growth is about 83°C) and have been isolated from marine hydrothermal vents. Although they are not considered methanogens, they use coenzymes F_{420} and methanopterin to produce tiny amounts of methane. Because they lack the genes encoding the critical enzyme methyl-CoM reductase (figure 20.15,

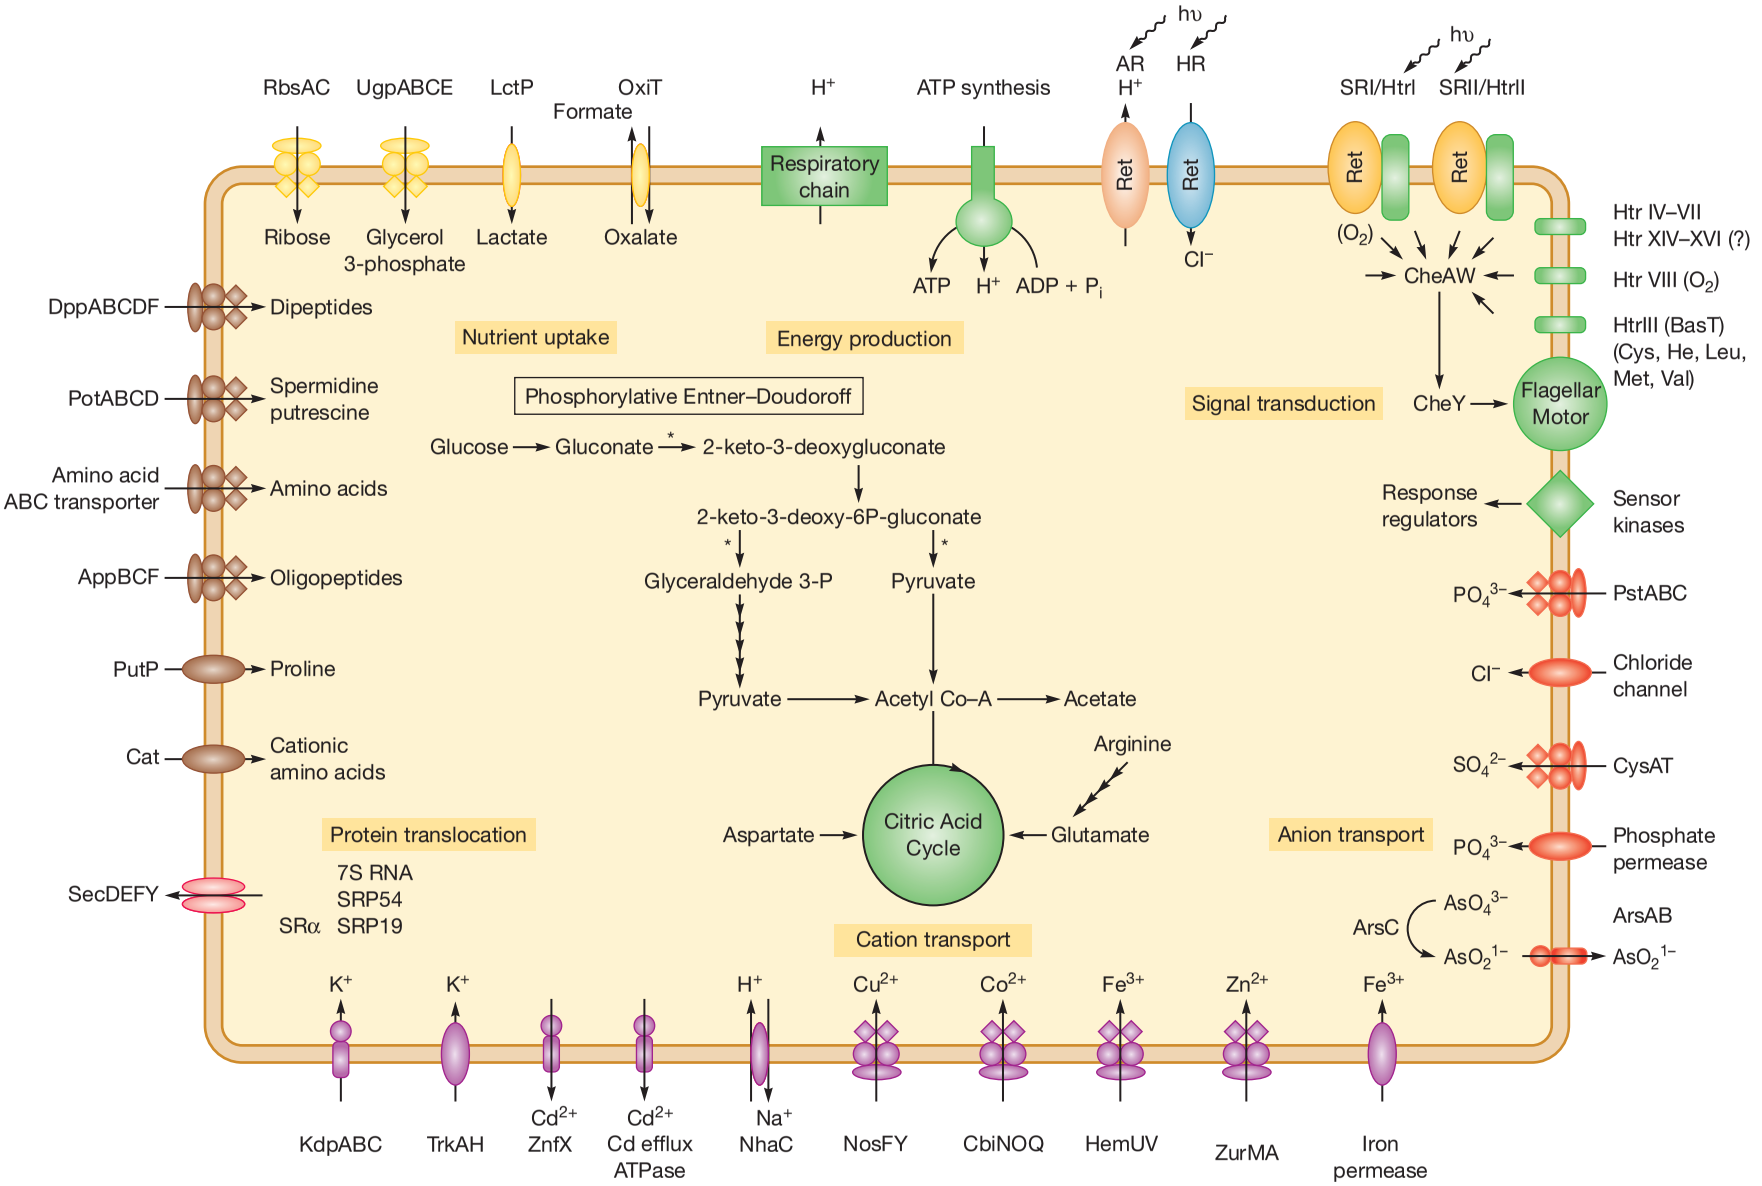

Figure 20.19 **Genomic Reconstruction of *Halobacterium* NRC-1.** ATP synthesis occurs through respiratory-dependent chemiosmosis and the ATP synthase, light-driven proton pumping by archaerhodopsin (AR, pink oval), and chloride transport by halorhodopsin (HR, blue oval). Nutrient uptake systems are shown in brown and yellow; names of transporters correspond with the gene(s) encoding them; the substrates transported are shown in the inside of the transporter. Cation transporters are shown in purple and anion transporters in red. Sensory rhodopsins (orange) and 17 light, oxygen, and amino acid receptors (Htr proteins) regulate chemotaxis and are thus shown linked to the flagellar motor through the chemotaxis protein CheY.

step 5), the mechanism by which methane is made remains unclear. Some species are autotrophic and, like methanogens, use the reductive acetyl-CoA pathway to assimilate CO_2.

A recently characterized thermophilic euryarchaeote that is not yet listed in *Bergey's Manual* bears mention. The isolated *Aciduliprofundum* strain, *Candidatus* Aciduliprofundum boonei is an acidophile that requires a pH of 3.3 to 5.8 and a temperature between 60 and 75°C for growth. Culture-independent analysis shows that members of this genus are often abundant in microbial communities growing at hydrothermal vents with actively venting sulfide deposits. It follows that A. boonei is a sulfur- and iron-reducing heterotroph. Its significance is twofold. It is the first thermoacidophile (as opposed to acid-tolerant) microbe to be isolated from environments rich in sulfide deposits. Also, its abundance at such sites implies that it is important in sulfur and iron cycling in these ecosystems. ▶▶| *Biogeochemical cycling sustains life on Earth (section 28.1)*

Retrieve, Infer, Apply

1. Why are the growth yields of most methanogens much lower than those of microbes that grow aerobically?
2. Why do you think methanogenesis requires so many cofactors? (Hint: What would happen to CO_2 and CH_3 if they were not bound to larger molecules?)
3. What is the ecological and practical importance of methanogens?
4. Where are extreme halophiles found, and what is unusual about their cell walls and growth requirements?
5. What is the difference between sensory rhodopsin and archaerhodopsin? Find examples of each in figure 20.19.
6. How is *Thermoplasma* able to live in acidic, very hot coal refuse piles when it lacks a cell wall?
7. In what way are members of the genus *Archaeoglobus* similar to methanogens, and how do they differ from other extreme thermophiles?

Key Concepts

20.1 Overview of *Archaea*

- *Archaea* contains a highly diverse group of microbes with respect to morphology, reproduction, physiology, and ecology. Although best known for their growth in anoxic, hypersaline, and high-temperature habitats, they also inhabit marine Arctic, temperate, and tropical waters.
- Archaea may be divided into six physiological groups: methanogenic archaea, sulfate reducers, extreme halophiles, cell wall-less archaea, extremely thermophilic S^0-metabolizers, and mesophilic ammonia oxidizers (**table 20.1**).
- The second edition of *Bergey's Manual* divides *Archaea* into two phyla, *Crenarchaeota* and *Euryarchaeota*; however, the phylum *Thaumarchaeota* was recently recognized (**figure 20.2**).
- Autotrophic archaea generally use one of three pathways for CO_2 assimilation: the reductive acetyl-CoA pathway, the 3-hydroxypropionate/4-hydroxybutyrate (HP/HB) cycle, or the dicarboxylate/4-hydroxybutyrate (DC/HB) cycle. Acetate is incorporated either by the glyoxylate or methylaspartate cycle. Most other anabolic pathways appear to be similar to those found in bacteria (**table 20.2; figures 20.3** to **20.5**).
- Although much of archaeal catabolism appears similar to that of bacteria, archaea differ with respect to glucose catabolism, using modified versions of the Embden-Meyerhof and Entner-Doudoroff pathways (**figures 20.6** and **20.7**).

20.2 Phylum *Crenarchaeota:* Metabolically Diverse Thermophiles

- The extremely thermophilic S^0-metabolizers in the phylum *Crenarchaeota* depend on sulfur for growth and are frequently acidophiles. The sulfur may be used as an electron acceptor in anaerobic respiration or as an electron donor by chemolithotrophs. Many are strict anaerobes and grow in geothermally heated soil and water that is rich in sulfur (**table 20.3**).

20.3 Phylum *Thaumarchaeota:* Mesophilic Ammonia Oxidizers

- The discovery of an archaeal-specific lipid, now called thaumarchaeol, led to the discovery of globally distributed marine, mesophilic archaea.
- These mesophiles are placed in the phylum *Thaumarchaeota* and are united by their capacity to oxidize ammonia. They are found in many marine and terrestrial habitats, where they can be important contributors to nitrification.

20.4 Phylum *Euryarchaeota:* Methanogens, Haloarchaea, and Others

- The phylum *Euryarchaeota* contains five major physiological groups: methanogens, haloarchaea, thermoplasms, extremely thermophilic S^0-reducers, and sulfate-reducing archaea.
- Methanogenic archaea are strict anaerobes that obtain energy through the synthesis of methane. They have several unusual cofactors that are involved in methanogenesis (**figures 20.14** and **20.15**).

- Anaerobic methane-oxidizing archaea belong to *Methanomicrobiales* and *Methanosarcinales,* and are commonly found in association with sulfate-reducing bacteria. These methanotrophs oxidize methane by reversing the methanogenic pathway.
- Extreme halophilic archaea are aerobic chemoorganotrophs that require at least 1.5 M NaCl for growth. They are found in habitats such as salterns and salt lakes.
- *Halobacterium salinarum* can carry out phototrophy without chlorophyll or bacteriochlorophyll by using archaerhodopsin, which employs retinal to pump protons across the plasma membrane (**figures 20.18** and **20.19**).
- The thermophilic *Thermoplasma* spp. grow in hot, acidic coal refuse piles and survive despite the lack of a cell wall. Another thermoplasm, *Picrophilus* spp. grow at pH 0.
- The class *Thermococci* contains extremely thermophilic organisms that can reduce sulfur to sulfide.
- The extreme thermophiles in the genus *Archaeoglobus* differ from other archaea in using a variety of electron donors to reduce sulfate. They also contain methanogen cofactors F_{420} and methanopterin.

Compare, Hypothesize, Invent

1. Some believe that archaea should not be separate from bacteria because both groups are prokaryotic. Do you agree or disagree? Explain your reasoning.
2. Explain why the fixation of CO_2 by *Thermoproteus* spp. using the DC/HB cycle is not photosynthesis.
3. When the temperature increases, some archaea change their shapes from elongated rods into spheres. Suggest one reason for this change.
4. Why would ether linkages be more stable in membranes than ester lipids? How would the presence of tetraether linkages stabilize a thermophile's membrane?
5. Suppose you wished to isolate an archaeon from a hot spring in Yellowstone National Park. How would you go about it?
6. Thermophilic archaea capable of ammonia oxidation to nitrite were discovered in enrichment cultures derived from microbial mats from the Siberian Garga hot spring. To demonstrate the presence of these microbes and their ability to oxidize ammonia, the authors did the following:
   - Screened for α- and β-proteobacterial 16S rRNA genes and the bacterial gene that encodes the key enzyme in ammonia oxidation (*see chapter 22*).
   - Screened for archaeal-specific 16S rRNA and archaeal-specific genes that encode the ammonia oxidation subunits AmoA and AmoB.
   - Constructed two phylogenetic trees—one based on the archaeal 16S rRNA genes and one based on the AmoA and AmoB amino acid sequences as compared to other archaeal AmoA and AmoB sequences.
   - Performed reverse-transcriptase PCR using mRNA extracted from the enrichment cultures. Primers were specifically targeted archaeal *amoA* nucleotide sequences.

   What was the rationale (i.e., what were the authors testing) for each procedure? The authors concluded that a thermophilic ammonia-oxidizing archaeote was responsible for the conversion of ammonia to nitrite in this system; what was the likely result of each test?

Deinococci, Mollicutes, and Nonproteobacterial Gram-Negative Bacteria

Biofuel production is an active area of microbiological research.

Cyanobacteria Stimulate Broad Appeal for Biofuel Production

Biofuels could be part of a comprehensive, global energy solution. They are renewable and can be produced domestically. But there is a downside. In the United States, most biofuel is made from corn, thereby co-opting thousands of acres of land for producing energy rather than food. This has the unintended consequence of driving food prices higher. Given that about 14% of the world's population is undernourished, this is not the best use of arable land.

Some scientists have turned from corn to cyanobacteria for an answer. Globally, there are a number of projects that seek to turn these Gram-negative bacteria, once known as blue-green algae, into a source of biofuel. One approach, used by researchers at Arizona State University's Biodesign Institute, involves harvesting lipids from the cyanobacteria that belong to the genus *Synechocystis*. These microbes can be genetically engineered to increase production of the kinds of lipids used in biodiesel. Their growth requirements are simple: CO_2, phosphorus, and trace elements. Because *Synechocystis* spp. fix atmospheric N_2, there is no need for petroleum-based nitrogenous fertilizer. And it gets even better: it may be possible to feed the cyanobacterium CO_2 generated by power plants, thereby reducing emissions of this greenhouse gas. Lastly, cyanobacterial lipid production is more than 100 times more efficient per acre than plants, and their growth need not eliminate land from food production.

Not far from Arizona, bioengineers at the University of Texas are using a different approach to capitalize on the benefits of cyanobacteria. Like others, they would like to replace corn as a biofuel source. The use of corn is expensive, involving enzymatic, chemical, and mechanical methods to break down cellulose into its glucose monomers, which is then fermented to ethanol (*see section 42.2*). They have developed a strain of the cyanobacterium *Oscillatoria* that secretes high levels of glucose, sucrose, and cellulose. Importantly, unlike plant cellulose, cyanobacterial cellulose is not mixed with lignin and other recalcitrant compounds, making it more easily fermented. Thus these cyanobacteria can easily provide the starting materials for biofuel fermentation and avoid the sacrifice of thousands of acres to the growth of a food product for biofuel generation.

These projects are only two of many under development around the world that aim to harness cyanobacteria for biofuel generation. In this chapter, we cover these microbes as well as nine other phyla of Gram-negative bacteria (**figure 21.1**). This includes a variety of morphologically and physiologically amazing microbes. From deinococci, which can withstand levels of ionizing radiation that would kill a human, to the spirochetes that cause syphilis, this chapter truly illustrates the depth of microbial diversity.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Draw a Gram-negative bacterial cell wall and list its constituent parts (section 3.4)
- ✔ Differentiate between swimming and gliding motility (section 3.8)
- ✔ List environmental factors that influence microbial growth (section 7.4)
- ✔ Compare and contrast the growth and physiology of obligate aerobes, facultative anaerobes, and strict anaerobes (section 7.4)
- ✔ Describe the difference between heterotrophy and autotrophy (section 11.1)
- ✔ Define chemolithotrophy and identify an example of an electron donor and an acceptor (section 11.10)
- ✔ Compare and contrast oxygenic and anoxygenic phototrophy (section 11.11)

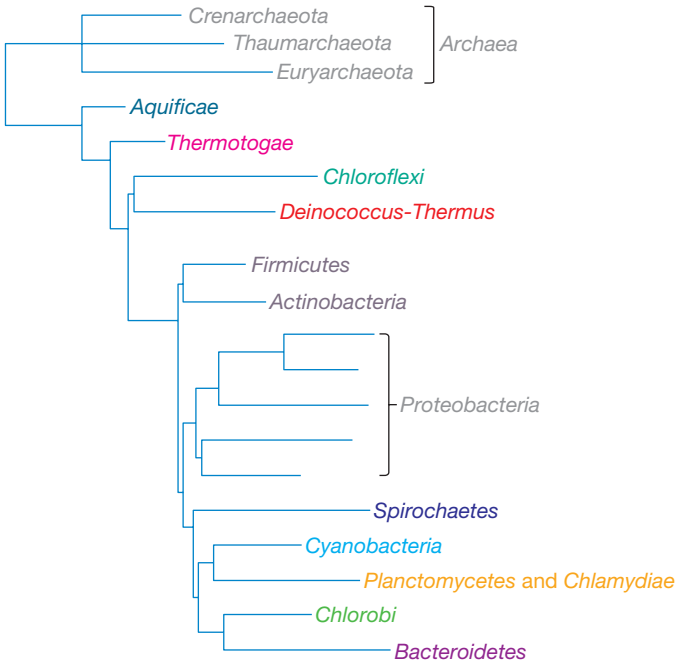

Figure 21.1 **Phylogenetic Relationships Among *Bacteria* and *Archaea*.** Nonproteobacterial Gram-negative bacteria are highlighted.

21.1 *Aquificae* and *Thermotogae* Are Ancient Bacterial Lineages

After reading this section, you should be able to:

- Compare and contrast the physiological and structural differences between members of the phyla *Aquificae* and *Thermotogae*

Thermophilic microbes are found in both the bacterial and archaeal domains, but to date, most hyperthermophilic microbes (those with optimum growth temperatures above 80°C) belong to *Archaea*. The phyla *Aquificae* and *Thermotoga* are two examples of bacterial hyperthermophiles.

The phylum *Aquificae* is thought to represent the deepest, oldest branch of *Bacteria*. Two of the best-studied genera are *Aquifex* and *Hydrogenobacter*. *Aquifex* spp. are chemolithoautotrophs that capture energy by oxidizing hydrogen, thiosulfate, and sulfur with oxygen as the terminal electron acceptor. The reductive citric acid cycle is used to fix CO_2 (*see figure 12.5*). *Aquifex pyrophilus* is a microaerophilic rod that has been shown to grow with a temperature optimum of 85°C and a maximum of 95°C. Because the genera *Aquifex* and *Hydrogenobacter* contain thermophilic chemolithoautotrophic species, it has been suggested that the original bacterial ancestor was probably thermophilic and chemolithoautotrophic. ⏮ *Chemolithotrophy (section 11.10)*

The second deepest branch is the phylum *Thermotogae*. Members of the genus *Thermotoga* (Greek *therme,* heat; Latin *toga,* outer garment), like *Aquifex,* are thermophiles with a growth optimum of 80°C and a maximum of 90°C. They are

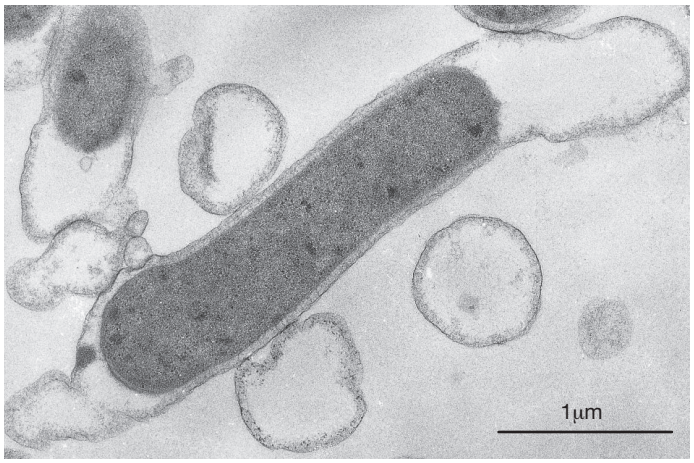

Figure 21.2 ***Thermotoga maritima*.** Note the loose sheath extending from each end of the cell.

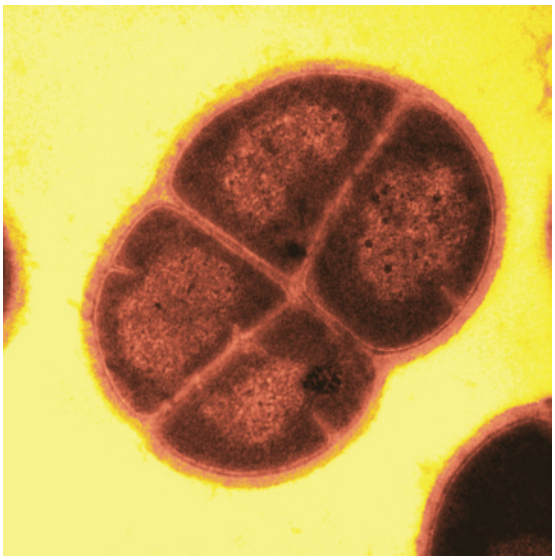
Gram-negative rods with an outer sheathlike envelope (like a toga) that can extend or balloon out from the ends of the cell (**figure 21.2**). They grow in active geothermal areas found in marine hydrothermal systems and terrestrial solfataric springs. In contrast to *Aquifex, Thermotoga* species are chemoorganotrophs with a functional glycolytic pathway that can grow anaerobically using protons, elemental sulfur, or ferric iron as terminal electron acceptors. Like other members of the phylum *Thermotogae,* the genomes of *Thermotoga* spp. have been subject to horizontal gene transfer (HGT). Among this phylum, estimates of genes of archaeal origin range from 25% to 50%. ⏮ *Horizontal gene transfer (section 16.4)*

21.2 *Deinococcus-Thermus* Includes Radiation-Resistant Bacteria

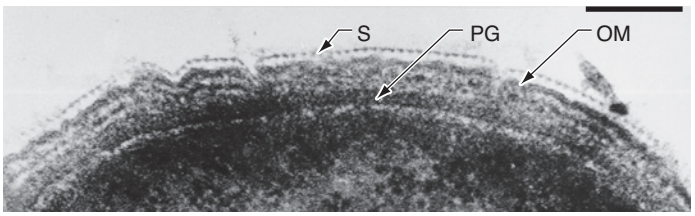
After reading this section, you should be able to:

- Explain why members of *Deinococcus-Thermus* have erroneously been considered Gram positive
- Describe habitats in which deinococci can be isolated
- Discuss the unique capacity of deinococci to tolerate desiccation and high doses of radiation

The phylum *Deinococcus-Thermus* contains the orders *Deinococcales* (Greek, *deinos,* unusual) and *Thermales*. There are only three genera in the phylum. Most are mesophilic, but *Thermus aquaticus* was one of the first thermophilic organisms discovered. It grows optimally at 70°C, and thermostable "Taq" DNA polymerase is commonly used in polymerase chain reactions. Deinococci are spherical or rod-shaped and nonmotile, and they are often seen in pairs or tetrads (**figure 21.3*a***). They are aerobic heterotrophs producing acid from only a few sugars. Although they stain Gram positive (and are sometimes referred to as such), their cell wall includes an outer membrane (figure 21.3*b*). They also differ from Gram-positive cocci in having



(a)



(b)

Figure 21.3 Deinococci. (a) A *Deinococcus radiodurans* tetracoccus, or cluster of four cells (average cell diameter 2.5 μm). (b) The cell wall of *D. radiodurans* with an S-layer (S), a peptidoglycan layer (PG), and an outer membrane (OM). Scale bar = 100 nm.

L-ornithine in their peptidoglycan, lacking teichoic acid, and having a plasma membrane with large amounts of palmitoleic acid rather than phosphatidylglycerol phospholipids. Their cell envelope also includes an S-layer. Almost all strains are extraordinarily resistant to all sources of oxidative stress, including desiccation and radiation; they can survive as much as 3 to 5 million rad of radiation. By contrast, exposure to 100 rad can be lethal to humans.

Deinococci can be isolated from ground meat, feces, air, freshwater, and other sources, but their natural habitat is not yet known. Their resistance to radiation results from their ability to repair a severely damaged genome, which consists of a circular chromosome, a megaplasmid, and a small plasmid. When exposed to high levels of radiation, radical oxygen species are generated and the genome is broken into hundreds of fragments. Amazingly, within 12 to 24 hours, the genome is pieced back together, ensuring viability. It is unclear how this is accomplished. Evidence suggests that while *Deinococcus radiodurans* DNA is not especially radiation resistant, its proteins are *(see figure 18.14).* The ability to accumulate high levels of Mn(II) helps protect the microbe from damage caused by radiation-induced toxic oxygen species. Interestingly, manganese ions selectively protect proteins, rather than DNA. Thus, unlike other microbes, *D. radiodurans* DNA repair enzymes survive severe oxidative stress.

21.3 Class *Mollicutes*, Phylum *Tenericutes:* Bacteria That Lack Cell Walls

After reading this section, you should be able to:

- Relate the structure of the mollicute cell envelope to their morphology
- Outline how arginine can be catabolized to yield ATP by substrate-level phosphorylation
- Draw the flux of protons that enables *Ureaplasma urealyticum* to generate a proton motive force despite the absence of an electron transport chain
- Illustrate how gliding motility is accomplished by mycoplasmas
- List several habitats in which mollicutes reside and relate this to their capacity to be pathogenic

Until recently the class *Mollicutes* was placed in the phylum *Firmicutes.* Although it is generally agreed that members of this class are related to certain clostridia (low G + C Gram-positive bacteria), the fourth volume of *Bergey's Manual of Systematic Bacteriology* lists *Mollicutes* in the phylum *Tenericutes* (Latin *tener,* tender, and *cutis,* skin). *Tenericutes* includes all bacteria that lack walls and do not synthesize peptidoglycan precursors. Members of *Mollicutes* are commonly called **mycoplasmas;** these bacteria are characterized by the absence of cell walls, their small genomes, and simplified metabolic pathways. Their small genomes appear to be the result of genome reduction such that they now lack a variety of metabolic capabilities, including the ability to synthesize peptidoglycan precursors.

Some of the major characteristics of the best-studied mycoplasmas are summarized in **table 21.1**. Because they are bound only by a plasma membrane, they are pleomorphic, varying in shape from spherical or pear-shaped microbes from 0.3 to 0.8 μm in diameter, to slender branched or helical filaments (**figure 21.4**). Some mycoplasmas (e.g., *M. genitalium*) have a specialized terminal structure that projects from the cell and gives them a flask or pear shape. This structure aids in attachment to eukaryotic cells. They are among the smallest bacteria capable of self-reproduction. Most species are facultative anaerobes, but a few are obligate anaerobes. When grown on agar, most form colonies with a "fried egg" appearance because they grow into the agar surface at the center while spreading outward on the surface at the colony edges (**figure 21.5**).

Mollicute genomes are among the smallest found among bacteria, ranging from 0.7 to 1.7 Mb (table 21.1). The genomes of the human pathogens *Mycoplasma genitalium, M. pneumoniae,* and *Ureaplasma urealyticum* have fewer than 1,000 genes, suggesting a minimal genome size for a free-living existence. Their limited number of genes reflects their inability to synthesize a number of macromolecules. For instance, because *M. genitalium* relies so heavily on its host's biosynthetic capacity, it has lost genes that encode enzymes needed to synthesize amino acids, purines, pyrimidines, and fatty acids. In addition, most species require sterols for growth, which they obtain from the host as cholesterol. Sterols are an essential component of the mycoplasma plasma membrane,

Table 21.1 Properties of Some Members of the Class *Mollicutes*

Genus	No. of Recognized Species	Genome Size (Mb)	Sterol Requirement	Habitat	Other Distinctive Features
Acholeplasma	13	1.50–1.65	No	Vertebrates, some plants and insects	Optimum growth 30–37°C
Anaeroplasma	4	1.50–1.60	Yes	Bovine or ovine rumen	Oxygen-sensitive anaerobes
Asteroleplasma	1	1.50	No	Bovine or ovine rumen	Oxygen-sensitive anaerobes
Entomoplasma	5	0.79–1.14	Yes	Insects, plants	Optimum growth 30°C
Mesoplasma	12	0.87–1.10	No	Insects, plants	Optimum growth 30°C; sustained growth in serum-free medium only with 0.04% detergent (Tween 80)
Mycoplasma	104	0.60–1.35	Yes	Humans, animals	Optimum growth usually 37°C
Spiroplasma	22	0.94–2.20	Yes	Insects, plants	Helical filaments; optimum growth at 30–37°C
Ureaplasma	6	0.75–1.20	Yes	Humans, animals	Urea hydrolysis

Figure 21.4 Mycoplasmas. A scanning electron micrograph of *Mycoplasma pneumoniae* shows its pleomorphic nature (×26,000).

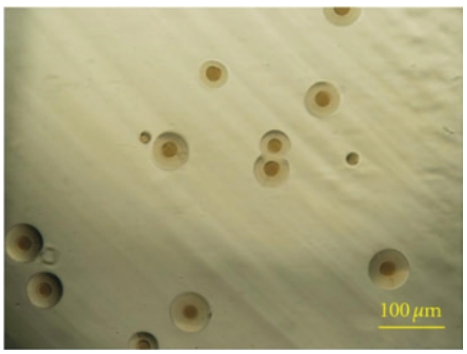

Figure 21.5 Mycoplasma Colonies. Note the "fried egg" appearance.

where they may facilitate osmotic stability in the absence of a cell wall. Some mycoplasmas produce ATP by the Embden-Meyerhof pathway and lactic acid fermentation. The pentose phosphate pathway seems to be functional in at least some mycoplasmas; none appears to have the complete tricarboxylic acid cycle. Arginine can be catabolized to generate ATP in the following series of reactions:

$$\text{Arginine} + H_2O \rightarrow \text{citrulline} + NH_3$$
$$\text{Citrulline} + P_i \rightarrow \text{ornithine} + \text{carbamyl-P}$$
$$\text{Carbamyl-P} + ADP \rightarrow ATP + CO_2 + NH_3$$

The first reaction is catalyzed by the enzyme arginine deaminase, which is found in several firmicutes, including *Bacillus* and *Clostridium* species. ▶▶| Firmicutes: *Low G + C bacteria (chapter 23)*

The small size of the mycoplasma genome has made it the model organism for development of a "synthetic" bacterium. As discussed in chapter 17 (*see p. 412*), this has resulted in the construction of a bacterium with a genome that has been chemically synthesized. This work provides proof of principle that cells can be manufactured to encode only those products desired by the biotechnologist. |◀◀ *Techniques & Applications 17.2*

Ureaplasma urealyticum, a causative agent of urinary tract infections, has an interesting way of conserving energy: it hydrolyzes urea (found in urine) to generate an electrochemical gradient via the accumulation of ammonia/ammonium (NH_3/NH_4^+). This gradient is responsible for the chemiosmotic potential that drives ATP synthesis (**figure 21.6**).

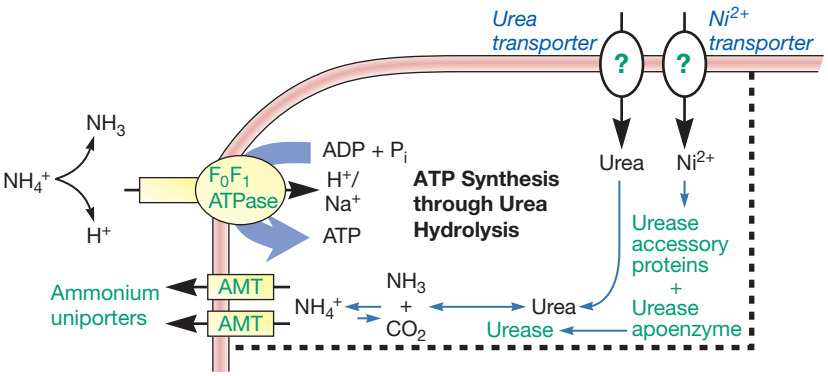

Figure 21.6 Energy Conservation in *Ureaplasma urealyticum*. To generate an electrochemical gradient through the accumulation of NH_3/NH_4^+, *U. urealyticum* is thought to import urea through specific transporters. Once inside the cell, urease (a nickel-binding enzyme) catalyzes the hydrolysis of urea to NH_3 and CO_2. Ammonia accepts a proton to become NH_4^+, which is exported through NH_4^+ uniporters (AMT). Once outside the cell, NH_4^+ is converted to NH_3 and H^+, providing the protons to drive ATP synthesis via the membrane-bound ATP synthase.

Some mycoplasmas are capable of gliding motility. Recall that gliding motility enables movement across solid surfaces. *Mycoplasma mobile* moves at a steady pace of 2 to 5 μm per second. This appears to be mediated by cell surface proteins that surround the "neck" of the cell (**figure 21.7**). In *M. mobile,* these proteins are thought to attach to the cytoskeleton and function like microscopic legs. Unlike flagellar motility, gliding in this microbe is powered by ATP hydrolysis. By contrast, most other motile mycoplasmas move more like inchworms, at a tenth of the speed of *M. mobile*. For instance the terminal structure of *M. pneumoniae* is covered with cytoskeletal proteins that may function as motors to cause the contraction and extension of the cell. ◀◀ *Twitching and gliding motility (section 3.8)*

Mycoplasmas are remarkably widespread and can be isolated from animals, plants, the soil, and even compost piles. Although their complex growth requirements can make their growth in pure (axenic) cultures difficult, at least 10% of the mammalian cell cultures in use are probably contaminated with mycoplasmas. This seriously interferes with tissue culture experiments and has resulted in the development of commercially available rapid tests for the detection of mycoplasmas in cell culture.

In animals, mycoplasmas colonize mucous membranes and joints, and often are associated with diseases of the respiratory and urogenital tracts. Mycoplasmas cause several major diseases in livestock; for example, contagious bovine pleuropneumonia in cattle (*M. mycoides*), chronic respiratory disease in chickens (*M. gallisepticum*), and pneumonia in swine (*M. hyopneumoniae*). Spiroplasmas have been isolated from insects, ticks, and a variety of plants. They cause disease in citrus plants, cabbage, broccoli, corn, honeybees, and other hosts. Arthropods often act as vectors and carry the spiroplasmas between plants. In humans, *U. urealyticum* and *M. hominis* are common parasitic microorganisms of the genital tract, and their transmission is related to sexual activity. Both mycoplasmas can opportunistically cause inflammation of the reproductive organs of males and females. In addition, *Ureaplasma urealyticum* is associated with premature delivery of newborns, as well as neonatal meningitis and pneumonia. *M. pneumoniae* causes primary atypical pneumonia ("walking pneumonia") in humans. ▶▶ *Mycoplasmal pneumonia (section 39.1)*

(b) *M. pneumoniae* has cytoplasmic motor proteins that cause the cell to expand and contract, so that it moves more slowly and at an uneven, inchwormlike pace.

21.4 Photosynthetic Bacteria Are Diverse

After reading this section, you should be able to:

- Assess the importance of photosynthetic pigments in the distribution of photosynthetic bacteria in nature
- Draw a generic chlorosome and identify the function of its structural elements
- Predict the habitat closest to your home where you might find members of the phyla *Chlorobi, Chloroflexi,* and *Cyanobacteria*
- Draw a generic cyanobacterial cell and label its intracellular structures
- List three types of specialized cells made by cyanobacteria and describe the function of each
- Compare and contrast the prochlorophytes with other cyanobacteria
- Draw a concept map describing the structure and physiology of the six types of photosynthetic bacteria listed in table 21.2

Historically, the term photosynthetic has been applied to both photoheterotrophic and photoautotrophic microbes. We continue to use this term in this way, but care should be taken not to assume that the capture of light energy (phototrophy) is always linked with CO_2 fixation (autotrophy). As we shall see, unlike plants, photosynthetic microbes often have more than one metabolic strategy and may uncouple phototrophy from autotrophy and grow photoheterotrophically.

Bacteria capable of chlorophyll-based photosynthesis have been identified in seven phyla, with the most recent discovered in 2014 when a chlorophyll-containing photoheterotrophic, Gram-negative bacterium belonging to the phylum *Gemmatimonadetes* was isolated from a freshwater lake in the Gobi Desert. However, because volume 1 of *Bergey's Manual* was published in 2001, it distributes distributes phototrophic bacteria between five bacterial phyla (table 21.2). The phylum *Chloroflexi* contains green nonsulfur bacteria, and the phylum *Chlorobi* includes green sulfur bacteria. Cyanobacteria are placed in their own phylum, *Cyanobacteria*. Purple bacteria are divided between three groups. Purple sulfur bacteria are placed in γ-proteobacteria (families *Chromatiaceae* and *Ectothiorhodospiraceae*). Purple nonsulfur bacteria are distributed between α-proteobacteria and β-proteobacteria. *A*erobic *An*oxygenic *P*hototrophs (AAnPs) are photoheterotrophs divided among α-, β-, and γ-proteobacteria. Finally, Gram-positive heliobacteria in the phylum *Firmicutes* are also photosynthetic. There appears to have been considerable horizontal transfer of photosynthetic genes among the five phyla. At least 50 genes related to photosynthesis are common to all five. In this chapter, we describe the cyanobacteria and green bacteria; purple bacteria are discussed in chapter 22, while heliobacteria are discussed in chapter 23.

Cyanobacteria differ fundamentally from the other photosynthetic bacteria because they perform **oxygenic photosynthesis:** they have photosystems I and II, use water as an electron donor, and generate oxygen during photosynthesis. In contrast, purple bacteria, green bacteria, and AAnPs have only one photosystem and use **anoxygenic photosynthesis.** Because they are unable to use water as an electron source, they employ other reduced molecules as electron donors. AAnPs and purple nonsulfur bacteria are photoorganoheterotrophs, so they use electrons obtained during the oxidation of organic substrates but make ATP from light energy. The purple and green sulfur bacteria use inorganic electron donors such as hydrogen sulfide, sulfur, and hydrogen, as well as organic matter, as an electron source for the reduction of $NAD(P)^+$ to NAD(P)H. Those that use sulfide as an electron source often form sulfur granules. Purple sulfur bacteria accumulate granules within their cells, whereas green sulfur bacteria deposit the sulfur granules outside their cells. ◀◀ *Phototrophy (section 11.11)*

Photosynthetic microbes are major contributors of fixed carbon, termed primary productivity, in a variety of habitats. The differences in photosynthetic pigments and oxygen requirements among photosynthetic bacteria have important ecological consequences. As shown in **figure 21.8**, chlorophylls

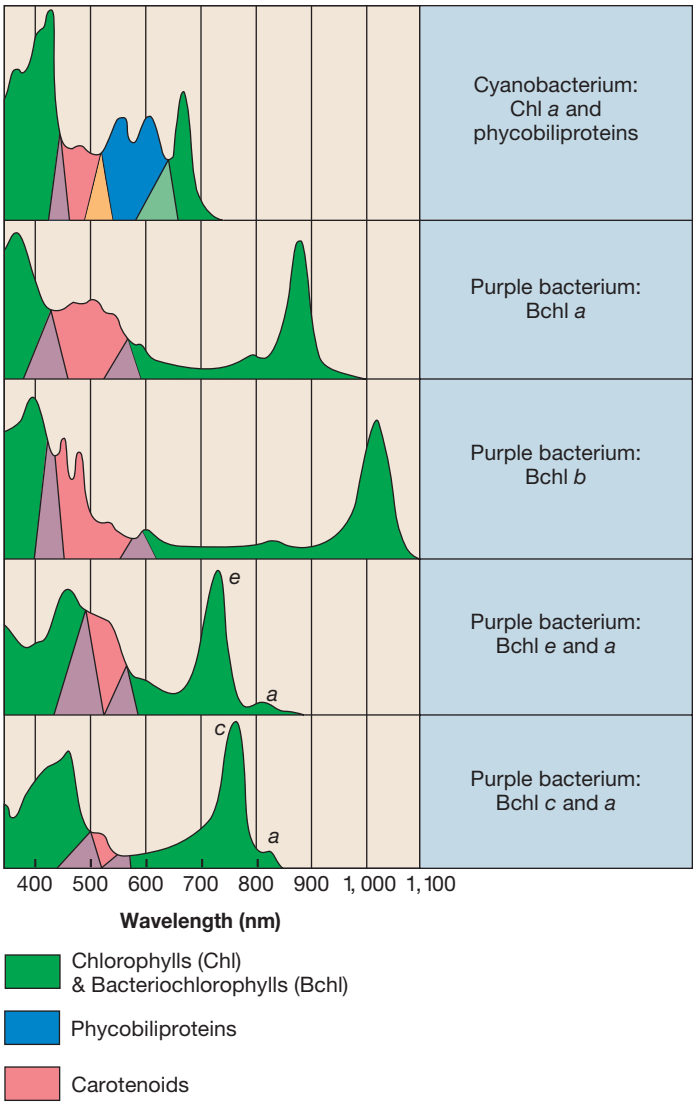

Figure 21.8 Photosynthetic Pigments. Absorption spectra of five photosynthetic bacteria showing the differences in absorption maxima and the contributions of various accessory pigments.

Table 21.2 Characteristics of the Major Groups of Gram-Negative Photosynthetic Bacteria

Characteristic	Green Sulfur	Green Nonsulfur	Purple Sulfur	Purple Nonsulfur	Aerobic Anoxygenic Phototrophs	Cyanobacteria
Major photosynthetic pigments	Bacteriochlorophylls *a* plus *c, d,* or *e*	Bacteriochlorophylls *a* and *c*	Bacteriochlorophyll *a* or *b*	Bacteriochlorophyll *a* or *b*	Bacteriochlorophyll *a*	Chlorophyll *a* plus phycobiliproteins. *Prochlorococcus* has divinyl derivatives of chlorophyll *a* and *b*
Morphology of photosynthetic membranes	Photosynthetic system partly in chlorosomes	Chlorosomes present when grown anaerobically	Photosynthetic system contained in spherical or lamellar membrane complexes that are continuous with the plasma membrane	Photosynthetic system contained in spherical or lamellar membrane complexes that are continuous with the plasma membrane	Few, if any, intracytoplasmic membranes	Thylakoid membranes lined with phycobilisomes
Photosynthetic electron donors	H_2, H_2S, S^0	Photoheterotrophic donors—a variety of sugars, amino acids, and organic acids; photoautotrophic donors—H_2S, H_2	H_2, H_2S, S^0	Usually organic molecules: sometimes reduced sulfur compounds or H_2	A variety of sugars, amino acids, and organic acids	H_2O
Sulfur deposition	Outside of the cell	N/A[1]	Inside the cell[2]	Outside of the cell in a few cases	N/A	N/A
Nature of phototrophy	Anoxygenic	Anoxygenic	Anoxygenic	Anoxygenic	Anoxygenic	Oxygenic (some are also facultatively anoxygenic)
General metabolic type	Obligate anaerobic photolithoautotrophs	Usually photoheterotrophic; sometimes photoautotrophic or chemoheterotrophic (when aerobic and in the dark)	Obligate anaerobic photolithoautotrophs	Usually anaerobic photoorgano-heterotrophs; some facultative photolithoautotrophs; some are chemo-organoheterotrophs in the dark	Aerobic photoorgano-heterotrophs	Aerobic photo-lithoautotrophs
Motility	Many nonmotile; some glide; some have gas vesicles	Gliding	Motile with polar or peritrichous flagella	Motile with polar flagella or nonmotile; some have gas vesicles	Some are motile with a single or a few polar or subpolar flagella	Nonmotile, swimming motility without flagella; some glide; some have gas vesicles
Taxonomic distribution	*Chlorobi*	*Chloroflexi*	γ-proteobacteria	α-proteobacteria, β-proteobacteria (*Rhodocyclus*)	α-proteobacteria, β-proteobacteria, γ-proteobacteria	*Cyanobacteria*

2 With the exception of *Ectothiorhodospira*.

(Chl), bacteriochlorophylls (Bchl), and their associated accessory pigments have narrow absorption spectra. Microbes therefore use accessory pigments to broaden their energy input. These pigments collect light of different wavelengths and transfer it to Chl or Bchl, where it is converted to chemical energy. Oxygenic cyanobacteria and diatoms dominate the aerated upper layers of freshwater and marine microbial communities, where they absorb large amounts of red and blue light. Anoxygenic purple and green photosynthetic bacteria inhabit the deeper anoxic zones that are rich in hydrogen sulfide and other reduced compounds that can be used as electron donors. Their Bchl and accessory pigments enable their use of light in the far-red spectrum (i.e., > 750 nm) that is not used by other photosynthetic organisms (compare the Bchl *a* and Bchl *b* with Chl *a* in figure 21.8). Bchl absorption has additional peaks between 350 to 550 nm, allowing growth at greater depths because shorter-wavelength light can penetrate water farther.

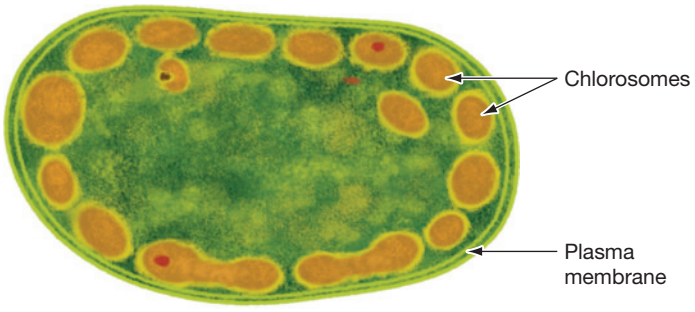
Before we describe the established phyla, it is worth mentioning an interesting chlorophyll-containing thermophilic bacterium in the phylum *Acidobacteria* discovered in Yellowstone National Park hot springs in 2007. This Gram-negative bacterium contains bacteriochlorophylls *a* and *c* under oxic conditions and grows photoheterotrophically. The discovery of 16S rRNA sequences in Thailand and Tibet similar to those found at Yellowstone suggests a global distribution of this thermophile. The phylum *Acidobacteria* is small, but it may be far more diverse than previously imagined. Indeed, the number of phototrophic microbes may exceed our long-held beliefs.

Phylum *Chlorobi*: Green Sulfur Bacteria

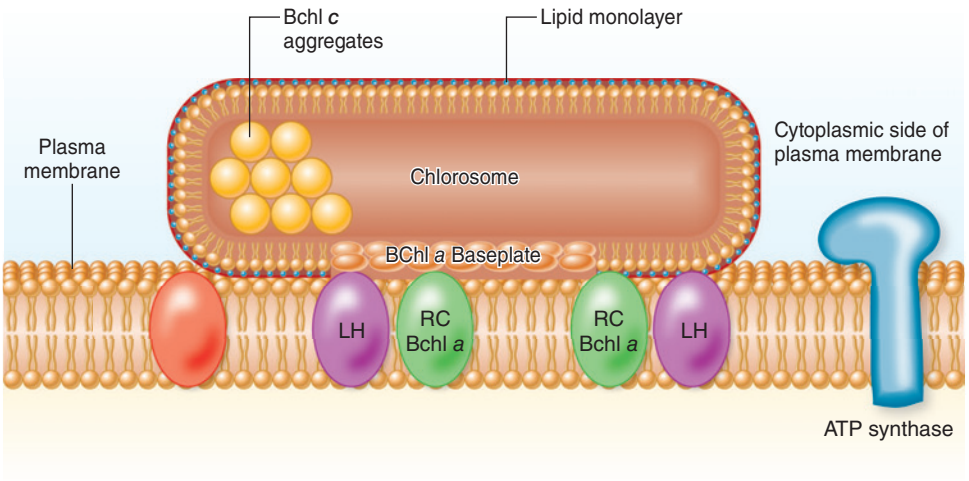
Members of the phylum *Chlorobi* are commonly called **green sulfur bacteria.** This is a small group of obligately anaerobic photolithoautotrophs that use hydrogen sulfide, elemental sulfur, and hydrogen as electron sources. When sulfide is oxidized, elemental sulfur is deposited outside the cell. Their photosynthetic pigments are located in ellipsoidal vesicles called **chlorosomes** or chlorobium vesicles, which are attached to the plasma membrane by a proteinaceous baseplate that contains Bchl *a* molecules (**figure 21.9**). The chlorosome membrane is an unusual lipid monolayer, rather than bilayer. Within chlorosomes, bacteriochlorophyll molecules (Bchl *c, d,* or *e*) are grouped into rodlike structures held together by carotenoids and lipids. The light harvested by these pigments is transferred by baseplate Bchl *a* to reaction centers in the plasma membrane, which also contain Bchl *a*. The ATP produced by photophosphorylation is used to fuel CO_2 fixation by the reductive citric acid cycle (*see figure 12.5*); the more familiar Calvin-Benson cycle is used only by aerobes.

These bacteria flourish in the anoxic, sulfide-rich zones of lakes. Although they lack flagella and most are nonmotile, members of at least one genus glides. Some species have gas vesicles to adjust their depth for optimal light and hydrogen sulfide (*see figure 3.36*). Those without gas vesicles are found in sulfide-rich muds at the bottom of lakes and ponds.

Green sulfur bacteria are very diverse morphologically. They may be rods, cocci, or vibrios; some grow singly, and others form chains and clusters. They are either grass-green or chocolate-brown in color. Representative genera are *Chlorobium, Prosthecochloris,* and *Pelodictyon.*



(a)



(b)

Figure 21.9 Green Sulfur Bacteria. (a) Light-harvesting chlorosomes surround the inside perimeter of the cytoplasmic membrane. Antenna bacteriochlorophylls (Bchl *c, d,* or *e*) transfer light energy to reaction center Bchl *a* in the plasma membrane. (b) A chlorosome is attached to the inner surface of the plasma membrane by a baseplate composed of a lipid monolayer and Bchl *a* molecules. The chlorosome absorbs light by Bchl *c, d,* or *e* molecules aligned in rod-shaped complexes (Bchl *c* is shown here). The reaction center (RC) is located in the plasma membrane and contains only Bchl *a.* The light-harvesting complex (LH) and ATP synthase are also located in the plasma membrane.

Phylum *Chloroflexi*: Green Nonsulfur Bacteria

The phylum *Chloroflexi* is a deep and ancient branch of the bacterial tree. It has two orders: one consists of thermophilic, facultatively photosynthetic bacteria (*Chlorflexales*), and the other consists of nonphotosynthetic thermophiles and mesophiles (*Herpetosiphonales*). Members of the genus *Chloroflexus* make up the majority of photosynthetic **green nonsulfur bacteria.** However, the term green nonsulfur is a misnomer because not all members of this group are green, and some can use sulfide. *Chloroflexus* spp. are filamentous, gliding bacteria often isolated from neutral to alkaline hot springs, where they grow in the form of orange-reddish mats, usually in association with cyanobacteria. They possess small chlorosomes with accessory Bchl *c*. The light-harvesting complexes contain Bchl *a* and are in the plasma membrane. *Chloroflexus* spp. are metabolically very diverse. Some are facultative anaerobes, others are anaerobic, and while some are chemoorganotrophic, most are photoheterotrophic. They can carry out anoxygenic photosynthesis using sulfide or hydrogen as a source of electrons. Heterotrophic growth is supported by pyruvate, acetate, glycerol, and glucose oxidation. When growing autotrophically, they use an unusual pathway, the 3-hydroxypropionate bi-cycle to fix CO_2 (**figure 21.10**). An interesting aspect of this pathway is that the left half produces glyoxylate, which is then used in the right half to make pyruvate.

Members of the nonphotosynthetic, gliding, rod-shaped, or filamentous genus *Herpetosiphon* are aerobic chemoorganotrophs with respiratory metabolism. They can be isolated from freshwater and soil habitats.

1. Which of the phototrophs discussed perform anoxygenic photosynthesis? Which are also capable of chemoorganoheterotrophy?
2. What is the function of chlorosomes? How does their unique structure contribute to this function?
3. Compare the capacity of green nonsulfur (*Chloroflexi*) and green sulfur bacteria (*Chlorobi*) to position themselves in light of optimum wavelength.

Phylum *Cyanobacteria*: Oxygenic Photosynthetic Bacteria

Cyanobacteria are the largest and most diverse group of photosynthetic bacteria. Originally studied by botanists, they were classified as *Chlorophyceae,* erroneously known as blue-green algae. *Bergey's Manual* describes 56 genera and divides cyanobacteria into five subsections (**table 21.3**). At present all taxonomic schemes must be considered tentative, and while many genera have been assigned, species names have not yet been designated in most cases.

Recall that endosymbiotic cyanobacteria are thought to have evolved into chloroplasts. It follows that the cyanobacterial photosynthetic apparatus closely resembles that of eukaryotes; cyanobacteria have chlorophyll *a* and photosystems I and II, and thereby

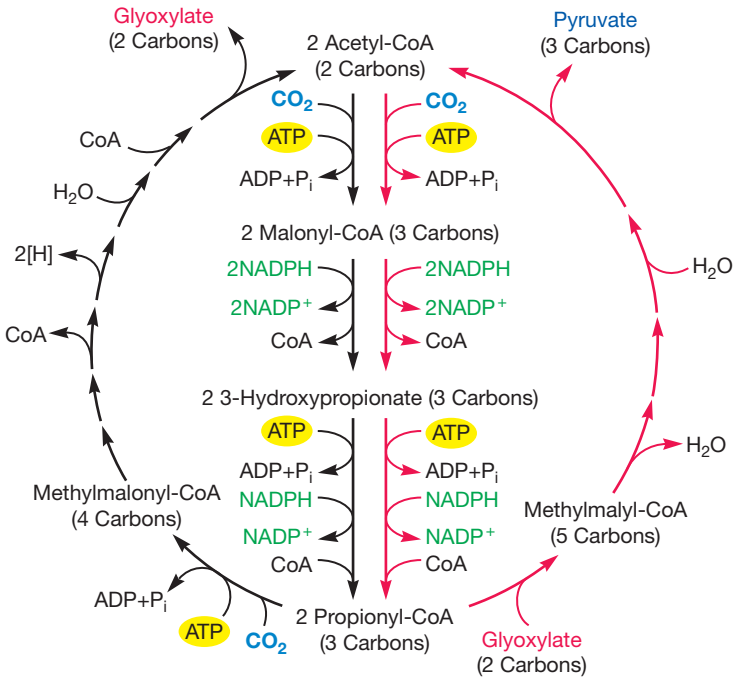

Figure 21.10 The 3-Hydroxypropionate Bi-Cycle. This pathway functions when photosynthetic members of the phylum *Chloroflexi* grow autotrophically; CO_2 exists as HCO_3^- when it is added to intermediates of the pathway.

perform oxygenic photosynthesis. Light-harvesting and electron transport chain components are located in thylakoid membranes to which particles called **phycobilisomes** are attached (**figure 21.11**). Phycobilisomes are protein complexes made up of **phycobiliprotein** pigments, particularly **phycocyanin** and **phycoerythrin,** held together by linker proteins (figure 21.11*b*). Each phycobilisome consists of a core phycobiliprotein pigment, allophycocyanin, surrounded by other pigments arranged in stacklike structures. Each pigment absorbs light of different wavelengths, and this arrangement enables the efficient transfer energy to photosystem II. ◀◀ *Evolution of the three domains of life (section 19.5)*

Carbon dioxide is assimilated through the Calvin-Benson cycle (*see figure 12.4*). The enzymes needed for this process are found in internal structures (microcompartments) called **carboxysomes.** During daylight hours, when cyanobacteria fix carbon for anabolic purposes, they also synthesize **glycogen** as a reserve carbohydrate to supply electrons needed for respiration at night. Some cyanobacteria also store extra nitrogen as polymers of arginine and aspartic acid called **cyanophycin** granules. Phosphate is stored in polyphosphate granules. Because cyanobacteria lack the enzyme α-ketoglutarate dehydrogenase (α-KDH), it was long thought that they lack a fully functional TCA cycle. Recently two enzymes that bypass the need for α-KDH were identified in a unicellular cyanobacterium belonging to the genus *Synechococcus.* In this microbe, and most cyanobacteria, the first enzyme converts α-ketoglutarate to succinic semi-aldehyde, which is then oxidized to succinate by the second enzyme; the intermediate succinyl-CoA is not produced (*see figure 11.8*) ◀◀ *Microcompartments (section 3.6)*

Table 21.3 Characteristics of the Cyanobacterial Subsections

Subsection	General Shape	Reproduction and Growth	Heterocysts	Other Properties	Representative Genera
I	Unicellular rods or cocci; nonfilamentous aggregates	Binary fission, budding	–	Nonmotile or swim without flagella	*Chroococcus* *Gleocapsa* *Prochlorococcus* *Synechococcus*

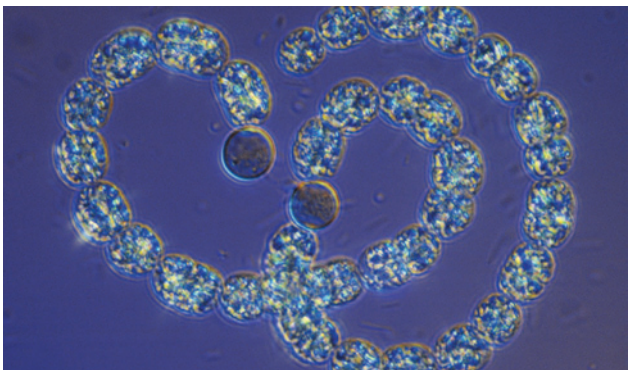
(b) *Chroococcus turgidus*



(d) *Anabaena spiroides*

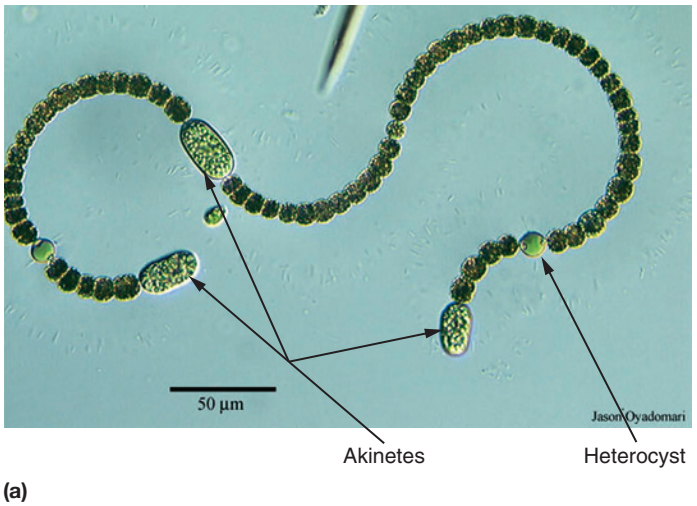
Figure 21.12 Cyanobacteria Are Morphologically Diverse. (a) *Oscillatoria* trichomes seen with Nomarski interference-contrast optics (×250). (b) *Chroococcus turgidus* produces a gelatinous sheath that can surround one, two, or four cells. (c) *Nostoc* sp. produces heterocysts in the absence of combined nitrogen; here it has only vegetative cells. (d) The cyanobacteria *Anabaena spiroides* with heterocysts. (×1,000).

Although most cyanobacteria are obligate photolithoautotrophs, a few can grow in the dark as chemoheterotrophs by oxidizing glucose and a few other sugars. Under anoxic conditions, *Oscillatoria limnetica* oxidizes hydrogen sulfide instead of water and carries out anoxygenic photosynthesis much like green photosynthetic bacteria. *Oscillatoria* is one of several cyanobacterial genera whose members produce geosmins, volatile organic compounds that often have an earthy odor. When populations of these cyanobacteria become dominant in lakes and rivers, this can be a public nuisance, even changing the taste of drinking water. ▶▶| *Microorganisms in marine and freshwater ecosystems (chapter 30)*

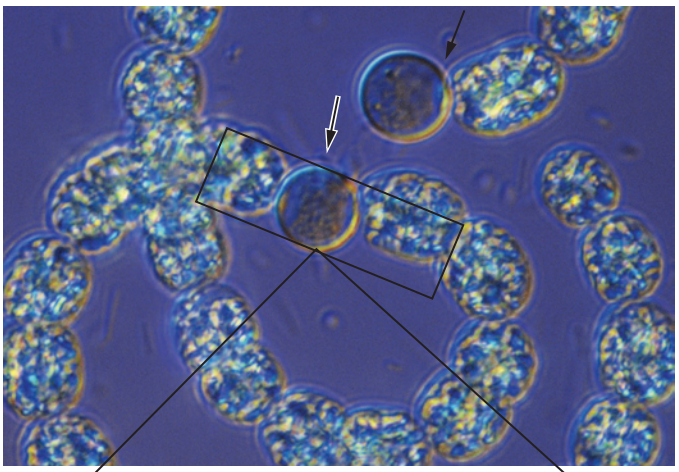
Cyanobacteria also vary greatly in shape and appearance. They range in diameter from about 1 to 10 μm and may be unicellular, exist as colonies of many shapes, or form filaments called trichomes (**figure 21.12*a***). A **trichome** is a row of bacterial cells that are in close contact with one another over a large area. Although many cyanobacteria appear blue-green because of phycocyanin, isolates from the open ocean are red or brown because their phycobilisomes contain the pigment phycoerythrin (figure 21.11*b*). Because each pigment evolved to absorb light of different wavelengths, cyanobacteria modulate the relative amounts of these pigments in response to available light in a process known as **chromatic adaptation.** When orange light is sensed, the production of phycocyanin (absorption peak at 618 nm) is stimulated, whereas blue and blue-green light promote the production of phycoerythrin (absorption peaks at 490, 546, and 576 nm). Chromatic adaptation means that cyanobacteria must be able to sense light quality, and they use a variety of strategies to do so, including sensory rhodopsins (*see p. 479*), plantlike proteins called phytochromes, and membrane-associated receptors that sense ultraviolet and blue light. Many cyanobacterial species use gas vacuoles to position themselves in optimum illumination in the water column—a form of **phototaxis.** Gliding motility is used by many filamentous cyanobacteria, including those found in dense microbial assemblages in sediments called microbial mats (*see figure 29.10*). Although cyanobacteria lack flagella, about one-third of the marine *Synechococcus* strains swim at rates up to 25 μm per second. Swimming motility is not used for phototaxis; instead, it appears to be used for chemotaxis toward simple nitrogenous compounds such as urea. The mechanisms for both gliding and swimming motility in cyanobacteria remain unresolved. |◀◀ *Chemotaxis (section 3.8)*

Cyanobacteria show great diversity with respect to reproduction and employ a variety of mechanisms: binary fission, budding, fragmentation, and multiple fission. In the last process, a cell enlarges and then divides several times to produce many smaller progeny called **baeocytes** (*see figure 7.2*), which are released upon the rupture of the parental cell. Some baeocytes

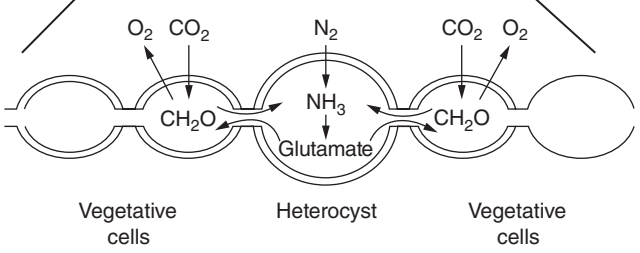
disperse through gliding motility. Fragmentation of filamentous cyanobacteria can generate small, motile filaments called **hormogonia.** Some filamentous species develop **akinetes,** specialized, dormant, thick-walled resting cells that are resistant to desiccation (**figure 21.13*a***). These later germinate to form new filaments.



(a)



(b)



(c)

Figure 21.13 **Cyanobacteria with Akinetes and Heterocysts.**
(a) The filamentous cyanobacterium *Anabaena* with akinetes and heterocysts. (b) *Anabaena* heterocysts (arrow) and vegetative cells. (c) Heterocysts fix dinitrogen to form glutamate, which is exchanged with adjacent vegetative cells for carbohydrate. Heterocysts use only photosystem I, so photosynthesis is anoxygenic in these differentiated cells.

MICRO INQUIRY *Why do you think NH_3 is converted to the amino acid glutamate in heterocysts before its transfer to neighboring vegetative cells?*

Many filamentous cyanobacteria fix atmospheric nitrogen by means of special cells called **heterocysts** (figure 21.13). Around 5 to 10% of the cells develop into heterocysts when these cyanobacteria are deprived of both nitrate and ammonia, their preferred nitrogen sources. Within these specialized cells, photosynthetic membranes are reorganized and the proteins that make up photosystem II and phycobilisomes are degraded. Photosystem I remains functional to produce ATP, but no oxygen is generated. Lack of O_2 production is critical because the N_2-fixing enzyme nitrogenase is extremely oxygen sensitive. Heterocysts develop thick cell walls, which slow or prevent O_2 diffusion into the cell, and any O_2 present is consumed during respiration. Heterocyst structure and physiology ensure that these specialized cells remain anaerobic; the heterocyst is dedicated to nitrogen fixation, not reproduction. Nutrients are obtained from adjacent vegetative cells, while the heterocysts contribute fixed nitrogen in the form of amino acids. Nitrogen fixation also is carried out by some cyanobacteria that lack heterocysts. Some fix nitrogen under dark, anoxic conditions in microbial mats. Planktonic forms such as those belonging to the genus *Trichodesmium* fix nitrogen and contribute significantly to the marine nitrogen budget *(see figure 30.9).* ⏮ *Nitrogen fixation (section 12.5)* ⏭ *Nitrogen cycle (section 28.1)*

An important group of cyanobacteria is collectively referred to as **prochlorophytes** (genera *Prochloron, Prochlorococcus,* and *Prochlorothrix*). These microbes differ from other cyanobacteria by the presence of chlorophyll *b* as well as *a,* and the lack of phycobilins. This pigment arrangement imparts a grass-green color. As the only bacteria to possess chlorophyll *b,* the ancestors of unicellular prochlorophytes are considered the best candidates for the endosymbionts that gave rise to chloroplasts. ⏮ *Evolution of the three domains of life (section 19.5)*

The three recognized prochlorophyte genera are quite different from one another. Members of the genus *Prochloron* were first discovered as symbionts growing either on the surface or within the cloacal cavity of marine colonial ascidian invertebrates (commonly called "sea squirts"). These bacteria are single-celled, spherical, and 8 to 30 µm in diameter. By contrast, those in the genus *Prochlorothrix* are free living, with cylindrical cells that form filaments growing in freshwater.

Prochlorococcus spp. are tiny coccobacilli less than 1 µm in diameter that flourish in marine plankton. They differ from other prochlorophytes in having divinyl chlorophyll *a* and *b,* and α-carotene, instead of chlorophyll *a* and β-carotene. Other cyanobacteria use monovinyl chlorophyll *a*; the difference between mono- and divinyl chlorophyll is the presence of a double bond between carbons attached to pyrrole ring II (*see figure 11.29*). *Prochlorococcus marinus* is globally distributed in the ocean between the latitudes 40°N and 40°S and to 200 meters in depth, making it the most abundant photosynthetic organism on Earth.

Prochlorococci have a profound effect on the global carbon cycle. Together with members of the genus *Synechococcus,*

Figure 21.14 Bloom of Cyanobacteria and Algae in a Eutrophic Pond.

Prochlorococcus accounts for at least one-third of global CO_2 fixation. These microbes have coevolved to take maximum advantage of incident light. *Synechococcus* spp. occupy the upper 25 meters of the open ocean, where white and blue-green light can be harvested. In the waters beneath *Synechococcus,* two ecotypes of *Prochlorococcus* species exist: the high-light ecotype grows between about 25 to 100 meters, while the low-light ecotype lives from 80 to 200 meters, where the waters are penetrated by blue-violet light. This prevents the two genera of cyanobacteria from competing for the essential resource of light. ⏮ *Microbial evolutionary processes (section 19.5)* ⏭ *Microorganisms in the open ocean are adapted to nutrient limitation (section 30.2)*

In addition to those in coastal and open ocean waters, many other cyanobacteria inhabit a wide range of other habitats. A variety of cyanobacteria live in symbiotic association with protists and fungi. Thermophilic species may grow at temperatures up to 75°C in neutral to alkaline hot springs. Because these photoautotrophs are so hardy, they are primary colonizers of soils and surfaces that are devoid of plant growth. Some unicellular forms even grow in the fissures of desert rocks. In nutrient-rich warm ponds and lakes, filamentous cyanobacteria such as *Anacystis* and *Anabaena* spp. can reproduce rapidly to form blooms (**figure 21.14**). The release of large amounts of organic matter upon the death of the bloom microorganisms stimulates the growth of chemoheterotrophic bacteria. These microbes subsequently deplete available oxygen. This kills fish and other organisms. Some species can produce toxins that can kill animals that drink the water. Other cyanobacteria (e.g., *Oscillatoria* spp.) are so pollution resistant and characteristic of freshwater with high organic matter content that they are used as water pollution indicators. ⏭ *Microorganisms in coastal ecosystems are adapted to a changeable environment (section 30.2)*

21.5 Phylum *Planctomycetes:* Bacteria with Intracellular Compartments

After reading this section, you should be able to:

- Draw the unusual structural features of planctomycetes
- Identify the electron donor and acceptor used in the anammox reaction
- Explain why the anammox reaction is important to the global flux of nitrogen

The phylum *Planctomycetes* was largely underappreciated until recently. Bacteria in this phylum are morphologically unique, having compartmentalized cells (**figure 21.15**). Although each species is unique, all follow a basic cellular organization that includes a plasma membrane closely surrounded by a proteinacious cell wall that lacks peptidoglycan. At least one candidate species is known to have an S layer. The intracytoplasmic membrane is separated from the plasma membrane by a peripheral, ribosome-free region called the paryphoplasm (sometimes referred to as the pirellulosome). Some planctomycetes, such as *Gemmata obscuriglobus,* enclose their genome in a compartment called the nuclear body. Unlike a eukaryotic nucleus, the nuclear body contains ribosomes as well as nucleic acids. Members of the genus *Planctomyces* attach to surfaces through a stalk and holdfast. Most of these bacteria have life cycles in which sessile cells bud to produce motile swarmer cells. The swarmer cells are flagellated and swim for a while before attaching to a substrate and beginning budding reproduction.

Members of the genera *Brocadia, Kuenenia, Scalindua,* and *Anammoxoglobus* lack a nuclear body but possess another compartment, the **anammoxosome.** This is the site of *ana*erobic *amm*onia *oxi*dation, called the **anammox reaction,** or simply anammox. This unique form of chemolithoautotrophy employs ammonium ion (NH_4^+) as the electron donor and nitrite (NO_2^-) as the terminal electron acceptor—it is reduced to nitrogen gas (N_2) (**figure 21.16**). Hydrazine (N_2H_4) is an important intermediate in anammox. It is normally a cellular toxin, but in this case its very negative reduction potential

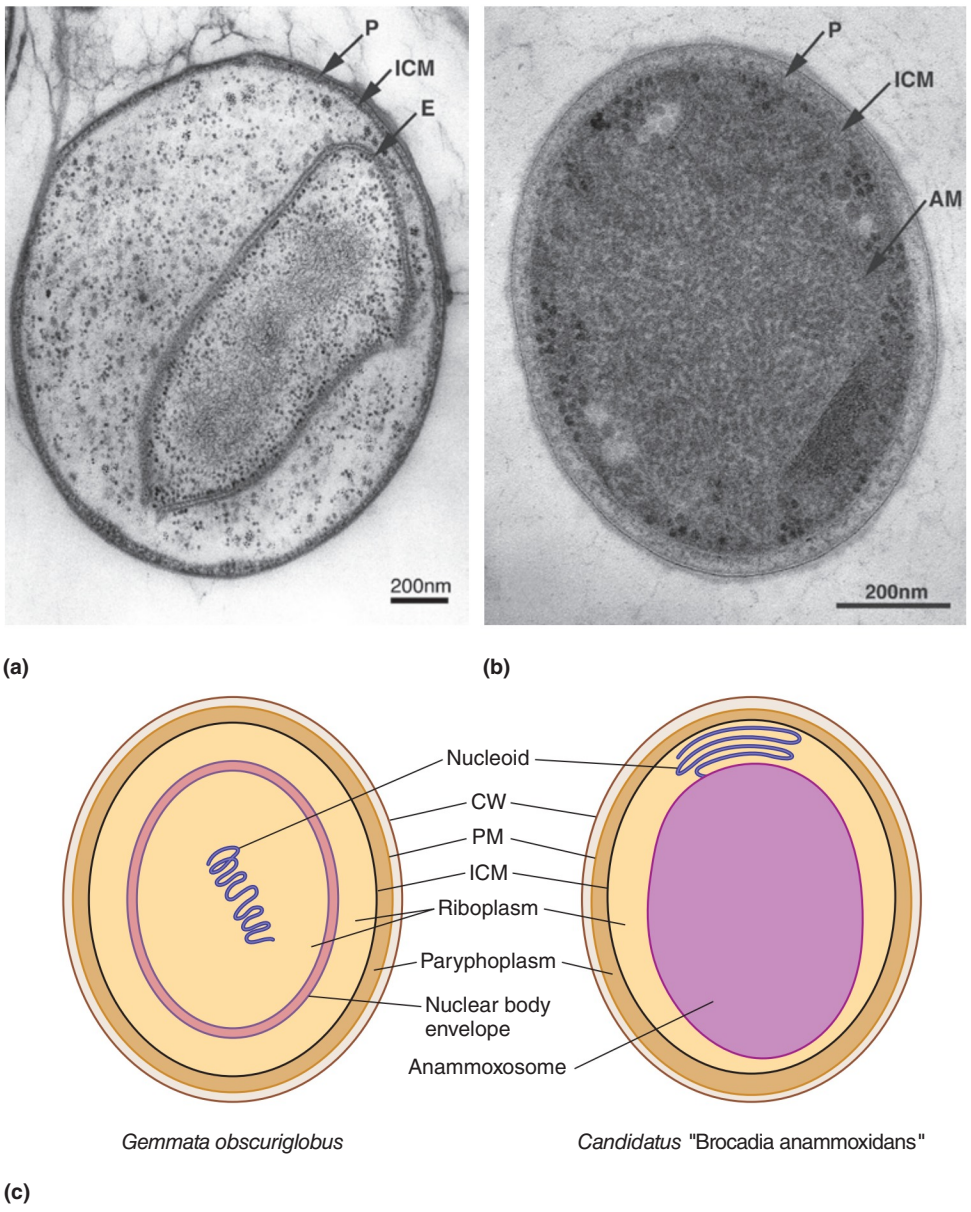

Figure 21.15 **Planctomycete Cellular Compartmentalization.** (a) An electron micrograph of *Gemmata obscuriglobus* showing the nuclear body envelope (E), the intracytoplasmic membrane (ICM), and the paryphoplasm (P). (b) An electron micrograph of the anaerobic ammonia-oxidizing planctomycete *Candidatus* Brocadia anammoxidans. The anammoxosome is labeled AM. (c) Schematic drawings corresponding to (a) and (b): cell wall (CW), plasma membrane (PM).

enables it to donate electrons to ferredoxin. The four high-energy electrons carried by reduced ferredoxin can then be used to produce a proton motive force (PMF) that drives ATP synthesis by an ATP synthase embedded in the anammoxosome membrane. Reduced ferredoxin is also used in CO_2 fixation.

One interesting feature of the physiology of anammox bacteria is that they use nitrite not only as the electron acceptor for ammonium oxidation and generation of a PMF but also as an electron donor for CO_2 fixation, which is accomplished using the reductive acetyl-CoA pathway (*see figure 20.3*). Therefore nitrite acts in both anabolic and catabolic processes, as shown in the following reactions:

An anabolic reaction:

$$2NO_2^- + CO_2 + H_2O \rightarrow CH_2O + 2NO_3^-$$

And a catabolic reaction:

$$NO_2^- + NH_4^+ \rightarrow N_2 + 2H_2O$$

The anammoxosome is bounded by a single bilayer membrane that contains ladderane lipids (*see figure 3.32*). These lipids are unique among planctomycetes and they are thought to form an impermeable barrier, preventing the escape of toxic anammox intermediates into the riboplasm. It is important to note that anammox is estimated to contribute as much as 70% to the cycling of nitrogen in the world's oceans. ▶▶| *Nitrogen cycle (section 28.1)*

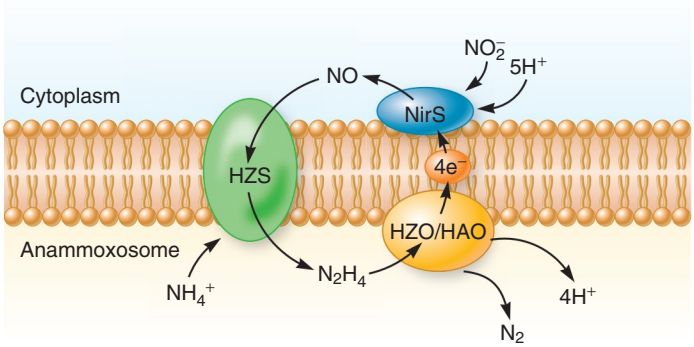

Figure 21.16 **The Anammox Reaction.** Ammonium (NH_4^+) combines with nitric oxide (NO) to form hydrazine (N_2H_4) in a reaction catalyzed by hydrazine synthase (HZS). Oxidation of hydrazine by a hydrazine/hydroxylamine oxidoreductase (HZO/HAO) results in the formation of one N_2 and four protons. The electrons are passed to NO_2^-, which is reduced by nitrite:nitric oxide reductase (NirS) to form another molecule of NO and the cycle continues.

MICRO INQUIRY *How does a planctomycete use the anammox reaction to generate a proton motive force?*

21.6 Phylum *Chlamydiae:* Obligate Intracellular Parasites

After reading this section, you should be able to:

- Explain the term obligate intracellular parasite
- Diagram the chlamydial life cycle
- Deduce why chlamydia can survive despite significant metabolic limitations

Chlamydiae are Gram-negative obligate intracellular parasites. This means they must grow and reproduce within host cells. Although their ability to cause disease is widely recognized, many species grow within protists and animal cells without adverse effects. These hosts represent a natural reservoir for chlamydiae. Within the single class *Chlamydiae,* there are four families, of which *Chlamydiales* is most well known. This family was founded with the single genus, *Chlamydia*. In 1999 several species were split from this genus and placed in a new genus, *Chlamydophila*. Although controversial, this was based on molecular data including 16S rRNA sequences and DNA-DNA hybridization. Since that time the complete genome sequences of many species in both genera have been published, fueling continued debate and recommendations to reunite the genera. Both genera include human and animal pathogens, including *Chlamydophila pneumoniae, Chlamydophila psittici,* and *Chlamydia trachomatis*. In the human host, *C. trachomatis* is responsible for the most common sexually transmitted disease, nongonococcal urethritis. This microbe is also the most common cause of preventable blindness in the world. These diseases are discussed in chapter 39. ⏮ *Microbial taxonomy and phylogeny are largely based on molecular characteristics (section 19.3)*

Members of the genera *Chlamydia* and *Chlamydophilia* are nonmotile, coccoid bacteria, ranging in size from 0.2 to 1.5 μm. For many years the presence of peptidoglycan was debated, because although the genes for its synthesis are found on the genomes of sequenced species, peptidoglycan could not be detected. Recently a new approach to labeling D-amino acids demonstrated peptidoglycan in *Chlamydia trachomatis*. Chlamydiae are extremely limited metabolically, relying on their host cells for key metabolites, including ATP. Although they have an ATP synthase, it is run in reverse such that the hydrolysis of ATP generates a proton motive force used to drive the uptake of nutrients from the host. Like other intracellular parasites, its genome is small at 1.0 to 1.3 Mb. Comparative genomics reveals that some chlamydial genes were acquired by horizontal gene transfer (HGT) from free-living bacteria to a common chlamydial ancestor, and HGT accounts for the transfer of genes from chlamydiae to their protist hosts in the genera *Trypanosoma* and *Leishmania*. ⏭ Euglenozoa *(section 25.2)*

Chlamydial reproduction is unique. It begins with the attachment of an **elementary body** (**EB**) to the host cell surface (**figure 21.17**). EBs are 0.2 to 0.6 μm in diameter, contain electron-dense nuclear material and a rigid cell wall, and are infectious. They achieve osmotic stability in the extracellular environment by cross-linking their outer membrane proteins, and possibly periplasmic proteins, with disulfide bonds. Host cells become infected with EBs by endocytosing them. An EB is held in an endosome that evades fusion with lysosomes. There the EB differentiates into a **reticulate body** (**RB**) and undergoes binary fission, which continues until the host cell dies. Reticulate bodies are 0.5 to 1.5 μm in diameter and have less dense nuclear material and more ribosomes than EBs; their walls are also more flexible. After 20 to 25 hours, RBs prepare to leave the host cell and seek new host cells by differentiating into infectious EBs. The host cell lyses and releases EBs 48 to 72 hours after infection.

Chlamydial metabolism is very different from that of other bacteria. It had been thought that chlamydiae cannot catabolize carbohydrates or synthesize ATP. *Chlamydophila psittaci,* one of the best-studied species, lacks both flavoprotein and cytochrome electron transport chain carriers but has a membrane translocase that acquires host ATP in exchange for ADP. The protist parasite *Chlamydia* UWE25 cannot synthesize NAD^+ but synthesizes a transport protein for the import of host NAD^+. Thus some chlamydiae may be energy parasites that are completely dependent on their hosts for ATP. However, in addition to two genes for ATP/ADP translocases, the *C. trachomatis* genome also has genes for substrate-level phosphorylation, electron transport, and oxidative phosphorylation. When supplied with precursors from the host, RBs can synthesize DNA, RNA, glycogen, lipids, and proteins. They also can synthesize at least some amino acids and coenzymes. The EBs have minimal metabolic activity and cannot take in ATP or synthesize proteins. They are designed exclusively for transmission.

21.7 Phylum *Verrucomicrobia* Includes Human Symbionts and Methylotrophs

After reading this section, you should be able to:

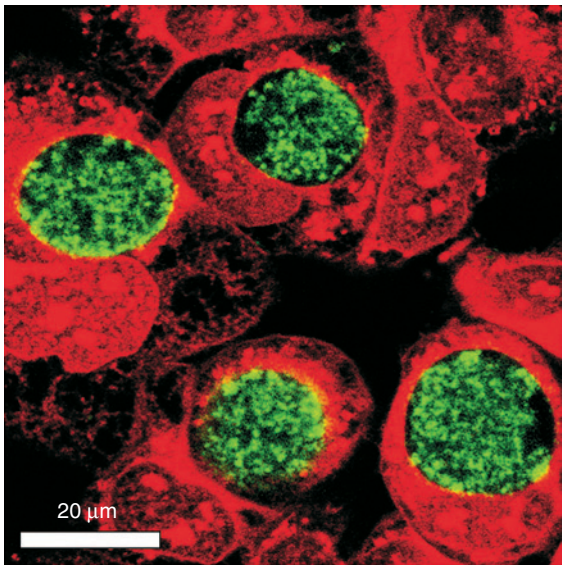
- Describe habitats where methane oxidation might occur
- List unusual features that unite some members of *Planctomycetes, Verrucomicrobia,* and *Chlamydiae*

Although the phylum *Verrucomicrobium* has just a few cultured representatives, it has attracted attention, as it is one of the phyla within the "PVC superphylum." This superphylum includes *Planctomycetes, Verrucomicrobia, Chlamydiae,* and several others. This grouping is supported by various phylogenetic markers and the observation that some genera within each of these phyla have complex internal membranes, synthesize sterols, and lack the cell division protein FtsZ. Because these features are not uniformly present, it is believed that the last common ancestor of these microbes had all these characteristics, which were subsequently lost by some. This has led some to the

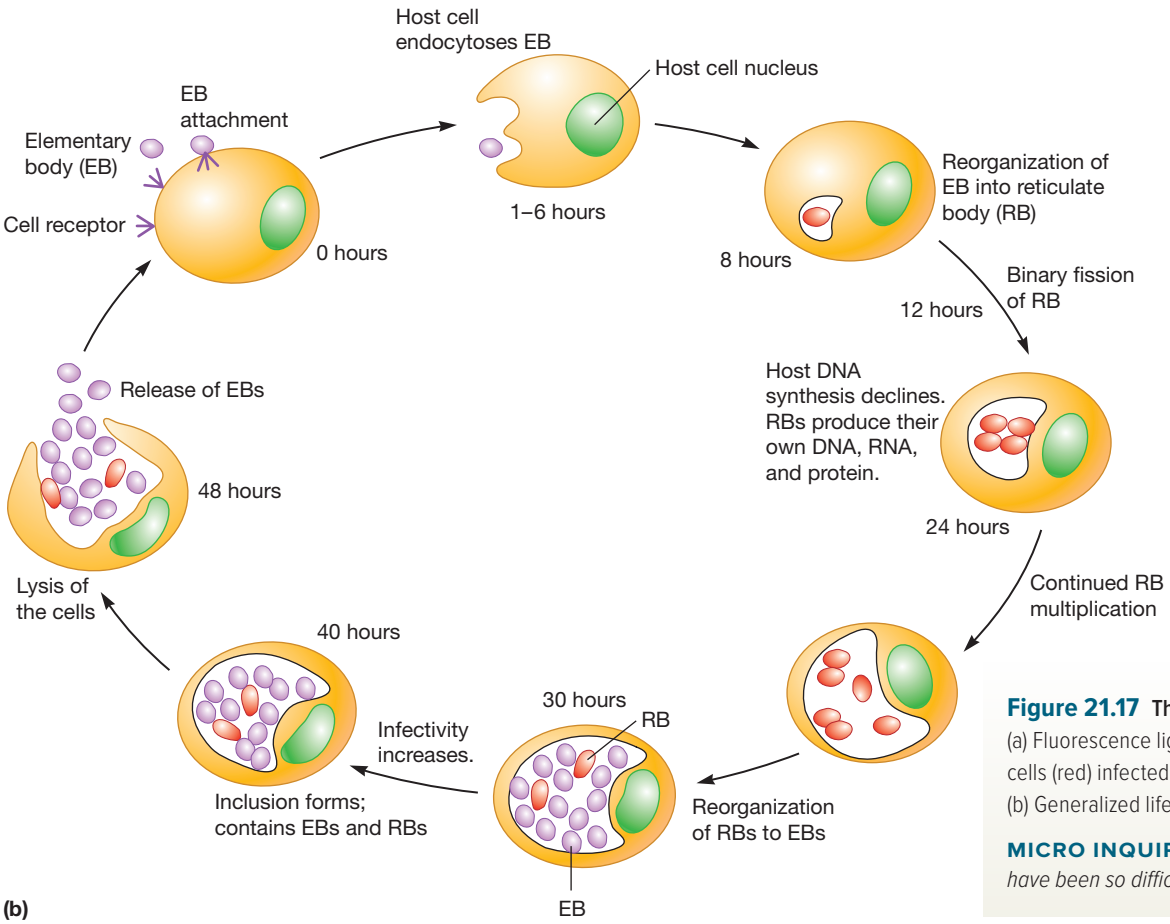
controversial suggestion that these organisms might be relatives of the ancestral microorganism that gave rise to both archaea and eukaryotes (*see figure 1.2*).

Recent investigations have revealed some interesting members of the phylum *Verrucomicrobia* for example, in 2007 a new member of this phylum was reported, *Acidimethylosilex fumarolicum*. The discovery and cultivation of this bacterium is noteworthy because it is thermophilic, acidophilic, and methanotrophic; that is, it can grow using methane as a carbon and energy source.

To be used as a carbon source, methane must be oxidized. Methane oxidation is significant because methane is an important greenhouse gas. For many years, it was thought that only 13 genera of aerobic α- and β-proteobacteria could oxidize methane. We now know that certain archaea anaerobically oxidize methane, usually when growing in association with sulfate-reducing bacteria. In all cases, methane oxidation ceases in acid environments below pH 4.2. However, it had been noted that methane is produced abiotically in certain geochemically active areas. These sites are also rich in H_2S, which microbes convert to sulfuric acid (H_2SO_4), so the pH can be as low as 1.0. Researchers hypothesized that despite the low pH, aerobic methane oxidation might occur in such environments. They used PCR to directly amplify from soil a methane monooxygenase gene conserved in proteobacterial methanotrophs. Enrichment cultures were then used to isolate *A. fumarolicum*. This bacterium grows between pH 0.8 and 5.8 with a temperature optimum of 55°C. Since the discovery of *A. fumarolicum* in Italy, other *Verrucomicrobia* isolates have been found in similar sites across the globe. These bacteria demonstrate that methanotrophy is more widespread and that this phylum is more diverse than previously thought. Indeed, the discovery of additional novel *Verrucomicrobia*



(a)



(b)

Figure 21.17 The Chlamydial Life Cycle. (a) Fluorescence light micrograph of human cells (red) infected with *C. trachomatis* (green). (b) Generalized life cycle of chlamydiae.

MICRO INQUIRY *Why do you think RBs have been so difficult to study?*

strains is anticipated as environmental clone libraries from a variety of ecosystems contain SSU rRNA of microbes that may be assigned to this phylum. ⏮ *Methanotrophy (section 20.4)* ⏭ *Order* Methylococcales *consists of C1-metabolizing bacteria (section 22.3)*

Another member of the phylum *Verrucomicrobia* has received a great deal of recent attention: *Akkermansia mucinophila*. This bacterium makes up 3 to 5% of the typical human gut microbial community and, as discussed in chapter 32, has been shown to diminish obesity-related systemic inflammation. As its name suggests, *A. mucinophila* consumes mucus and was initially grown in pure culture by providing gastric mucin as the sole carbon source. It is an obligate anaerobe with a fermentative metabolism, nonmotile and coccobacillus in shape. ⏭ *Cooperation (section 32.1)*

Retrieve, Infer, Apply

1. Describe planctomycetes and their distinctive morphological and metabolic properties.
2. Explain how some planctomycetes produce N_2.
3. Briefly describe the steps in the chlamydial life cycle. Why do you think chlamydiae differentiate into specialized cell types for infection and reproduction?
4. How does chlamydial metabolism differ from that of other bacteria?
5. What might have been some of the culture conditions used to isolate *A. fumarolicum?*

21.8 Phylum *Spirochaetes:* Bacteria with a Corkscrew Morphology

After reading this section, you should be able to:

- Draw a spirochete cell as it would be observed in a scanning electron micrograph and in cross section by transmission electron microscopy
- Describe how the unusual flagellar arrangement is well suited for motility in common spirochete habitats

The phylum *Spirochaetes* (Greek *spira,* a coil, and *chaete,* hair) contains Gram-negative, chemoorganotrophic bacteria distinguished by their structure and mechanism of motility. Carbohydrates, amino acids, long-chain fatty acids, and long-chain fatty alcohols may serve as carbon and energy sources. **Table 21.4** summarizes some of the more distinctive properties of selected genera.

Spirochetes are morphologically unique. They are slender, long bacteria (0.1 to 3.0 μm by 5 to 250 μm) with a flexible, helical shape (**figure 21.18**). The central protoplasmic cylinder, which contains cytoplasm and the nucleoid, is bounded by a plasma membrane and a Gram-negative cell wall (**figure 21.19**). Two to more than a hundred flagella, called **axial fibrils** or **periplasmic flagella,** extend from both ends of the cylinder and often overlap one another in the center third of the cell (*also see figure 3.47*). The whole complex of periplasmic flagella lies inside a flexible outer

Table 21.4 Characteristics of Spirochete Genera

Genus	Dimensions (μm) and Flagella	Oxygen Relationship	Carbon + Energy Source	Habitats
Spirochaeta	0.2–0.75 × 5–250; 2–40 periplasmic flagella (almost always 2)	Facultatively anaerobic or anaerobic	Carbohydrates	Aquatic and free living
Cristispira	0.5–3.0 × 30–180; ≥100 periplasmic flagella	Thought to be facultatively anaerobic	N.A.	Mollusk digestive tract
Treponema	0.1–0.4 × 5–20; 2–16 periplasmic flagella	Anaerobic or microaerophilic	Carbohydrates or amino acids	Mouth, intestinal tract, and genital areas of animals; some are pathogenic (syphilis, yaws)
Borrelia	0.2–0.5 × 3–20; 14–60 periplasmic flagella	Anaerobic or microaerophilic	Carbohydrates	Mammals and arthropods; pathogens (relapsing fever, Lyme disease)
Leptospira	0.1 × 6–24; 2 periplasmic flagella	Aerobic	Fatty acids and alcohols	Free living or pathogens of mammals, usually located in the kidney (leptospirosis)
Leptonema	0.1 × 6–20; 2 periplasmic flagella	Aerobic	Fatty acids	Mammals
Brachyspira	0.2 × 1.7–6.0; 8 periplasmic flagella	Anaerobic	Carbohydrates	Mammalian intestinal tract
Serpulina	0.3–0.4 × 7–9; 16–18 periplasmic flagella	Anaerobic	Carbohydrates and amino acids	Mammalian intestinal tract

1 N.A., information not available.

Figure 21.18 ***Treponema pallidum,*** **the Causative Agent of Syphilis.** These spirochetes range from 6 to 20 μm in length.

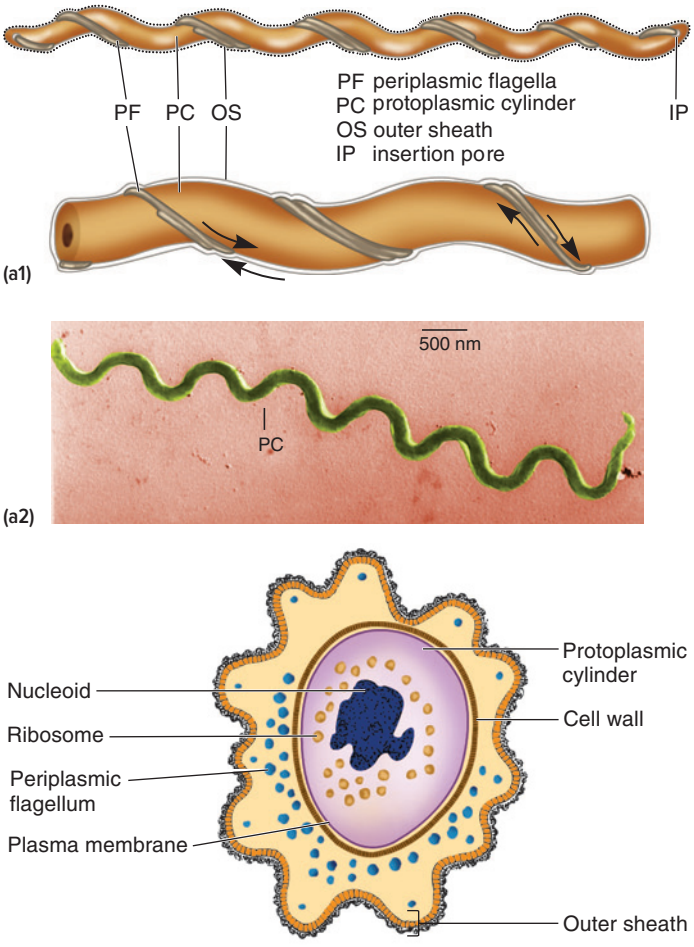


Figure 21.19 **Spirochete Morphology.** (a1) A surface view of spirochete structure as interpreted from electron micrographs. (a2) A longitudinal view of *Treponema pallidum*. (b) A cross section of a typical spirochete showing morphological details.

membrane sheath. This outer sheath is made of lipid, protein, and carbohydrate, and varies in structure between different genera. Its precise function is unknown, but the sheath is essential because spirochetes die if it is damaged or removed. The outer membrane sheath of *Treponema pallidum,* the causative agent of syphilis, has few proteins exposed on its surface. This helps the spirochete avoid attack by host antibodies. *T. pallidum* is also discussed in chapter 18 (*see figure 18.12*). ▶▶| *Syphilis (section 39.3)*

Spirochete motility is uniquely adapted to movement through viscous solutions. Like the external flagella of other bacteria, the periplasmic flagella rotate. This results in the rotation of the outer membrane sheath in the opposite direction relative to the protoplasmic cylinder, and the cell moves in a corkscrewlike movement through the medium (**figure 21.20**). Flagellar rotation also enables flexing and crawling on solid substrates. Thus, periplasmic flagella mediate movement through liquids and on solid surfaces.

Spirochetes are exceptionally diverse ecologically and grow in habitats ranging from mud to the human mouth. Members of the genus *Spirochaeta* are free-living and often grow in anoxic and sulfide-rich freshwater and marine environments. Some species of the genus *Leptospira* grow in oxic water and moist soil. Some spirochetes form symbiotic associations with other organisms and are found in a variety of locations: the hindguts of termites and wood-eating roaches, the digestive tracts of mollusks (*Cristispira*) and mammals, and the oral cavities of animals (*Treponema denticola, T. oralis*). Spirochetes from termite hindguts and freshwater sediments can fix nitrogen. Spirochetes coat the surfaces of many protists that live in the guts of termites and wood-eating roaches. For example, the flagellate *Mixotricha paradoxa,* a termite symbiont, is covered with slender spirochetes (0.15 by 10 μm in length) that are firmly attached and help move the protist. ▶▶| *Microorganism-insect mutualisms (section 32.1)*

Borrelia burgdorferi is one of several *Borrelia* species that cause Lyme disease. It is an unusual bacterium in several respects. Like many other intracellular bacteria, *B. burgdorferi* lacks genes for many cellular biosynthetic pathways. For instance, *N*-acetyl glucosamine (NAG) is required for growth. Recall that NAG is a component of peptidoglycan; *B. burgdorferi* may also use it as an energy source. The microbe uses the Embden-Meyerhof pathway to oxidize glucose monomers to pyruvate. Consistent with the microaerophilic nature of the bacterium, *B. burgdorferi* lacks a TCA cycle and oxidative phosphorylation.

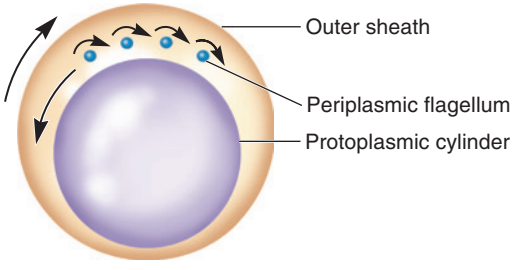

Figure 21.20 **Spirochete Motility.** A hypothetical mechanism for spirochete motility.

21.9 Phylum *Bacteroidetes* Includes Important Gut Microbiota

After reading this section, you should be able to:

- Explain how the human is host to members of this phylum
- Describe unusual carbon substrates used by some bacteroidetes
- Explain the proposed mechanism for *Flavobacterium johnsoniae* gliding motility, and relate gliding motility to the microbe's capacity to degrade complex organic substrates

The phylum *Bacteroidetes* is very diverse. All known members are chemoheterotrophs, and many contribute to the digestion of cellulose, agar (a component of seaweed), chitin (found in arthropod shells and fungal cell walls), proteins, and many other macromolecules. They are common in a variety of terrestrial and marine environments, as well as sewage treatment plants where they presumably contribute to the treatment process. ▶▶| *Wastewater treatment processes (section 43.2)*

The genus *Bacteroides* contains anaerobic, Gram-negative, nonspore-forming rods; motility is rare. They are important constituents of the human intestinal tract and the rumen of ruminants. *Bacteroides ruminicola* is a major component of the rumen flora; it ferments starch, pectin, and other carbohydrates. About 30% of the bacteria cultured from human feces are members of the genus *Bacteroides,* and these organisms may provide extra nutrition by degrading cellulose, pectins, and other complex carbohydrates. Although they often benefit their hosts, they are also involved in human disease. Some are associated with diseases of major organ systems, ranging from the central nervous system to the skeletal system. *B. fragilis* is a particularly common anaerobic pathogen found in abdominal, pelvic, pulmonary, and blood infections. Another important pathogen within the *Bacteroidetes* phylum is *Porphyromonas gingivalis,* which as its species name suggests, is associated with human gum disease. *P. gingivalis* is related to members of the genus *Bacteroides* and shares many features with them, such as anaerobic growth. ▶▶| *The rumen ecosystem (section 32.1); Normal microbiota of the human body adapt to many sites (section 32.3)*

Many genera within the phylum *Bacteroidetes* are yellow to orange because of carotenoid or flexirubin pigments. Some of the flexirubins are chlorinated, which is unusual for biological molecules. Members of the genera *Cytophaga* and *Sporocytophaga* are aerobes that actively degrade cellulose. *Sporocytophaga* species produce spherical resting cells called microcysts. Most members of the genus *Flavobacterium* are free-living soil or aquatic bacteria, but some are pathogens of vertebrate hosts. *Flavobacterium columnare* causes columnaris, a highly contagious fish infection that results in major fish kills in natural systems, commercial aquaculture, and home aquaria.

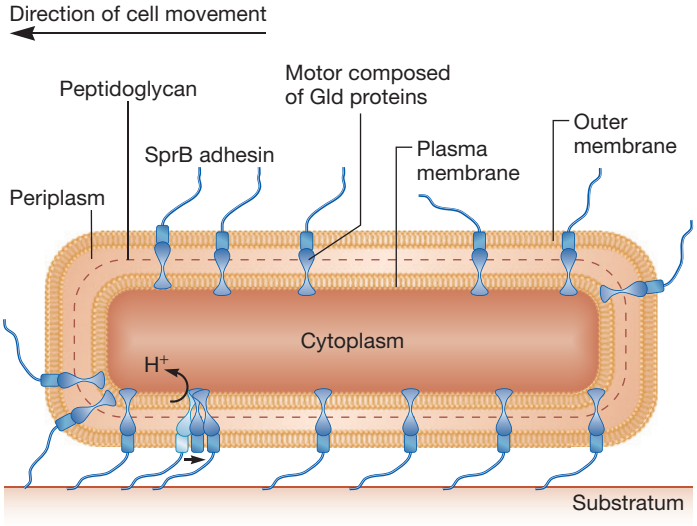

Figure 21.21 Proposed Mechanism for *Flavobacterium johnsoniae* Gliding Motility. Gld proteins within the cell envelope are thought to form motors that propel adhesins such as SprB along the cell surface.

MICRO INQUIRY *How would you test whether or not Gld proteins are necessary for gliding motility? Explain the experiment you would perform and what your prediction would be.*

The **gliding motility** so characteristic of members of the genera *Cytophaga, Sporocytophaga,* and *Flavobacterium* can be very rapid; gliding members of the phylum *Bacteroidetes* typically travel 120 μm per minute, but some are considerably faster. Low nutrient levels usually stimulate gliding. Unlike flagellar-mediated swimming motility, the mechanisms that enable gliding motility are not well understood and are not highly conserved across bacterial phyla. Gliding members of the phylum *Bacteroidetes,* such as *Flavobacterium johnsoniae,* depend on motility proteins that are unique to this phylum. Some of these are called glide (Gld) proteins and are thought to assemble into motors that cross the plasma membrane and extend into the periplasm (**figure 21.21**). Like the motor proteins in flagellar basal bodies, the Gld proteins probably harvest the energy of the proton motive force. Gld proteins are thought to propel large, surface proteins called SprB, resulting in cell movement along helical tracks. |◀◀ *Twitching and gliding motility (section 3.8)*

Gliding motility gives a bacterium many advantages. Many aerobic chemoheterotrophic gliding bacteria actively digest insoluble macromolecular substrates such as cellulose

and chitin, and gliding motility is ideal for searching these out. Because many of the digestive enzymes are cell wall-associated, the bacteria must be in contact with insoluble nutrient sources; gliding motility makes this possible. Gliding movement is well adapted to drier habitats and to movement within solid masses such as soil, sediments, and rotting wood that are permeated by small channels. Finally, gliding bacteria, like flagellated bacteria, can position themselves at optimal levels of oxygen, hydrogen sulfide, light intensity, temperature, and other factors that influence growth and survival.

Retrieve, Infer, Apply

1. Draw and label a diagram of spirochete morphology, locating these structures: protoplasmic cylinder, periplasmic flagella, and outer membrane sheath.
2. Compare periplasmic flagella with the flagella of other bacteria. Why is spirochete motility especially well suited for movement through viscous fluids?
3. List the major physiological properties of the genus *Bacteroides*.
4. List three advantages of gliding motility.
5. Why are cytophagas ecologically important?

Key Concepts

21.1 *Aquificae* and *Thermotogae* Are Ancient Bacterial Lineages

- *Aquifex* and *Thermotoga* contain hyperthermophilic, Gram-negative rods that are the two deepest or oldest phylogenetic branches of *Bacteria*.
- *Aquifex* spp. are chemolithoautotrophs. *Thermotoga* spp. are chemoorganotrophs.

21.2 *Deinococcus-Thermus* Includes Radiation-Resistant Bacteria

- Members of the order *Deinococcales* are aerobic cocci and rods that have an unusual cell wall.
- *Deinococcus radiodurans* is distinctive because of its tremendous resistance to desiccation and radiation.

21.3 Class *Mollicutes*, Phylum *Tenericutes:* Bacteria That Lack Cell Walls

- Mycoplasmas stain Gram negative because they lack cell walls and cannot synthesize peptidoglycan, but many require sterols for growth.
- Many mycoplasmas are plant and animal pathogens. They are some of the smallest bacteria capable of self-reproduction.

21.4 Photosynthetic Bacteria Are Diverse

- Cyanobacteria carry out oxygenic photosynthesis; purple and green bacteria use anoxygenic photosynthesis.
- The four most important groups of purple and green photosynthetic bacteria are the purple sulfur bacteria, the purple nonsulfur bacteria, both of which are proteobacteria; green sulfur bacteria (phylum *Chlorobi*), and green nonsulfur bacteria in the phylum *Chloroflexi* (**table 21.2**).
- The bacteriochlorophyll pigments of purple and green bacteria enable them to live in deeper, anoxic zones of aquatic habitats.
- Green sulfur bacteria are obligately anaerobic photolithoautotrophs that use hydrogen sulfide, elemental sulfur, and hydrogen as electron sources.
- Green nonsulfur bacteria include members of the genus *Chloroflexus*, gliding thermophilic filaments metabolically similar to purple nonsulfur bacteria. Both *Chlorobi* and *Chloroflexus* spp. have chlorosomes, which function to harvest light that is transferred to the reaction center in the plasma membrane (**figure 21.9**).
- Cyanobacteria carry out oxygenic photosynthesis by means of a photosynthetic apparatus similar to that of the eukaryotes. Phycobilisomes contain the light-harvesting pigments phycocyanin and phycoerythrin (**figure 21.11**).
- Cyanobacteria reproduce by binary fission, budding, multiple fission, and fragmentation by filaments to form hormogonia. Some produce dormant akinetes.
- Many nitrogen-fixing cyanobacteria form heterocysts, specialized cells in which nitrogen fixation occurs (**figure 21.13**).
- Members of the *Prochlorococcus* taxon are the most abundant photosynthetic organism on Earth. Together with other unicellular cyanobacteria in the genus *Synchcoccus,* they account for about one-third of global carbon fixation.

21.5 Phylum *Planctomycetes:* Bacteria with Intracellular Compartments

- Members of the phylum *Planctomycetes* lack peptidoglycan in their cell walls and undergo budding division.
- Planctomycetes have unusual cellular compartmentalization, and some perform the anammox reaction (**figures 21.15 and 21.16**).

21.6 Phylum *Chlamydiae:* Obligate Intracellular Parasites

- Chlamydiae are nonmotile, coccoid, Gram-negative bacteria that lack peptidoglycan and must reproduce within the cytoplasmic vacuoles of host cells by a life cycle involving elementary bodies (EBs) and reticulate bodies (RBs) (**figure 21.17**).

21.7 Phylum *Verrucomicrobia* Includes Human Symbionts and Methylotrophs

- A thermoacidophilic member of this phylum is the first microbe known to oxidize methane at very low pH. It is methanotrophic, meaning it can use methane as a carbon and energy source.

21.8 Phylum *Spirochaetes:* Bacteria with a Corkscrew Morphology

- Spirochetes are slender, long, helical, Gram-negative bacteria.
- Spirochetes are motile by means of periplasmic flagella underlying an outer membrane sheath or outer membrane (**figures 21.18–21.20**).

21.9 Phylum *Bacteroidetes* Includes Important Gut Microbiota

- Members of the phylum *Bacteroidetes* are obligately anaerobic, chemoorganotrophic, nonsporing, motile, or nonmotile rods of various shapes.
- Some of these bacteria are important rumen and intestinal symbionts; others can cause disease. Many are important in degrading cellulose, chitin, and other macromolecules in terrestrial and aquatic environments.
- Gliding motility is present in a diverse range of bacteria; in members of *Bacteroidetes,* gliding is mediated by a unique group of transmembranous and surface proteins (**figure 21.21**).

Compare, Hypothesize, Invent

1. The cyanobacterium *Anabaena* grows well in liquid medium that contains nitrate as the sole nitrogen source. Suppose you transfer some of these filaments to the same medium except it lacks nitrate. Describe the morphological and physiological changes you would observe.
2. Compare the structural and functional differences between chlorosomes and thylakoid membranes. Do you think this is an example of convergent evolution—two structures evolving separately to fulfill the same function, or divergent evolution—two structures that arose from a single ancestor but adapted to meet the particular needs of the organism that bears them? What other data would you need (apart from structure and function) to answer this question?
3. Many types of movement are employed by bacteria discussed in this chapter. Review them and propose mechanisms by which energy (ATP or proton gradients) might drive the locomotion.
4. Some believe that an ancient planctomycete evolved into the first eukaryotic cell. List the similarities and differences between these bacteria and a eukaryotic cell, and develop a hypothesis that would account for the cellular and molecular events needed for this transition.
5. Microbiologists using transmission electron microscopy have examined the cellular structure of a thermoacidophilic methanotroph belonging to the phylum *Verrucomicrobia* that was isolated from an acidic hot spring in Kamchatka, Russia. Surprisingly, this microbe has polyhedral microcompartments that look much like carboxysomes (figure 21.10). By contrast, proteobacterial methanotrophs possess intracytoplasmic membranes in which methane monooxygenase is embedded. This enzyme uses O_2 to oxidize CH_4. What do you think is the utility of such enzyme compartmentalization? How would you determine if methane monooxygenase is localized to the polyhedral inclusion bodies found in thermoacidiphilic methanotrophs? Assuming the monooxygenase is confined to these structures, why do you think enzyme compartmentalization evolved in both types of bacteria?

   Read the original paper: Islam, R., et al. 2008. Methane oxidation at 55°C and pH 2 by a thermoacidophilic bacterium belonging to the *Verrucomicrobia* phylum. *Proc. Natl. Acad. Sci. USA*. 105:300.
6. In 2014 a team of Chinese and Czech microbiologists reported the discovery a new microbe capable of photoheterotrophic growth isolated from a freshwater lake in the Gobi Desert. The group performed many experiments to characterize this isolate, including 16S rRNA followed by whole-genome sequencing. Predict what they discovered in these analyses that supported the conclusions that the microbe is a member of the phylum *Gemmatimonadetes,* that it is a photoheterotroph, and that it acquired its genes for photosynthesis via horizontal gene transfer from purple sulfur bacteria.

   Read the original paper: Zeng, Y., et al. 2014. Functional type 2 photosynthetic reaction centers found in the rare bacterial phylum *Gemmatimonadetes. Proc. Nat. Acad. Sci., USA*. 111:7795–7800.

Proteobacteria

Bison in Yellowstone National Park, as shown here, have been the cause of much controversy. Ranchers surrounding the park fear that bison may infect their cattle with brucellosis when they forage outside park boundaries during the winter.

Bison and Brucellosis Spark Controversy

Winter in Yellowstone National Park is said to be a "magical" time for visitors. But for the roughly 4,900 Yellowstone bison, winter brings the challenge of finding enough to eat. And as these iconic animals forage, some find themselves overstepping the bounds of the park. That's when things get complicated.

Brucellosis is a disease of ruminant animals caused by the bacterium *Brucella abortus.* As its name implies, it causes miscarriages in pregnant animals. Because Yellowstone bison may be asymptomatic carriers of *B. abortus,* ranchers fear they will infect cattle when they wander out of the park. Unfortunately, the first sign of infection is when an animal aborts a highly contagious stillborn calf.

In 2000 federal, state, and tribal agencies sought to address fears of disease transmission with a bison management plan aimed at maintaining a sustainable wild population without negative impact on the cattle industry. The basics include hazing and transport, screening animals for *B. abortus* exposure, and slaughter for those testing positive. Hazing—a process that can include anything from noisemakers to helicopters to rubber bullets—is used to discourage bison from leaving the park and to capture those that have. Bison found outside the park are transported to designated capture areas where they are tested for brucellosis. Those with *B. abortus* antibodies (seropositive) are sent to slaughter. Seronegative calves and yearlings are vaccinated and sent to a separate holding area along with seronegative adults. These animals are tagged and released back into the park in the spring.

There is only one problem with this management plan: no one likes it. Many ranchers fear that wandering bison will decimate their cattle. They recall a time when brucellosis cost the cattle industry $400 million annually. Others rebut that there has never been a documented case of brucellosis transmission from Yellowstone bison to cattle. They remind the public of the vast herds of bison that were so grossly overhunted that by 1902 only 50 remained in Yellowstone. Meanwhile, each winter hundreds of out-of-bounds bison are transported, tested, and either vaccinated and released or culled. At the same time, the public lands have been opened for regulated hunting of bison. It seems that the only thing the pro- and anti-bison factions can agree upon is that the current management plan has neither reduced the prevalence of brucellosis in the bison herd nor generated a sustainable population.

So what will be the fate of Yellowstone bison? The delicate balancing act between ranching, tourism, and environmental conservation will continue to drive any modifications to the bison management plan. It is in many ways odd to think that the future of these 1-ton animals rests upon a microbe that measures only 2 μm.

B. abortus is a member of the vast phylum ***Proteobacteria.*** This diverse group of microbes includes many pathogens as well as bacteria that play key roles in nutrient cycling. Comparison of 16S rRNA sequences reveals five lineages of descent within the phylum (**figure 22.1**). When reading the chapter, challenge yourself to find attributes of environmental microbes that are also found in proteobacterial pathogens.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Draw a Gram-negative cell wall and list its constituent parts (section 3.4)
- ✔ Differentiate between swimming and gliding motility (section 3.8)
- ✔ List environmental factors that influence microbial growth with a particular emphasis on oxygen (section 7.4)
- ✔ Describe the difference between heterotrophy and autotrophy (section 11.1)
- ✔ Compare anaerobic and aerobic respiration and fermentation (sections 11.7 and 11.8)
- ✔ Draw an electron transport chain indicating the relative standard reduction potentials of the electron donor, acceptor, and electron transporters (sections 10.4 and 11.6)
- ✔ Define chemolithotrophy and identify an example electron donor and acceptor (section 11.10)
- ✔ Compare and contrast oxygenic and anoxygenic phototrophy (section 11.11)
- ✔ Summarize the function of the Calvin-Benson cycle and the enzyme nitrogenase (sections 12.3 and 12.5)

22.1 Class *Alphaproteobacteria* Includes Many Oligotrophs

After reading this section, you should be able to:

- Describe the oligotrophic environments inhabited by some α-proteobacteria
- Outline the metabolic flexibility of some purple photosynthetic bacteria
- Draw the photosynthetic apparatus found in purple photosynthetic bacteria and label its constituent parts
- List two unusual metabolic features of rickettsias and relate these to their intracellular lifestyle
- Diagram the life cycles of *Hyphomicrobium* and *Caulobacter* spp.
- Compare and contrast the relationship between *Rhizobium* and *Agrobacterium* spp. and plants
- Identify the electron donors and the electron acceptor used in nitrification
- List the physiological and taxonomic groups of microbes capable of nitrification

Since *Bergey's Manual of Systematic Bacteriology* was published in 2005, there have been several reassessments of the proposed phylogeny and taxonomy of *Alphaproteobacteria*. Some of these studies are based on rRNA sequences, while other analyses include additional vertically transmitted, slowly evolving essential genes. Here we present one recently developed phylogenetic tree based on rRNA homologies (**figure 22.2**). Important updates include the new orders *Magnetococcales,* made up of marine magnetotactic, bacteria, and *Pelagibacterales,* which includes the world's most abundant microorganisms, belonging to the SAR11 clade. Also, note the branch just above *Pelagibacterales* in figure 22.2 labeled "Promitochondrion." This represents the extinct lineage of bacteria that, through endosymbiosis, gave rise to eukaryotic mitochondria and related organelles. The placement of this lineage is controversial, as is the placement of *Rickettsiales*. ⏮ *Evolution of the three domains of life (section 19.5)*

A wide variety of bacteria belong to the class *Alphaproteobacteria,* including most of the oligotrophic proteobacteria (those capable of growing at low nutrient levels). Others have evolved to live within plant and animal cells as either mutualists, whereby both kinds of organisms benefit, or as pathogens. Some α-proteobacteria have unusual metabolic modes such as methylotrophy—the ability to grow using one-carbon compounds as their sole carbon source (*Methylobacterium*), chemolithotrophy (*Nitrobacter*), and the ability to fix nitrogen (*Rhizobium*). **Table 22.1** summarizes the general characteristics of many of the bacteria discussed in the following sections.

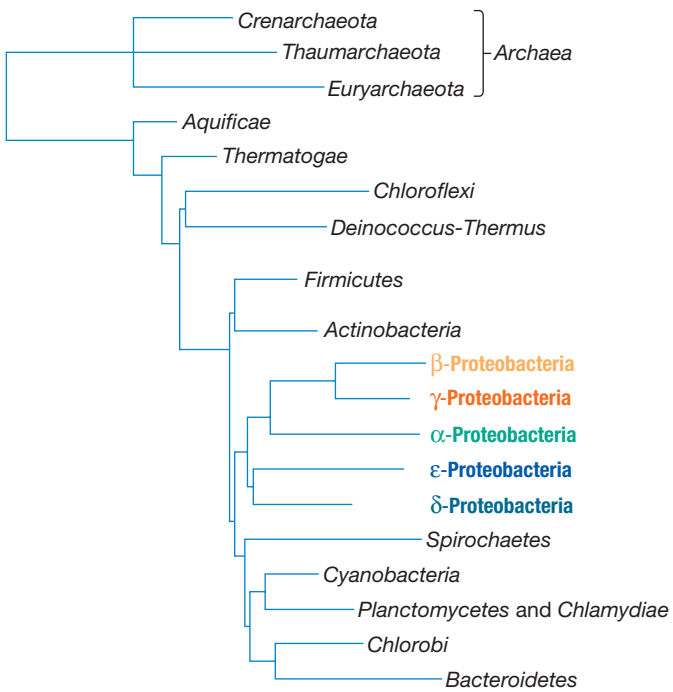

Figure 22.1 Phylogenetic Relationships Among *Bacteria* and *Archaea*. Proteobacterial groups are highlighted.

Purple Nonsulfur Bacteria Perform Anoxygenic Photosynthesis

All **purple nonsulfur bacteria** are α-proteobacteria, with the exception of *Rhodocyclus* (β-proteobacteria). These bacteria use anoxygenic photosynthesis and possess bacteriochlorophylls *a* or *b* (*see table 21.2*). Their photosynthetic apparatus is continuous with the plasma membrane. The plasma membrane is invaginated, making many intracellular folds (**figure 22.3*a,b***). These *i*ntra*c*ytoplasmic *m*embranes (ICMs) increase the surface area, thereby providing more space for *p*hotos*y*nthetic *u*nits (PSUs). Each PSU includes a *r*eaction *c*enter (RC), consisting of

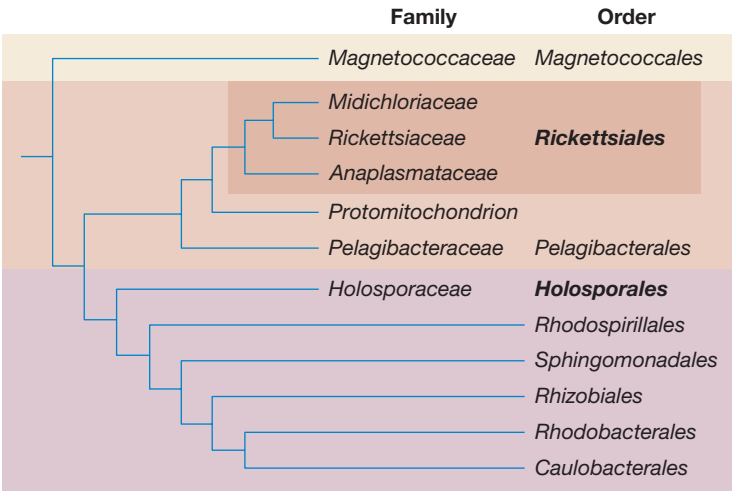

Figure 22.2 Proposed Subclasses of Alphaproteobacteria. Three proposed subdivisions are *Magnetococcidae, Rickettsidae,* and *Caulobacteridae*. Protomitochondrion is an extinct organism that gave rise to the mitochondrial family of organelles of eukaryotes.

Table 22.1 Characteristics of Selected α-Proteobacteria

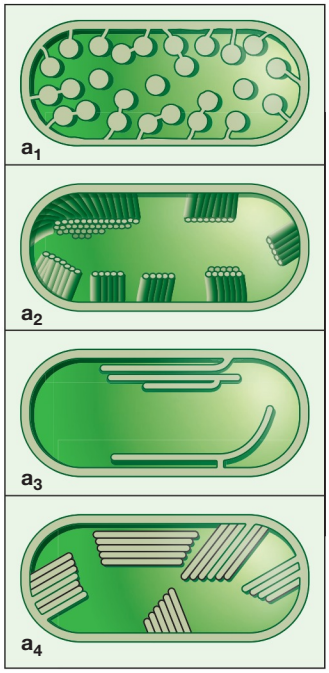
Genus	Dimensions (μm) and Morphology	Genome Size (Mb)	Oxygen Requirement	Other Distinctive Characteristics
Agrobacterium	0.6–1.0 × 1.5–3.0; motile with peritrichous flagella, nonsporing rods	2.5	Aerobic	Chemoorganotrophs that can invade plants and cause tumors
Caulobacter	0.4–0.6 × 1–2; comma-shaped with polar flagellum and prostheca with holdfast	4.0	Aerobic	Chemoorganotrophic and oligotrophic; asymmetric cell division
Hyphomicrobium	0.3–1.2 × 1–3; rod-shaped or oval with polar prosthecae	3.6	Aerobic	Reproduce by budding; methylotrophic
Nitrobacter	0.5–0.9 × 1.0–2.0; rod- or pear-shaped, sometimes motile by flagella	3.4	Aerobic	Chemolithotrophs, oxidize nitrite to nitrate
Rhizobium	0.5–1.0 × 1.2–3.0; motile rods with flagella	5.1	Aerobic	Invade leguminous plants to produce nitrogen-fixing root nodules
Rhodospirillum	0.7–1.5 wide; spiral cells with polar flagella	4.4	Anaerobic, microaerophilic, aerobic	Anoxygenic photoheterotrophs under anoxic conditions
Rickettsia	0.3–0.5 × 0.8–2.0; short nonmotile rods	1.1–1.3	Aerobic	Obligate intracellular parasites
Pelagibacter	0.2 × 0.5; rod-shaped	1.3	Aerobic	Chemoorganotrophic; proteorhodopsin present
Magnetococcus	1–2 in diameter, roughly spherical; two bundles of flagella at single pole; single chain of cytoplasmic magnetite crystals	4.7	Microaerophilic	Chemoorganotrophic and chemolithotrophic; magnetotactic

a protein-bacteriochlorophyll (Bchl) complex that absorbs light in the infrared range. The RC-Bchl is responsible for donating electrons to the electron transport chain that results in a proton motive force sufficient to fuel ATP synthesis. The energy required for charge separation is supplied by the photons directly absorbed by the RC-Bchl or transferred from a light-harvesting complex. All purple bacteria (nonsulfur and sulfur) have a primary light-harvesting complex called LH-I closely associated with the RC. Most also have additional light-harvesting complexes, called LH-II (figure 22.3*c*). Light-harvesting complexes are composed of Bchl *a* and carotenoid pigments. LH-IIs encircle the RC/LH-I complex. This maximizes the efficiency of energy transfer. ⏮ *Light reactions in anoxygenic photosynthesis (section 11.11); Photosynthetic bacteria are diverse (section 21.4)*

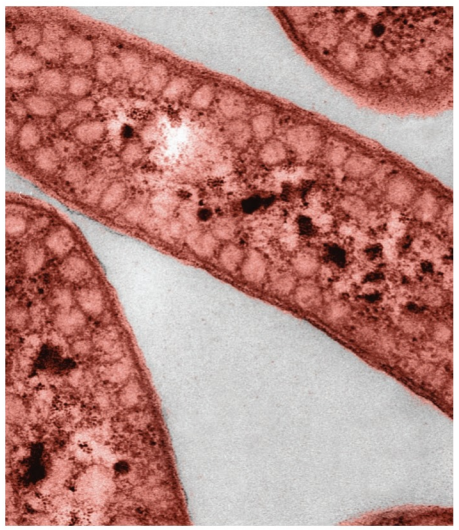
Purple nonsulfur bacteria vary considerably in morphology. Most are motile by polar flagella. They may be spirals (*Rhodospirillum*), rods (*Rhodopseudomonas*), half circles or circles (*Rhodocyclus*), or they may even form prosthecae and buds (*Rhodomicrobium*). They are most prevalent in the mud and water of lakes and ponds with abundant organic matter and low sulfide levels.

Purple nonsulfur bacteria show exceptional metabolic flexibility. Normally they grow anaerobically as photoorganoheterotrophs, trapping light energy and employing organic molecules as both electron and carbon sources (table 22.1). Although they are called nonsulfur bacteria, some species can oxidize very low, nontoxic levels of sulfide to sulfate, but they do not oxidize elemental sulfur. Some can use also use hydrogen as an electron source. In the absence of light, most purple nonsulfur bacteria grow aerobically as chemoorganoheterotrophs, but some species carry out fermentation anaerobically. Oxygen inhibits bacteriochlorophyll and carotenoid synthesis so that cultures growing aerobically in the dark are colorless.

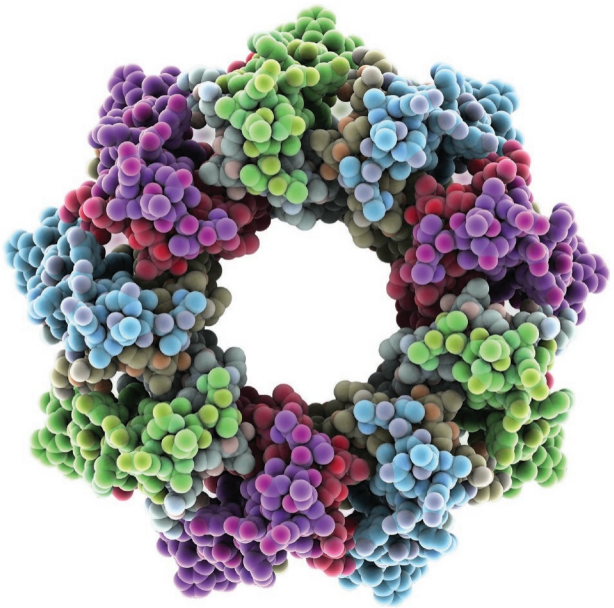
Rhodospirillum rubrum is perhaps the best-studied purple nonsulfur bacterium. It exemplifies the metabolic flexibility of this group. The "decision-making" process this microbe uses is displayed in **figure 22.4**. When in oxic conditions, the photosynthetic apparatus is inhibited, and it grows chemoorganotrophically. However, when oxygen is not present, it can use one of three metabolic options, depending on the presence of light and fixed carbon. These include fermentation, photoheterotrophy, or photoautotrophy. When growing phototrophically, *R. rubrum* makes photopigments that give it a rich red color. *R. rubrum*



(a) Intracytoplasmic membranes



(b) *R. rubrum*



(c) Integral light-harvesting complex

Figure 22.3 The Photosynthetic Apparatus of Purple Bacteria. (a) The arrangement of intracytoplasmic membranes (ICMs) varies, but in all cases, they are associated with the plasma membrane. (a_1) ICMs that resemble vesicles are found in the nonsulfur α-proteobacteria *Rhodospirillum rubrum* and *Rhodobacter capsulatus,* and the sulfur γ-proteobacteria *Chromatium vinusum* and *Thiocapsa roseopersicina.* (a_2) Tubelike ICMs are found in *T. pfennigii.* (a_3) ICMs arranged in small stacks are seen in *Rhodospirillum molischianum* and the γ-proteobacterium *Ectothiorhodospira mobilis*. (a_4) *Rhodopseudomonas palustris* has larger stacked ICMs. (b) A transmission electron micrograph of *Rhodospirillum* sp. grown anaerobically in the light shows vesicle-like ICMs. (c) Molecular model of light-harvesting complex-II (LH-II) from *Rhodopseudomonas acidophila.* LH-II in this organism contains bacteriochlorophyll *a* and carotenoids that transfer electrons to the centrally located reaction center (RC) and closely associated light-harvesting complex I (LH-I); not shown.

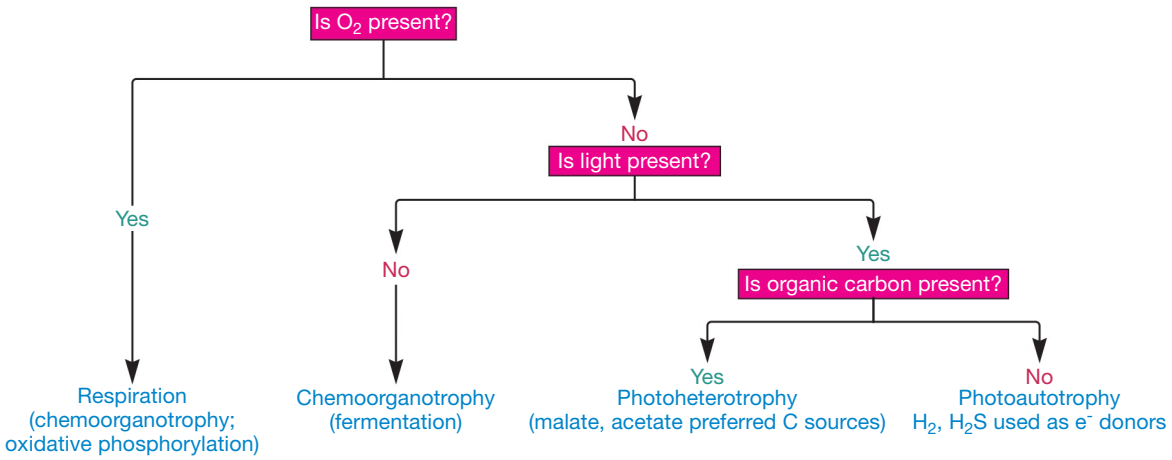


Figure 22.4 The Metabolic Flexibility of *Rhodospirillum rubrum*. This microbe can switch from one type of metabolism to another, depending on the availability of light and oxygen.

MICRO INQUIRY *What would* Rhodospirillum rubrum *use for carbon and energy sources if grown (a) anaerobically in the dark in the presence of malate, (b) anaerobically in the light without organic carbon, and (c) aerobically in the light in the presence of malate?*

has sparked the interest of industrial microbiologists because it produces novel biodegradable plastics when grown on β-hydroxycarboxylic and *n*-alkanoic acids. ▶▶| *Biotechnology and industrial microbiology (chapter 42)*

In addition to the anaerobic anoxygenic photosynthesis displayed by the purple nonsulfur bacteria, some α-proteobacteria are capable of **aerobic anoxygenic photosynthesis** (**AAnP**). These aerobic bacteria are photoheterotrophs that catabolize carbon and other organic materials using O_2-dependent respiration. They supplement this chemoorganotrophic source of energy using Bchl *a*–dependent phototrophy. This allows them to shunt more organic carbon to anabolic pathways, thereby enhancing their growth. They are found in marine and freshwater environments, and are often present in microbial mat communities. Important α-proteobacterial genera include the α-proteobacteria *Erythromonas, Roseococcus, Porphyrobacter,* and *Roseobacter,* although metagenomic analysis reveals that a wider diversity of bacteria are capable of AAnP (*see table 21.2*). Their contribution to the global carbon cycle is an area of active investigation.

Rhodospirillum and *Azospirillum* (both in the family *Rhodospirillaceae*) are among several bacterial genera with species capable of forming **cysts** in response to nutrient limitation (**figure 22.5**). In addition to nutritional cues, cyst formation in both *R. centenum* and *A. brasilense* is regulated by the secretion and reuptake of cyclic GMP, a molecule better known for its role as a second messenger in eukaryotes. These resting cells differ from the well-characterized endospores made by Gram-positive bacteria, such as members of the genera *Bacillus* and *Clostridium*. Although cysts are also very resistant to desiccation, they are less tolerant of other environmental stresses such as heat and ultraviolet (UV) light. They have a thick outer coat and store an abundance of poly-β–hydroxybutyrate (PHB). Cyst-forming bacteria are not limited to α-proteobacteria; for instance, members of *Azotobacter,* which are γ-proteobacteria, also form cysts. |◀◀ *Inclusions (section 3.6); Bacterial endospores are a survival strategy (section 3.9)*

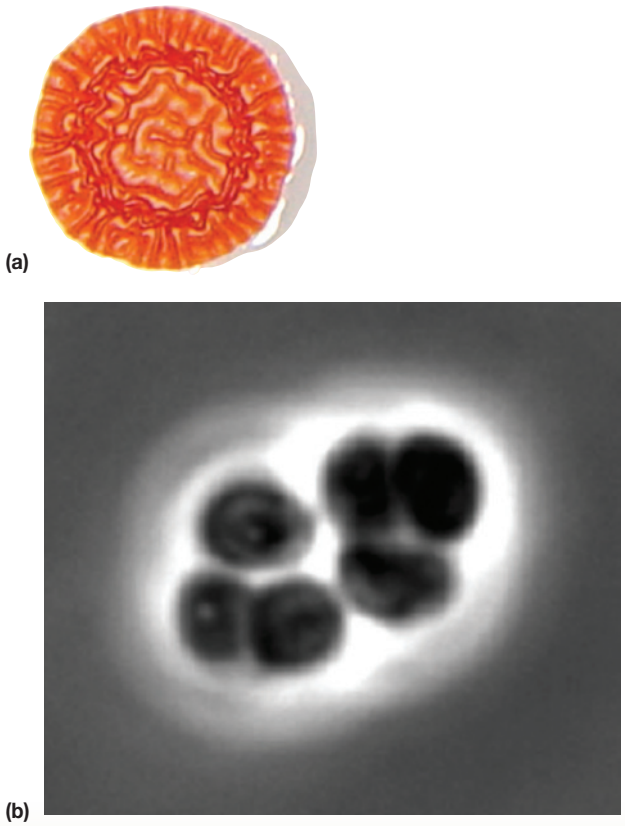

Figure 22.5 **Cyst Formation in *Rhodospirillum centenum*.**
(a) Colony morphology when grown on a medium that limits nutrients. (b) The cells within the colony (a) have formed cysts. In this species, cysts are most commonly found in clusters of four surrounded by a thick outer coat consisting of lipopolysaccharides and lipoproteins. Cysts are about 1 μm in diameter, nonmotile, and more spherical than growing cells.

MICRO INQUIRY *How are bacterial cysts different from the endospores of certain Gram-positive bacteria?*

Rickettsias Are Obligate Intracellular Bacteria

The genus *Rickettsia* contains rod-shaped, coccoid, or pleomorphic cells with typical Gram-negative walls and no flagella. Although their size varies, they tend to be very small (e.g., members of the genus *Rickettsia* are 0.3 to 0.5 μm in diameter and 0.8 to 2.0 μm long). All species are parasitic or mutualistic. The parasitic forms grow in vertebrate erythrocytes, macrophages, and vascular endothelial cells. Some also live in blood-sucking arthropods such as fleas, ticks, mites, or lice, which serve as vectors or primary hosts (**figure 22.6**).

Rickettsias are believed to have descended from a free-living, aerobic bacterium that became an intracellular parasite of an ancestral eukaryotic cell lacking organelles. In this way, the bacterium was able to assimilate many host substrates, making genes for the biosynthesis of these substrates unnecessary. Thus, as these genes mutated, there was no selection to

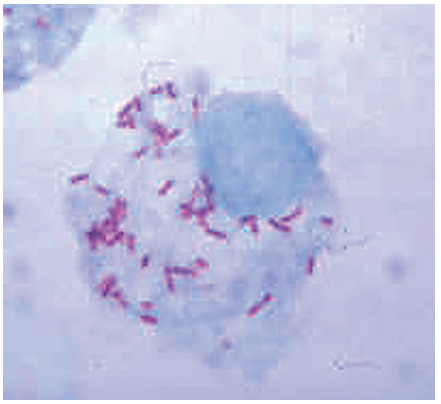

Figure 22.6 ***Rickettsia rickettsii.*** A tick hemolymph cell filled with *Rickettsia rickettsii,* the causative agent of Rocky Mountain spotted fever. These bacteria are very small, ranging in size from 0.2 × 0.5 μm to 0.3 × 2.0 μm.

prevent their loss and conversion to pseudogenes (genes that have lost the capacity to encode products due to mutation of critical elements, e.g., promoter, placement of an early stop codon). To decrease cellular energy burden, many pseudogenes were eventually lost. This gene reduction gave rise to a small genome that prevented the bacterium from living outside the host cell (*see figure 18.20*).

Rickettsias are therefore very different from most other bacteria in physiology and metabolism. They have lost the genes encoding glycolytic pathway enzymes, so they cannot use glucose as an energy source. Instead, they oxidize glutamate and tricarboxylic acid cycle intermediates such as succinate. The rickettsial plasma membrane has carrier-mediated transport systems for the assimilation of host cell nutrients and coenzymes. Its membrane also has a carrier that exchanges ADP for external ATP. However, *R. prowazekii* possesses a complete TCA cycle and a membrane-bound ATP synthase.

This genus includes important human pathogens including *R. prowazekii* and *R. typhi,* the causative agents of louse-borne and murine typhus, respectively, as well as *R. rickettsii,* which causes Rocky Mountain spotted fever. These microbes enter the host cell by inducing phagocytosis but immediately escape the phagocytic vacuole to reproduce by binary fission in the cytoplasm. Eventually the host cell bursts, releasing new organisms. ▶▶| *Phagocytosis (section 33.5); Rocky mountain spotted fever (section 39.2)*

Caulobacteraceae and *Hyphomicrobiaceae* Bacteria Reproduce in Unusual Ways

These two groups of α-proteobacteria have interesting life cycles that feature a prostheca or reproduction by budding. A **prostheca** (pl., prosthecae), also called a **stalk,** is an extension of the cell, including the plasma membrane and cell wall, that is narrower than the mature cell. **Budding** is a form of cellular reproduction that is distinctly different from binary fission. The bud first appears as a small protrusion at a single point on the mother cell and enlarges to form a mature cell. This new cell pinches free of the mother cell and is noticeably smaller than its parent. Most or all of the bud's cell envelope is newly synthesized. |◀◀ *Bacterial cell cycles can be divided into three phases (section 7.2)* *Appendaged Bacteria*

The families *Caulobacteraceae* and *Hyphomicrobiaceae* contain two of the best-studied prosthecate genera: *Hyphomicrobium* and *Caulobacter.* The genus *Hyphomicrobium* contains chemoorganotrophic, aerobic, budding bacteria that frequently attach to solid objects in freshwater, marine, and terrestrial environments. The vegetative cell measures about 0.5 to 1.0 by 1 to 3 μm (**figure 22.7**). At the beginning of the reproductive cycle, the mature cell produces a prostheca (also called a hypha) 0.2 to 0.3 μm in diameter that grows to several μm in length (**figure 22.8**). The chromosome replicates, and a copy moves into the hypha while a bud forms at its

Figure 22.7 Prosthecate, Budding Bacteria. *Hyphomicrobium facilis* with hypha and young bud.

end. As the bud matures, it produces one to three flagella, and a septum divides the bud from the hypha. The bud is finally released as an oval- to pear-shaped swarmer cell, which swims off, then settles down and begins budding. The mother cell may bud several times at the tip of its hypha.

Members of the genus *Hyphomicrobium* also have distinctive physiology and nutrition. Sugars and most amino acids do not support abundant growth; instead, these bacteria grow on ethanol and acetate, as well as 1-carbon (C1) compounds such as methanol, formate, and formaldehyde. This makes them facultative **methylotrophs** because they gain energy as well as carbon for biosynthesis from reduced C1 compounds (p. 511), as well as other, larger organic substrates. In fact, they are so efficient at acquiring C1 molecules they can grow in medium without an added carbon source (presumably the medium absorbs sufficient atmospheric carbon compounds). *Hyphomicrobium* spp. may comprise up to 25% of the total bacterial population in oligotrophic (nutrient-poor) freshwater habitats.

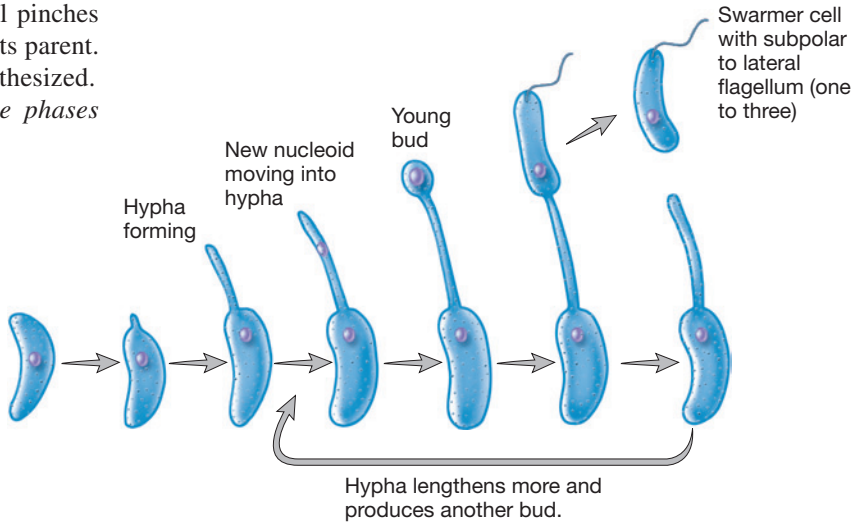

Figure 22.8 The Life Cycle of *Hyphomicrobium*.

Figure 22.9 ***Caulobacter*** **spp. Morphology and Reproduction.** (a) A cell dividing to produce a swarmer (×6,030). Note prostheca and flagellum. (b) A stalked cell and a flagellated swarmer cell (×6,030). (c) A rosette of cells as seen in the electron microscope.

MICRO INQUIRY *If* Caulobacter *bacteria were grown in a phosphate-limited broth, what would happen to the length of the stalks?*

Bacteria in the genus *Caulobacter* form vibroid-shaped cells (*see figure 7.9*), which alternate between polarly flagellated rods and cells that possess a prostheca and a **holdfast,** by which they attach to solid substrata (**figure 22.9**). Incredibly, the material secreted at the end of the *Caulobacter crescentus* holdfast is the strongest biological adhesion molecule known—a sort of bacterial superglue. These bacteria often adhere to other microorganisms and may absorb nutrients released by those microbes. The prostheca differs from that of *Hyphomicrobium* spp. in that it lacks cytoplasmic components and is composed almost totally of the plasma membrane and cell wall. It grows longer in nutrient-poor media and can reach more than 10 times the length of the cell body. The prostheca may improve the efficiency of nutrient uptake from dilute habitats by increasing surface area.

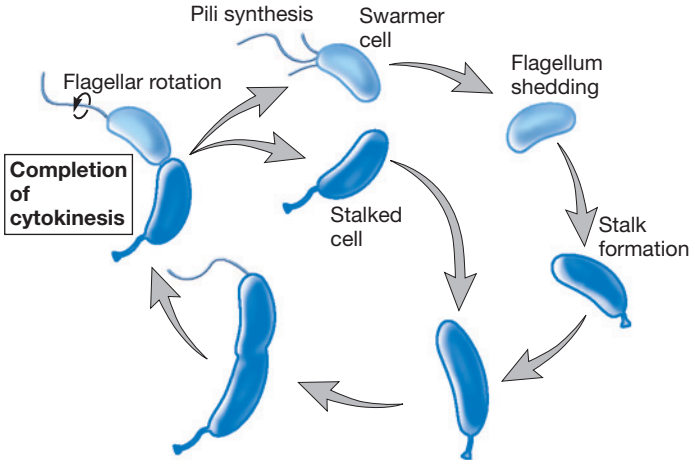

Figure 22.10 ***Caulobacter*** **Life Cycle.** Stalked cells attached to a substrate undergo asymmetric binary fission, producing a stalked and a flagellated cell, called a swarmer cell. The swarmer cell swims freely and makes pili until it settles, ejects its flagella, and forms a stalk. Only stalked cells can divide.

The life cycle of *Caulobacter crescentus* is a model for the investigation of the bacterial cell cycle (**figure 22.10**). When ready to reproduce, the cell elongates and a single polar flagellum forms at the end opposite the prostheca. The cell then undergoes asymmetric transverse binary fission to produce a flagellated swarmer cell that swims away. The swarmer, which cannot reproduce, comes to rest, ejects its flagellum, and forms a new prostheca on the formerly flagellated end. The new stalked cell then starts the cycle anew. This process takes about 2 hours to complete.

Order *Rhizobiales* Includes Important N_2-Fixing Bacteria

The order *Rhizobiales* of α-proteobacteria includes the family *Rhizobiaceae,* which includes aerobic bacteria in the genera *Rhizobium* and *Agrobacterium.* Members of the genus *Rhizobium* are motile rods that become pleomorphic (having many shapes) under adverse conditions. They live symbiotically within root nodules of legumes as specialized nitrogen-fixing cells called bacteroids. Bacteroid physiology is optimized for nitrogen fixation within the nodule (**figure 22.11**; *see also figure 31.9*). The presence of rhizobium nodules has led to the success of leguminous plants likes soybeans. Indeed, *Leguminosae* is the most successful plant family on Earth, with over 18,000 species. Within the nodules, the microbes fix atmospheric nitrogen to ammonia, making it available to the plant host. The process by which bacteria perform this fascinating and important symbiosis is discussed in chapter 31. ⏮ *Nitrogen fixation (section 12.5)* ⏭ *Rhizobia are symbionts of leguminous plants (section 31.3)*

The genus *Agrobacterium* differs from *Rhizobium* because it contains plant pathogens. Although genetic analysis supports assigning many species of *Agrobacterium* to the genus *Rhizobium,* like many others, we continue to refer to the genus as *Agrobacterium* as defined by *Bergey's Manual of Systematic Bacteriology.* Agrobacteria invade the crown, roots, and stems of many plants and transform plant cells into autonomously

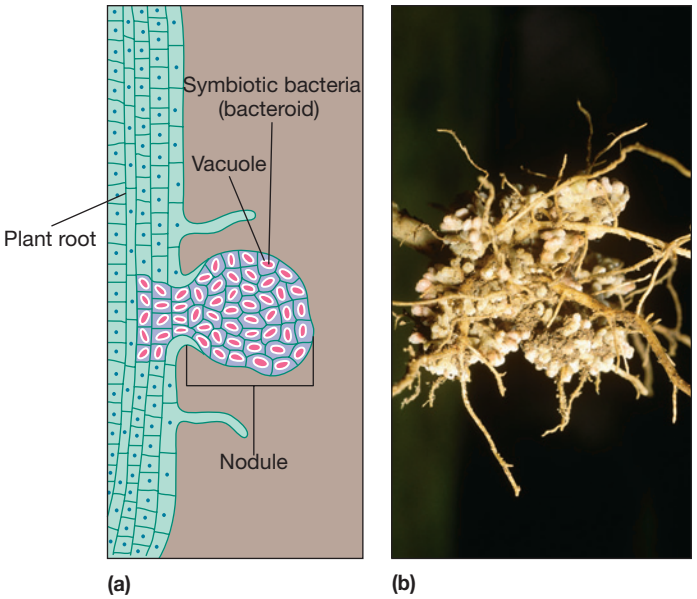

Figure 22.11 ***Rhizobium.*** (a) Diagram of differentiated bacteria, called bacteroids, in the nodule of a legume root. (b) Nodules on a legume root.

proliferating tumor cells (*see figures 31.12 and 31.13*). The best-studied species is *A. tumefaciens,* which enters many broad-leaved plants through wounds and causes crown gall disease (**figure 22.12**). The ability to produce tumors depends on a large Ti (for *t*umor *i*nducing) plasmid. Tumor production by *A. tumefaciens* is discussed in greater detail in chapter 31, while the use of the Ti plasmid in the genetic engineering of plants is covered in chapter 42 (*see figure 42.9*).

The order *Rhizobiales* also includes the family *Brucellaceae.* As described in the chapter-opening story, the genus *Brucella* contains important human and animal pathogens. Brucellosis, also called undulant fever, is a zoonotic disease—a disease transmitted from animals to humans. It is usually caused by tiny, faintly staining coccobacilli of the species *B. abortus, B. melitensis, B. suis,* or *B. canis.* ▶▶| *Brucellosis (section 39.5)*

Another group of microbes within the order *Rhizobiales* are obligate methylotrophs—bacteria whose growth is supported only by the assimilation of C1 compounds such as methanol and methylamine. These include members of the genera *Methylocystis* and *Methylosinus.* In addition to C1 compounds like formate, the microbes can also use methane as a carbon and energy source, so they are also considered **methanotrophs.** All methanotrophs have extensive intracellular membranes and form a resting cell; α-proteobacterial methanotrophs typically form exospores. **Exospores** are produced when a single cell differentiates into a dormant form with a thick cell wall. Exospores are not as environmentally resistant as endospores. Unlike endospores, which are made only by certain Gram-positive bacteria, exospores are produced by both Gram-positive and Gram-negative bacteria. Interestingly, like some other members of the order *Rhizobiales,* these methanotrophs can also fix nitrogen, but not in association with leguminous plants.

Figure 22.12 ***Agrobacterium.*** Crown gall tumor of a plant caused by *Agrobacterium tumefaciens.*

The use of a C1 compound as both a carbon and energy source can be simplified to a three-step process (**figure 22.13**). First, methane (or other single-carbon compound) is oxidized to formaldehyde. Next formaldehyde is either assimilated to produce biomass or oxidized to CO_2, and its electrons used to generate a proton motive force. The use of formaldehyde as the central intermediate is paradoxical because it is poisonous. The

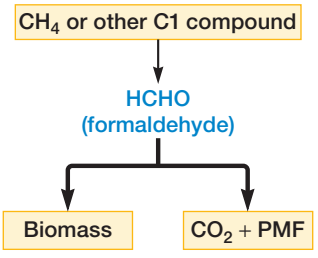

Figure 22.13 **Methanotrophy and Methylotrophy.** Methane or another reduced single-carbon compound (i.e., not CO_2) is converted to the toxic intermediate formaldehyde. This is tolerated only because it is rapidly incorporated into larger molecules to increase biomass or it is quickly oxidized to generate a proton motive force (PMF). Thick arrows indicate the conversion of formaldehyde must occur faster than it can accumulate in the cell.

key to survival is the speed at which formaldehyde is either oxidized to CO_2 or reduced and assimilated into cellular constituents. It is incorporated into cell material by the activity of one of two pathways; α-proteobacteria use the serine pathway (**figure 22.14**), which features the deamination of serine to generate acetyl-CoA. By contrast, γ-proteobacterial methylotrophs use the ribulose monophosphate pathway (p. 524).

The oxidation of methane (CH_4) to formaldehyde (HCHO) requires the formation of methanol (CH_3OH) as an intermediate. This was long thought to be exclusively an aerobic process because molecular oxygen is used in the process. Recently a methanotrophic proteobacterium was reported that oxidizes methane in anoxic environments by coupling methanotrophy with nitrite reduction (denitrification). In the process of reducing nitrite (NO_2^-) to nitrogen gas (N_2), molecular oxygen is released within the microbe, which it harnesses for methane oxidation. Oxidation of methane by bacteria is profoundly different than reverse methanogenesis used by some archaea (*see figure 28.3*). ⏮ *Methanogens and methanotrophs (section 20.4)* ⏭ *Carbon cycle (section 28.1)*

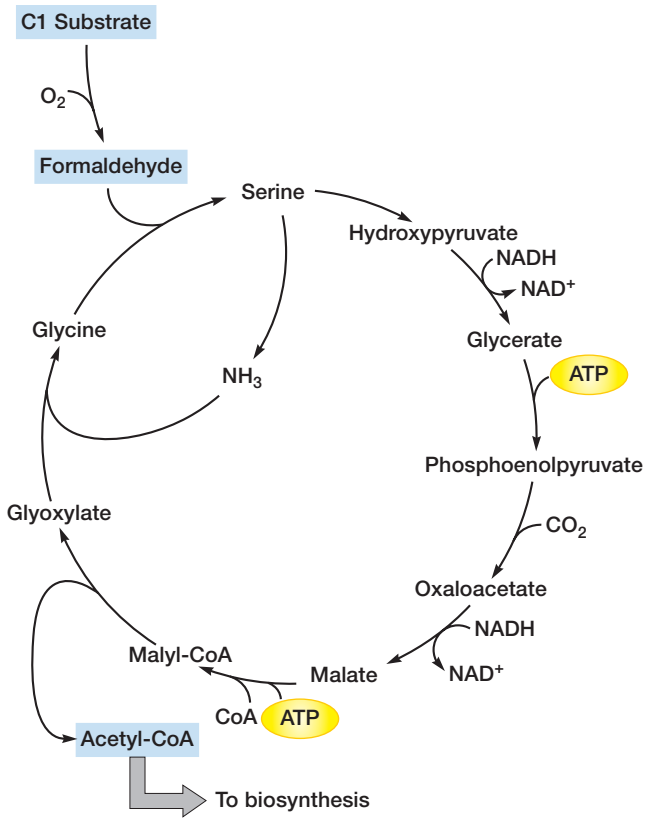

Figure 22.14 The Serine Pathway Is Used by α-Proteobacterial Methylotrophs to Assimilate C1 Compounds. The net yield of this pathway is an acetyl-CoA molecule that can be used in central metabolism. Note that two ATP are hydrolyzed and two NADH are oxidized.

MICRO INQUIRY *What steps are also found in the TCA cycle? What is the structural difference between serine and glycine?*

Nitrifying Bacteria Oxidize Ammonium or Nitrite to Gain Energy and Electrons

Nitrifying bacteria are a very diverse collection of microbes. Nitrifiers are chemolithoautotrophs that use either ammonium or nitrite as electron donors in a process called **nitrification.** Electrons are donated to an electron transport chain from ammonia, which is oxidized to nitrite, or from nitrite, which is then oxidized to nitrate (**figure 22.15**). Oxygen serves as the terminal electron acceptor. No microbe can perform both reactions, so some proteobacteria are classified as ammonia-oxidizing bacteria,

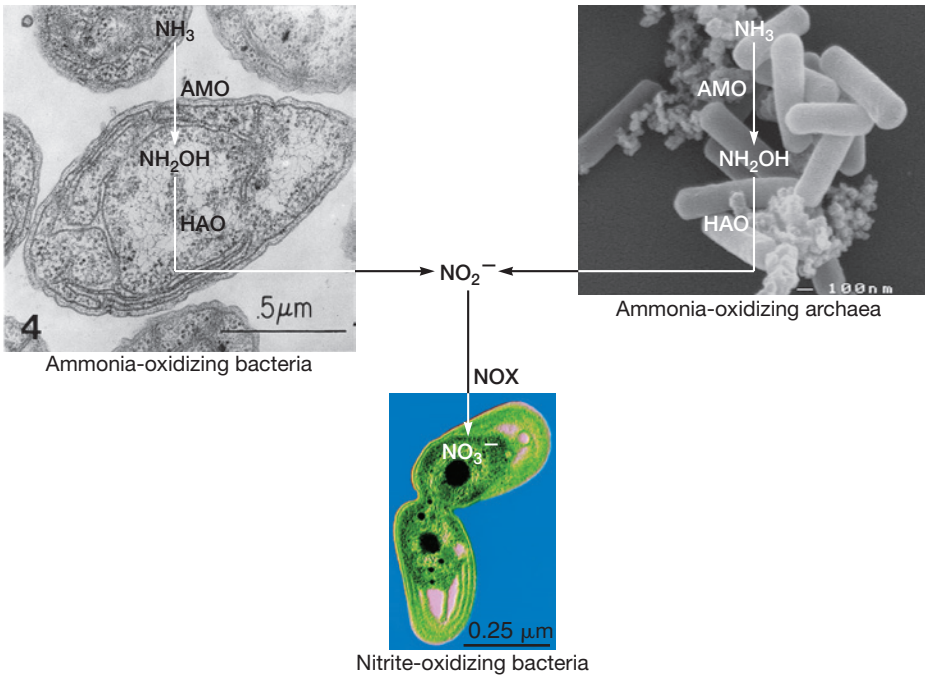

Figure 22.15 Nitrification. The process of nitrification involves three different groups of microorganisms. Ammonia-oxidizing bacteria (e.g., *Nitrosomonas europaea*) and archaea (*Nitrosopumilus maritimus*) use the enzyme ammonia monooxygenase (AMO) to convert ammonia to the intermediate hydroxylamine. Hydroxylamine oxidoreductase (HAO) then catalyzes the production of nitrite, which is released into the environment. Nitrite-oxidizing bacteria such as *Nitrobacter* sp. use nitrite oxidoreductase (NOX) to catalyze the oxidation of nitrite to nitrate.

MICRO INQUIRY *Why do nitrifying microbes possess intracellular membranes?*

Table 22.2 Selected Characteristics of Representative Nitrifying Bacteria

Species	Cell Morphology and Size (μm)	Reproduction	Motility	Cytomembranes	Habitat
Ammonia-Oxidizing Bacteria					
Nitrosomonas europaea (β-proteobacteria)	Rod; 0.8–1.1 × 1.0–1.7	Binary fission	−	Peripheral, lamellar	Soil, sewage, freshwater, marine
Nitrosococcus oceani (γ-proteobacteria)	Coccoid; 1.8–2.2 in diameter	Binary fission	+; 1 or more subpolar flagella	Centrally located parallel bundle, lamellar	Obligately marine
Nitrosospira briensis (β-proteobacteria)	Spiral; 0.3–0.4 in diameter	Binary fission	+ or −; 1 to 6 peritrichous flagella	Rare	Soil
Nitrite-Oxidizing Bacteria					
Nitrobacter winogradskyi (α-proteobacteria)	Rod, often pear-shaped; 0.5–0.9 × 1.0–2.0	Budding	+ or −; 1 polar flagellum	Polar cap of flattened vesicles in peripheral region of the cell	Soil, freshwater, marine
Nitrococcus mobilis (γ-proteobacteria)	Coccoid; 1.5–1.8 in diameter	Binary fission	+; 1 or 2 subpolar flagella	Tubular cytomembranes randomly arranged in cytoplasm	Marine

From Brenner, D. J., et al., eds. 2005. Bergey's Manual of Systemic Bacteriology, *2d ed., vol. 2: The Proteobacteria. Garrity, G. M. Ed-in-Chief. New York: Springer.*

while others are listed as nitrite-oxidizing bacteria (**table 22.2**). Interestingly, in 2014 *Nitrospira moscoviensis* was found to be the first nitrifying microbe also capable of using H_2 as an electron donor. Although most nitrifying bacteria are chemolithoautotrophs, some can also use reduced organic carbon sources and are considered chemolithoheterotrophs. ◀◀ *Chemolithotrophy (section 11.10)*

Bergey's Manual places nitrifying bacteria in several families. All terrestrial ammonia-oxidizing bacteria are β-proteobacteria, including *Nitrosomonas* and *Nitrosospira* in the *Nitrosomonadaceae* family, while marine ammonia oxidizers include both β-proteobacteria and γ-proteobacteria such as *Nitrosococcus* in the *Chromatiaceae* family. Nitrite oxidation is carried out by bacteria in the α-proteobacterial class, *Nitrobacter* (*Bradyrhizobiaceae* family), and the γ-proteobacteria class, *Nitrococcus* (*Ectothiorhodospiraceae* family). These microbes differ considerably in morphology and may be rod-shaped, ellipsoidal, spherical, spirillar, or lobate. They may possess either polar or peritrichous flagella. Often they have extensive membrane complexes in their cytoplasm. These intracellular membranes increase the surface area available for electron transport. Chemolithotrophy captures very little free energy, so reduced inorganic compounds such as ammonia or nitrite must be oxidized at a great rate in order to conserve enough energy to support growth. This is analogous to an old car that gets bad gas mileage; it must burn more gas (electrons) to cover the same distance (do work) than an efficient, newer car.

Nitrifying microorganisms make important contributions to the nitrogen cycle. Nitrification occurs rapidly in oxic soil treated with fertilizers containing ammonium salts. By converting ammonium to nitrite and then to nitrate, nitrification increases the availability of nitrogen to plants because nitrate is readily used by plants. The discovery of ammonia-oxidizing archaea has triggered a reassessment of the relative contribution of bacteria to global nitrification. ▶▶ *Nitrogen cycle (section 28.1)*

Magnetococcus: A Newly Discovered Genus

Magnetococcus marinus is the only spherical magnetotactic bacterium in pure culture (**figure 22.16**). The microbe has two sheathed bundles of flagella at one pole, a morphology called bilophotrichous. Magnetotaxis is mediated by a single row of magnetite crystals arranged within the cytoplasm (*see also figure 3.37*). It was isolated from the oxic/anoxic interface of an estuary and is obligately microaerophilic when grown in culture. It grows both chemoorganoheterotrophically, using acetate as a carbon source, or chemolithoautotrophically with thiosulfate or sulfide as electron donors. When growing autotrophically, it uses the reductive TCA cycle to fix CO_2 (*see figure 12.5*). ◀◀ *Inclusions (section 3.6)*

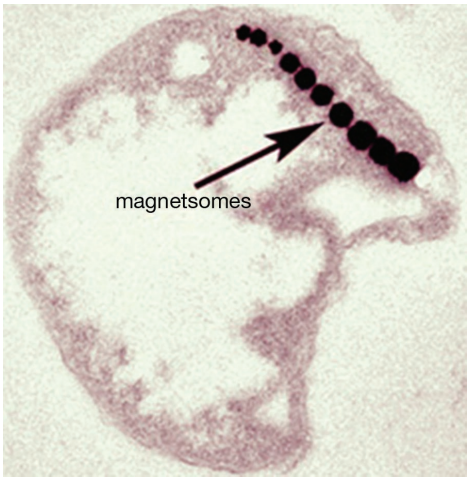

Figure 22.16 ***Magnetococcus marinus.*** Cells are roughly spherical with a single chain of magnetite crystals and two bundles of polar flagella (not shown) that mediate magnetotaxis through marine sediments. Average cell size is 1-2 μm.

SAR11 Clade, the Most Abundant Microorganisms on Earth

Candidatus Pelagibacter ubique is the sole cultured representative of the world's most abundant group of bacteria, called the SAR11 clade. "SAR" represents *Sar*gasso Sea, where these marine bacteria were first discovered. All members of the SAR11 clade are chemoorganoheterotrophs, and information about their physiology comes from combined analysis of cultures, the complete genome of *Ca*. P. ubique, and metagenomic sequences of environmental bacteria. These microbes appear to reverse the Embden-Meyerhof pathway for gluconeogenesis and use a modified version of the Enter-Douderoff pathway for glucose oxidation (**figure 22.17**). Culture experiments demonstrate that *Ca*. P. ubique can use glucose and low-molecular-weight organic acids as sole carbon sources, but metagenomic analysis suggests this is not true of all members of this clade.

The genome of *Ca*. P. ubique is 1.31 Mb, which is quite small for an independently growing microbe. As this bacterium evolved, it became optimized for a life with scant nutrients. The small size of its genome reflects the almost complete absence of intergenic nucleotides, with a median of only three nucleotides between genes. There are no pseudogenes, phage genes, or duplicated genes. It encodes a relatively large number of high-affinity transporters, as it is energetically cheaper to transport macromolecules than to make them *de novo*. Even its small cell size maximizes the surface-to-volume ratio (*see figure 3.5*). The discovery of genes for proteorhodopsin perplexed microbiologists, as initial experiments failed to show that light enhanced rates of growth, as predicted if this light-driven proton pump contributed to the production of ATP. However, when such experiments were later performed on cells starved for carbon, there was an observable growth advantage for cells cultivated in the light. ⏮ *Rhodopsin-based phototrophy (section 11.11)* ⏭ *Microorganisms in the open ocean are adapted to nutrient limitation (section 30.2)*

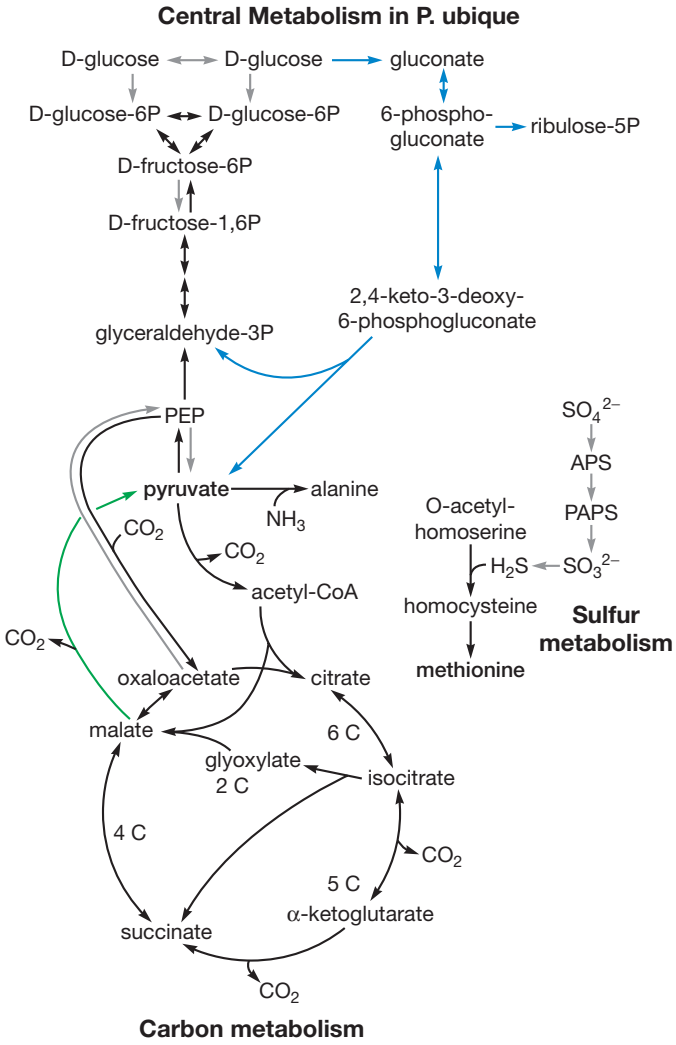

Figure 22.17 **Central Metabolism in *Ca.* P. ubique as Determined by Genome Analysis.** The upper half of the figure shows the Embden-Meyerhof pathway for glucose oxidation as used by many bacteria (gray arrows); *Ca.* P. ubique runs this pathway in reverse for gluconeogenesis (black arrows); glucose is oxidized by the modified Entner-Douderoff pathway shown with blue arrows. The bottom half of the figure shows the glyoxylate cycle; unlike other microbes that convert oxaloacetate to PEP (gray arrow), *Ca.* P. ubique starts gluconeogenesis by converting malate to pyruvate (green arrow), *Ca.* P. ubique lacks genes for assimilatory sulfate reduction (gray arrows), and requires reduced organic sulfur compounds such as methionine for growth. G3-P, 3-phosphoglycerate; 3-HP, 3-hydroxypyruvate

MICRO INQUIRY *Why can oxaloacetate and glucose, but not acetate, replace the need for pyruvate for growth?*

22.2 Class *Betaproteobacteria* Includes Chemoheterotrophs and Chemolithotrophs

After reading this section, you should be able to:

- List human diseases caused by *Neisseria* and *Bordetella* spp.
- Discuss the function of the sheath in the physiology of *Leptothrix* spp.
- Summarize the reactions used by *Nitrosomonas europaea* to oxidize ammonium to nitrite
- Differentiate between nitrification and denitrification, and identify the electron donors and acceptors for each
- Explain how sulfur-oxidizing bacteria obtain ATP from reduced sulfur species via substrate-level phosphorylation

β-proteobacteria are similar to α-proteobacteria metabolically but tend to use substances released from organic decomposition in anoxic habitats. Some of these bacteria use hydrogen, ammonia, volatile fatty acids, and similar substances. As with α-proteobacteria, there is considerable metabolic diversity; β-proteobacteria may be chemoorganotrophs, photolithotrophs, and chemolithotrophs.

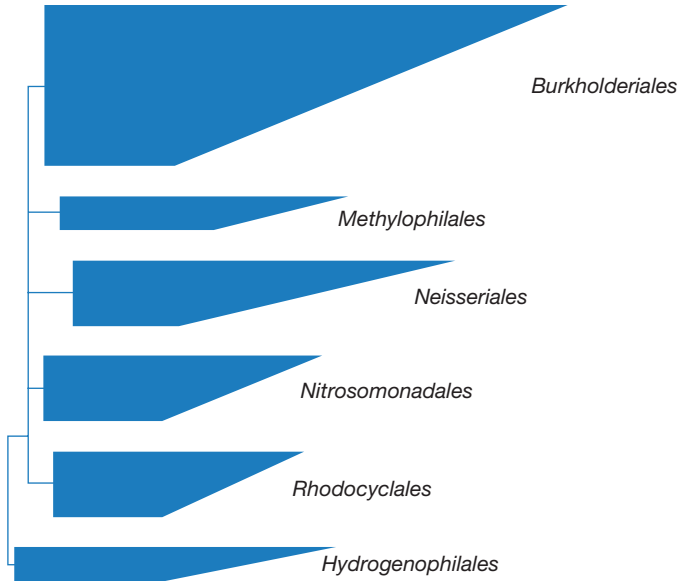

Figure 22.18 Phylogenetic Relationships Among Major Groups of β-Proteobacteria. The relationships are based on 16S rRNA sequence data.

The class *Betaproteobacteria* includes 12 families. **Figure 22.18** shows the phylogenetic relationships among major groups of β-proteobacteria, and **table 22.3** summarizes the general characteristics of many of the bacteria discussed in this

Table 22.3 Characteristics of Selected β-Proteobacteria

Genus	Dimensions (μm) and Morphology	Oxygen Requirement	Other Distinctive Characteristics
Bordetella	0.2–0.5 × 0.5–2.0; nonmotile coccobacillus	Aerobic	Require organic sulfur and nitrogen; mammalian parasite
Burkholderia	0.5–1.0 × 1.5–4; straight rods with single flagellum or a tuft at the pole	Aerobic, some capable of anaerobic respiration with NO_3^-	Poly-β-hydroxybutyrate as reserve; can be pathogenic
Leptothrix	0.6–1.5 × 2.5–15; straight rods in chains with sheath, free cells flagellated	Aerobic	Sheaths encrusted with iron and manganese oxides
Neisseria	0.6–1.9; cocci in pairs with flattened adjacent sides	Aerobic	Inhabitants of mammalian mucous membranes
Nitrosomonas	Size varies with strain; spherical to ellipsoidal cells with intracytoplasmic membranes	Aerobic	Chemolithotrophs that oxidize ammonia to nitrite
Sphaerotilus	1.2–2.5 × 2–10; single chains of cells with sheaths, may have holdfasts	Aerobic	Sheaths not encrusted with iron and manganese oxides
Thiobacillus	0.3–0.5 × 0.9–4; rods, often with polar flagella	Aerobic	All chemolithotrophic; oxidize reduced sulfur compounds to sulfate; some also capable of chemoorganotrophy

section. Because sequence data suggest that the separation between *Betaproteobacteria* and *Gammaproteobacteria* is less distinct than once thought, *Betaproteobacteria* may one day be merged with *Gammaproteobacteria*.

Order *Neisseriales* Includes Important Pathogens

Neisseria is the best-studied genus in the order *Neisseriales*. Members of this genus are nonmotile, aerobic, Gram-negative cocci that most often occur in pairs with adjacent sides flattened. They may have capsules and pili. These chemoorganotrophs inhabit the mucous membranes of mammals, and some are human pathogens. *Neisseria gonorrhoeae* is the causative agent of gonorrhea; *Neisseria meningitidis* is responsible for some cases of bacterial meningitis. ▶▶| *Meningitis (section 39.1); Gonorrhea (section 39.3)*

Order *Burkholderiales* Includes Recently Evolved Pathogens

The order *Burkholderiales* has three well-known families. *Burkholderia* is placed in the family *Burkholderiaceae*. Members of this genus are Gram-negative, aerobic, mesophilic straight rods. With the exception of one species, all are motile with a single polar flagellum or a tuft of polar flagella. Most species use poly-β-hydroxybutyrate as their carbon reserve. One of the most important species is *B. cepacia,* which can degrade over 100 different organic molecules and is very active in recycling organic materials in nature. Originally described as the plant pathogen that causes onion rot, it has emerged in the last 20 years as a major nosocomial (hospital-acquired) pathogen. It is a particular problem for cystic fibrosis patients. Two other species, *B. mallei* and *B. pseudomallei,* are pathogens that could be misused as bioterrorism agents. ▶▶| *Bioterrorism readiness is an integral component of public health microbiology (section 37.7)*

Surprisingly, two genera within the *Burkholderiaceae* family are capable of forming nitrogen-fixing symbioses with legumes much like the rhizobia (α-proteobacteria). Genome analysis of nitrogen-fixing *Burkholderia* and *Cupriavidus* (formerly *Ralstonia*) isolates reveals the presence of nodulation (*nod*) genes that are very similar to those of rhizobia. This suggests a common origin. It is thought these β-proteobacteria gained the capacity to form symbiotic, nitrogen-fixing nodules with legumes through horizontal gene transfer. |◀◀ *Horizontal gene transfer (section 16.4)*

Some members of the order *Burkholderiales* have a **sheath**—a hollow, tubelike structure surrounding a chain of cells. Sheaths often are close fitting, but they are never in intimate contact with the cells they enclose. Some contain ferric or manganic oxides. They have at least two functions. Sheaths help bacteria attach to solid surfaces and acquire nutrients from slowly running water as it flows past, even if it is nutrient-poor. Sheaths also protect against predators such as protozoa.

Two well-studied sheathed genera are in the family *Comamonadaceae*. *Sphaerotilus* bacteria form long, sheathed chains of rods attached to submerged plants, rocks, and other solid objects. These chains release swarmer cells with a bundle of flagella into the water, where they attach to an object by means of a holdfast and form a new chain. They grow best in slowly running, polluted freshwater. In fact, they thrive in activated sewage sludge and sometimes form tangled masses of filaments that interfere with the proper settling of sludge (*see figure 43.5*). *Leptothrix* spp. characteristically deposit large amounts of iron and manganese oxides in the sheath.

The family *Alcaligenaceae* contains the genus *Bordetella.* This genus is composed of Gram-negative, aerobic coccobacilli. They are chemoorganotrophs with respiratory metabolism and require organic sulfur and nitrogen (amino acids) for growth. As mammalian parasites, they multiply in respiratory epithelial cells. *B. bronchiseptica* is the causative agent of the canine condition kennel cough, and *B. pertussis* is a nonmotile, encapsulated species that causes pertussis (whooping cough); *B. parapertussis* is a closely related species that causes a milder form of the disease. ▶▶| *Pertussis (section 39.1)*

Order *Nitrosomonadales* Consists of Ammonia-Oxidizing Bacteria

A number of chemolithotrophs are found in the order *Nitrosomonadales* including the genera of nitrifying bacteria *Nitrosomonas* and *Nitrosospira* (figure 22.15). Both of these bacteria oxidize ammonia to nitrite; a metabolic and transport reconstruction based on the genome of *Nitrosomonas europaea* is shown in **figure 22.19**. This microbe uses the enzyme ammonia monooxygenase (AMO) and hydroxylamine oxidoreductase to oxidize ammonia to nitrite in the reaction:

$$NH_3 + O_2 + 2H^+ + 2e^- \rightarrow NH_3OH + H_2O \rightarrow NO_2 + 5H^+ + 4e^-$$

Of the four electrons released, two must return to AMO to continue ammonia oxidation, while the other two can be used either as reductants for biosynthesis or be donated to the electron transport chain to reduce the terminal electron acceptor, oxygen. Figure 22.19 also illustrates the autotrophic metabolism of this microbe, which uses the Calvin-Benson cycle to fix CO_2.

Order *Hydrogenophilales* Includes a Model Colorless Sulfur Bacterium

This small order contains the genus *Thiobacillus,* which are the best-studied **colorless sulfur bacteria,** so named because they use sulfur-containing compounds as energy sources but are not photosynthetic and therefore lack photosynthetic pigments. Many are unicellular, rod-shaped or spiral, sulfur-oxidizing bacteria that can be either nonmotile or flagellated (**table 22.4**). *Bergey's Manual* divides the colorless sulfur bacteria between two classes; for example, the genera *Thiobacillus* and *Macromonas* are β-proteobacteria, whereas the genera *Thiomicrospira, Thiobacterium, Thiospira, Thiothrix, Beggiatoa,* and others are γ-proteobacteria. Only some of these bacteria have been grown in pure culture.

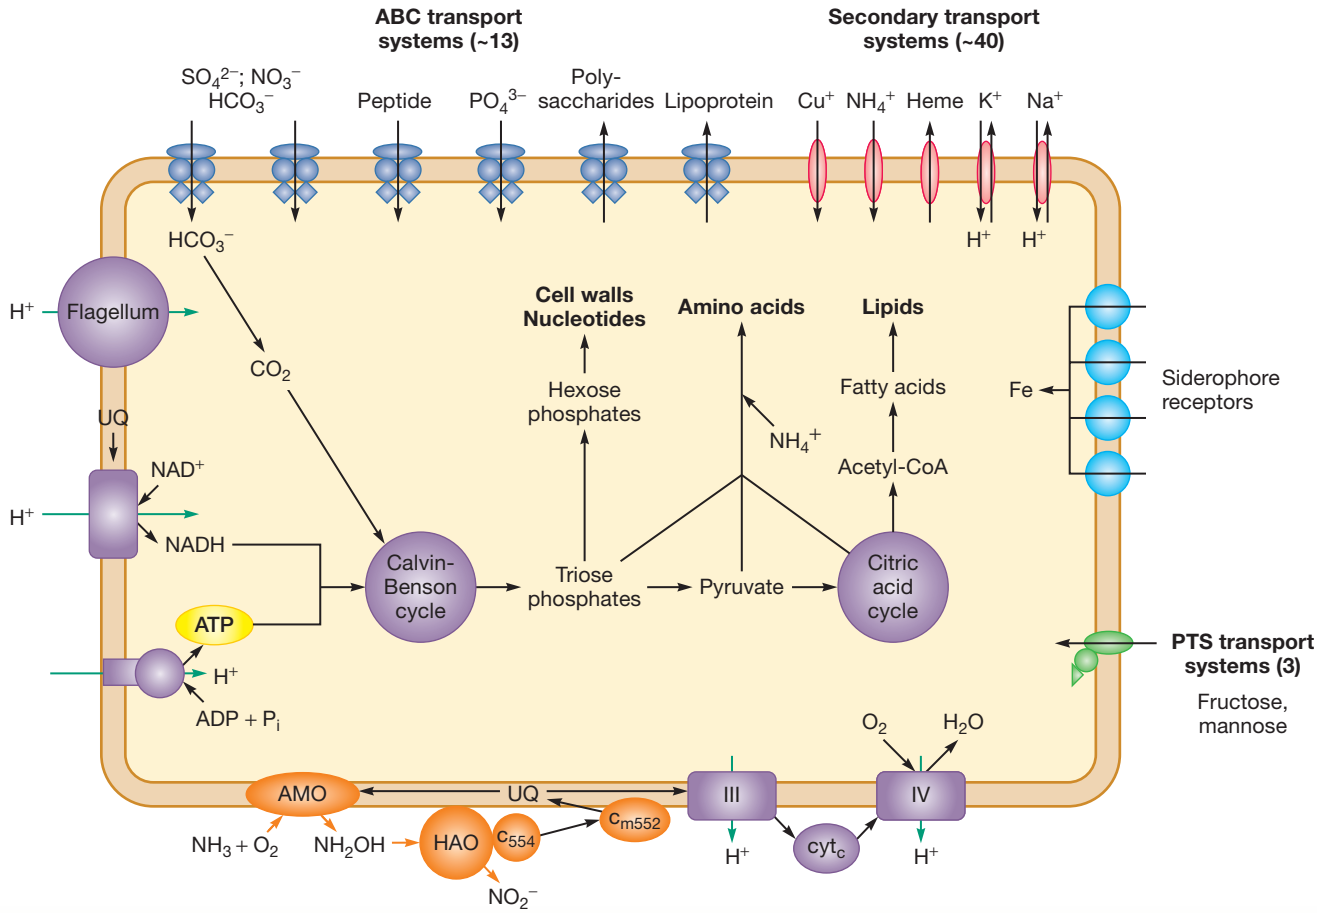

Figure 22.19 **Genomic Reconstruction of *Nitrosomonas europaea*.** This chemolithoautotroph uses the Calvin-Benson cycle to fix CO_2. Ammonia oxidation is catalyzed by a membrane-bound ammonia monooxygenase (AMO) and hydroxylamine oxidoreductase (HAO). Electrons from HAO flow through two cytochromes (c_{554} and cm_{552}) into an electron transport chain at the level of ubiquinone-cytochrome c oxidoreductase. O_2 is the terminal electron acceptor. Electrons from ammonia oxidation must also flow in reverse for NAD^+ and $NADP^+$ reduction. These enzymes, the flagellar motor, the ATP synthase, and secondary transport systems are fueled by the proton motive force established by ammonia oxidation.

MICRO INQUIRY *Suggest why* N. europaea *has PTS transport systems for the sugars fructose and mannose if it is autotrophic.*

Table 22.4 Colorless Sulfur-Oxidizing Genera

Genus	Cell Shape	Motility; Location of Flagella	Sulfur Deposit[1]	Nutritional Type
Thiobacillus	Rods	+; polar	Extracellular	Obligate or facultative chemolithotrophs
Thiomicrospira	Spirals, comma, or rod-shaped	– or +; polar	Extracellular	Obligate chemolithotrophs
Thiobacterium	Rods embedded in gelatinous masses	–	Intracellular[2]	Probably chemoorganoheterotrophs
Thiospira	Spiral rods, usually with pointed ends	+; polar (single or in tufts)	Intracellular	Unknown
Macromonas	Rods, cylindrical or bean-shaped	+; polar tuft	Intracellular[2]	Probably chemoorganoheterotrophs

1 When hydrogen sulfide is oxidized to elemental sulfur.
2 May use sulfur oxidation to detoxify H_2O_2.

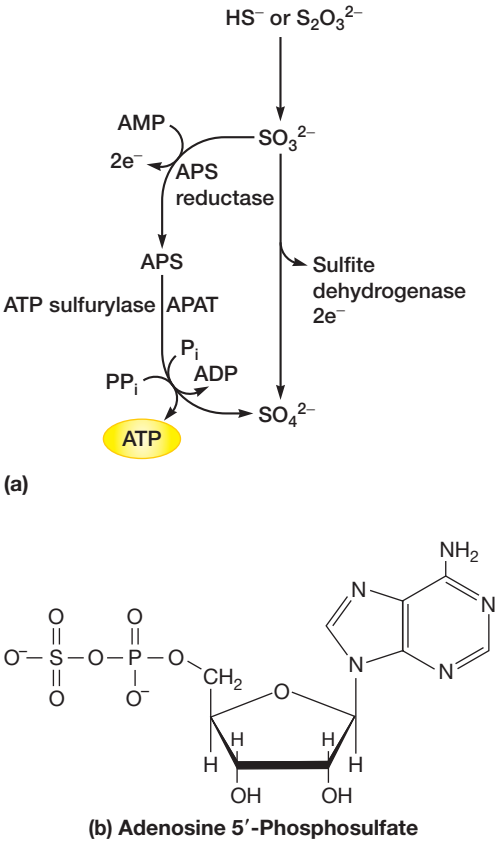

Figure 22.20 Sulfur Oxidation in *Thiobacillus ferrooxidans.* (a) Reduced sulfur compounds such as sulfide (HS^-) or thiosulfate ($S_2O_3^{2-}$) are oxidized to sulfite (SO_3^{2-}). Electrons from sulfite can be donated to an electron transport chain via sulfite dehydrogenase and used to generate a proton motive force. Alternatively, the enzyme APS reductase catalyzes the oxidation of sulfite to sulfate, which is used to convert adenosine monophosphate (AMP) to APS. ATP sulfurylase and APS:phosphate adenylyltransferase (APAT) then catalyze the exchange of the sulfate on APS with PP_i to generate ATP via substrate-level phosphorylation. (b) The structure of APS.

MICRO INQUIRY *Identify the reactions that contribute to substrate-level phosphorylation and those that might contribute to ATP synthesis by a membrane-bound ATP synthase.*

Thiobacillus spp. metabolism has been intensely studied. The genus includes obligate aerobes and facultative denitrifiers. They use a variety of reduced, inorganic sulfur compounds as energy and electron sources and oxygen as electron acceptor. ATP is generated in two ways, both of which require that the cell first oxidize sulfide or thiosulfate to sulfite (SO_3^{2-}; **figure 22.20*a***). When sulfite donates its electrons to an electron transport chain, ATP is made by oxidative phosphorylation and sulfate is the end product. Alternatively, sulfite can be bound to AMP to form the molecule adenosine 5′-phosphosulfate (APS, figure 22.20*b*). The sulfate in APS is next enzymatically replaced with PP_i, yielding sulfate and ATP though substrate-level phosphorylation. Although all *Thiobacillus* spp. are autotrophic, fixing CO_2 via the Calvin-Benson cycle (*see figure 12.4*), *T. novellus* and a few other species can also grow heterotrophically. ⏮ *Chemolithotrophy (section 11.10)*

The metabolic flexibility of *Thiobacillus denitrificans* has made it the focus of much investigation. Remarkably it can use either oxygen or nitrate as its terminal electron acceptor when growing chemolithotrophically, using hydrogen sulfide or thiosulfate to donate electrons to an electron transport chain. When using nitrate as a terminal electron acceptor, *T. denitrificans* can sequentially reduce nitrate to nitrogen gas—a process called **denitrification.** It can also use ferrous iron (Fe^{2+}) as an electron donor; this form of chemolithotrophy has been well documented in another species, *T. ferrooxidans*.

Sulfur-oxidizing bacteria have a wide distribution and great practical importance. *Thiobacillus* spp. are ubiquitous in soil, freshwater, and marine habitats. Many demonstrate great acid tolerance (e.g., *T. thiooxidans* grows at pH 0.5 and cannot grow above pH 6), and these bacteria prosper in habitats they have acidified by sulfuric acid production. Drainage from mining operations is arguably the most important high-sulfide, low-pH environment in the United States. *T. ferrooxidans* and *Leptospirillum ferrooxidans* control the levels of sulfide (as sulfuric acid and iron disulfide) in these waters. Acid mine drainage is inhospitable to life other than acidophilic bacteria and archaea and can pollute nearby streams and corrode natural and man made structures (**Microbial Diversity & Ecology 22.1**). Conversely, sulfur-oxidizing bacteria can be beneficial. Other, neutrophilic species can increase soil fertility by oxidizing elemental sulfur to sulfate. Thiobacilli are used in processing low-grade metal ores because of their ability to leach metals from ore. There is much interest in using *T. denitrificans* to decontaminate water with high levels of nitrate. ⏭ *Sulfur cycle (section 28.1)*

Retrieve, Infer, Apply

1. Members of which β-proteobacterial genera make important contributions to the environment? Which are human or animal pathogens?
2. What is the end product of ammonium oxidation?
3. Examine figure 22.19. How does *N. europaea* generate a proton motive force (PMF), and what processes does this PMF fuel?
4. How do colorless sulfur bacteria obtain energy by oxidizing sulfur compounds?
5. What role does iron play in the redox metabolism of *Thiobacillus ferrooxidans*?

MICROBIAL DIVERSITY & ECOLOGY

22.1 Acid Mine Drainage

Each year millions of tons of sulfuric acid flow to the Ohio River from the coal mines of the Appalachian Mountains. This sulfuric acid is of microbial origin and leaches enough metals from the mines to make the river reddish and acidic. The primary culprit is *Acidithiobacillus ferrooxidans,* a chemolithotrophic bacterium that derives its energy from oxidizing ferrous ion to ferric ion and sulfide ion to sulfate ion. The combination of these two energy sources is important because of the solubility properties of iron. Ferrous ion is somewhat soluble and can be formed at pH values of 3.0 or less in moderately reducing environments. However, when the pH is greater than 4.0 to 5.0, ferrous ion is spontaneously oxidized to ferric ion by O_2 in the water and precipitates as a hydroxide. If the pH drops below 2.0 to 3.0 because of sulfuric acid production by spontaneous oxidation of sulfur or sulfur oxidation by thiobacilli and other bacteria, the ferrous ion remains reduced, soluble, and available as an energy source. Remarkably, *A. ferrooxidans* grows well at such acidic pHs and actively oxidizes ferrous ion to an insoluble ferric precipitate. The water is rendered toxic for most aquatic life and unfit for human consumption.

The ecological consequences of this metabolic lifestyle arise from the common presence of pyrite (FeS_2) in coal mines. The bacteria oxidize both elemental components of pyrite for their growth and in the process form sulfuric acid, which leaches the remaining minerals.

Autoxidation or bacterial action

$$2FeS_2 + 7O_2 + 2H_2O \rightarrow 2Fe^{2+} + 4SO_4^{2-} + 4H^+$$

A. ferrooxidans

$$2Fe^{2+} + 1/2O_2 + 2H^+ \rightarrow 2Fe^{3+} + H_2O$$

Pyrite oxidation is further accelerated because the ferric ion generated by bacterial activity readily oxidizes more pyrite to sulfuric acid and ferrous ion. In turn, the ferrous ion supports further bacterial growth. It is difficult to prevent *A. ferrooxidans* growth as it requires only pyrite and common inorganic salts. Because *A. ferrooxidans* gets its O_2 and CO_2 from the air, the only feasible method of preventing its damaging growth is to seal the mines to render the habitat anoxic.

22.3 Class *Gammaproteobacteria* Is the Largest Bacterial Class

After reading this section, you should be able to:

- Relate the electron donors used by a variety of γ-proteobacteria to the habitats in which they thrive
- Describe the multicellular arrangements and unusual cellular morphologies displayed by some γ-proteobacteria
- Outline the oxidation of methane by methanotrophs
- Compare the intracellular life cycle of *Legionella* spp. to that of *Coxiella* spp.
- Describe four practical aspects of pseudomonads
- List at least five electron acceptors used by *Shewanella* cells and explain the term dissimilatory metal reduction
- Describe three strategies used by dissimilatory metal-reducing bacteria that enable their use of insoluble compounds as electron acceptors
- Compare and contrast the physiology and importance of members of *Vibrionales* with those in *Enterobacteriales* and *Pasteurellales*
- Summarize mixed acid fermentation
- Describe the use of metabolic assays to distinguish between enteric bacteria

As the largest class of *Proteobacteria,* **γ-proteobacteria** demonstrate an extraordinary variety of physiological types. According to some molecular analyses, *Gammaproteobacteria* is composed of several deeply branching groups. One consists of purple sulfur bacteria; a second includes intracellular parasites in the genera *Legionella* and *Coxiella.* The two largest groups contain a wide variety of nonphotosynthetic genera. These microbes can be grouped into rRNA superfamilies based on the degree of sequence conservation among rRNA (*see figure 19.3*). Ribosomal RNA superfamily I includes the families *Vibrionaceae, Enterobacteriaceae,* and *Pasteurellaceae.* These bacteria use the Embden-Meyerhof and pentose phosphate pathways to catabolize carbohydrates. Most are facultative anaerobes. Ribosomal RNA superfamily II contains mostly aerobes that often use the Entner-Doudoroff and pentose phosphate pathways to catabolize many different kinds of organic molecules. The genera *Pseudomonas, Azotobacter, Moraxella,* and *Acinetobacter* belong to this superfamily. ◀◀ *Microbial taxonomy and phylogeny are largely based on molecular characterization (section 19.3)*

The exceptional diversity of these bacteria is evident from the fact that *Bergey's Manual* divides γ-proteobacteria into 14 orders and 28 families. **Figure 22.21** illustrates the phylogenetic relationships among major groups and selected γ-proteobacteria,

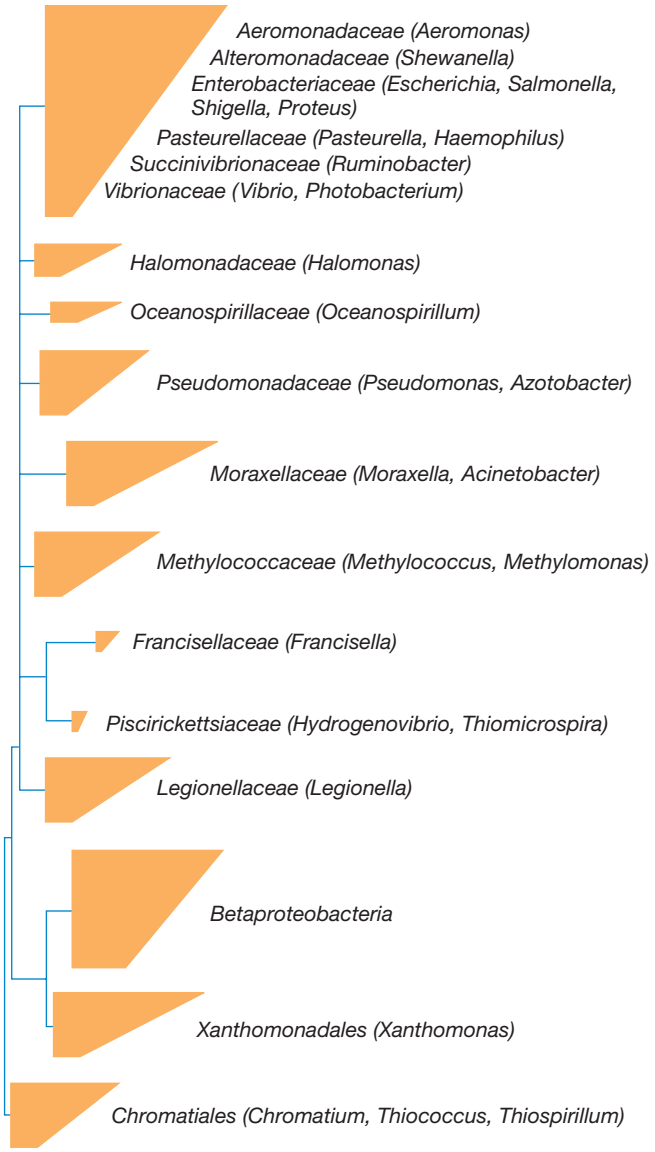

Figure 22.21 Phylogenetic Relationships Among γ-Proteobacteria. The major phylogenetic groups based on 16S rRNA sequence comparisons. Representative genera are given in parentheses. Each tetrahedron in the tree represents a group of related organisms; its horizontal edges show the shortest and longest branches in the group. Multiple branching at the same level indicates that the relative branching order of the groups cannot be determined from the data. The placement of *Betaproteobacteria* has given rise to the suggestion that this class should be merged with *Gammaproteobacteria*.

and **table 22.5** outlines the general characteristics of some of the bacteria discussed in this section.

Purple Sulfur Bacteria Perform Anoxygenic Photosynthesis

Purple sulfur bacteria are strict anaerobes and usually photolithoautotrophic. *Bergey's Manual* places **purple sulfur bacteria** in the order *Chromatiales,* which has two families: *Chromatiaceae* and *Ectothiorhodospiraceae. Ectothiorhodospira* is composed of red, spiral-shaped, polarly flagellated cells that deposit sulfur globules externally. Internal photosynthetic membranes are organized as lamellar stacks (figure 22.3).

The majority of purple sulfur bacteria are in the family *Chromatiaceae*. Recall that during anoxygenic photosynthesis, electrons are required for the reduction of NADPH. These microbes use hydrogen sulfide as an electron donor and deposit the resulting oxidized sulfur granules internally; often they further oxidize the sulfur to sulfate. Hydrogen also may serve as an electron donor. *Thiospirillum, Thiocapsa,* and *Chromatium* spp. are typical purple sulfur bacterial genera, although a *Thiocapsa* isolate is able to use nitrite as an electron donor during anoxygenic photosynthesis. These bacteria are found in anoxic, sulfide-rich zones of lakes, marshes, and lagoons where large blooms can occur under certain conditions (**figure 22.22**). ▶▶| *Light reactions in anoxygenic photosynthesis (section 11.11)*

Order *Thiotrichales* Includes Large Filamentous Bacteria

The largest family in the order *Thiotrichales* is *Thiotrichaceae.* This family has several genera whose members oxidize sulfur compounds. Morphologically both rods and filamentous forms are present, but the most striking members are filamentous.

Two genera in this family are *Beggiatoa* and *Leucothrix,* which contain well-studied gliding species. *Beggiatoa* spp. are microaerophilic and grow in sulfide-rich habitats such as sulfur springs, freshwater with decaying plant material, rice paddies, salt marshes, and marine sediments. Their filaments contain short, disklike cells (**figure 22.23**). These bacteria oxidize hydrogen sulfide to form large sulfur grains located in pockets formed by invaginations of the plasma membrane. *Beggiatoa* spp. also oxidize the sulfur to sulfate when donating electrons to the electron transport chain for energy production. Many strains grow heterotrophically with acetate as a carbon source, and some incorporate CO_2 autotrophically. Carbon fixation typically occurs using the Calvin-Benson cycle, but there is metagenomic evidence that some *Beggiatoa* from marine sediments perform the reductive TCA cycle as well (*see figure 12.5*). Freshwater species are much smaller than marine.

Members of three genera of *Thiotrichales—Beggiatoa, Thioploca,* and *Thiomargarita*—are notable because they form large mats on the seafloor near hydrothermal vents and adjacent to nutrient-rich coasts where methane seeps out of Earth's crust. These filamentous microbes are among the largest known bacteria. For example, *Thiomargarita* spp. can be over 100 μm in diameter (about twice as thick as a fingernail) and hundreds of centimeters long (**figure 22.24**). All three groups grow in bundles, making them even more conspicuous. These bacteria appear hollow because they form large intracellular vacuoles where high concentrations of nitrate (up to 500 mM) are stored. Sulfur inclusions are found in a thin layer of cytoplasm around the vacuoles.

Table 22.5 Characteristics of Selected γ-Proteobacteria

Genus	Dimensions (μm) and Morphology	Oxygen Requirement	Other Distinctive Characteristics
Azotobacter	1.5–2.0; ovoid cells, pleomorphic, peritrichous flagella or nonmotile	Aerobic	Can form cysts, fix nitrogen nonsymbiotically
Beggiatoa	1–200 × 2–10; colorless cells form filaments, either single or in bundles	Aerobic or microaerophilic	Gliding motility; can form sulfur inclusions with hydrogen sulfide present
Chromatium	1–6 × 1.5–16; rod-shaped or ovoid, straight or slightly curved, polar flagella	Anaerobic	Anoxygenic photolithoautotrophs that can use sulfide; sulfur stored within the cell
Ectothiorhodospira	0.7–1.5 in diameter; vibrioid- or rod-shaped, polar flagella	Anaerobic, some aerobic or microaerophilic	Internal lamellar stacks of membranes; deposit sulfur granules outside cells
Escherichia	1.1–1.5 × 2–6; straight rods, peritrichous flagella or nonmotile	Facultatively anaerobic	Mixed acid fermenters; formic acid converted to H_2 and CO_2, lactose fermented, citrate not used
Haemophilus	<1.0 in width, variable lengths; coccobacilli or rods, nonmotile	Aerobic or facultatively anaerobic	Fermentative; require growth factors present in blood; parasites on mucous membranes
Leucothrix	Long filaments of short cylindrical cells, usually holdfast is present	Aerobic	Dispersal by gonidia, filaments don't glide; rosettes formed; chemoorganotrophic
Methylococcus	0.8–1.5 × 1.0–1.5; cocci with capsules, nonmotile	Aerobic	Can form cysts; use methane, methanol, and formaldehyde as sole carbon and energy sources
Photobacterium	0.8–1.3 × 1.8–2.4; straight, plump rods with polar flagella	Facultatively anaerobic	Two species can emit blue-green light; Na^+ needed for growth
Pseudomonas	0.5–1.0 × 1.5–5.0; straight or slightly curved rods, polar flagella	Aerobic or facultatively anaerobic	Respiratory metabolism with oxygen or nitrate as acceptor; some use H_2 or CO as energy source
Vibrio	0.5–0.8 × 1.4–2.6; straight or curved rods with sheathed polar flagella	Facultatively anaerobic	Fermentative or respiratory metabolism; sodium ions stimulate or are needed for growth; oxidase positive

Figure 22.22 Purple Photosynthetic Sulfur Bacteria. Purple photosynthetic sulfur bacteria growing in a salt marsh.

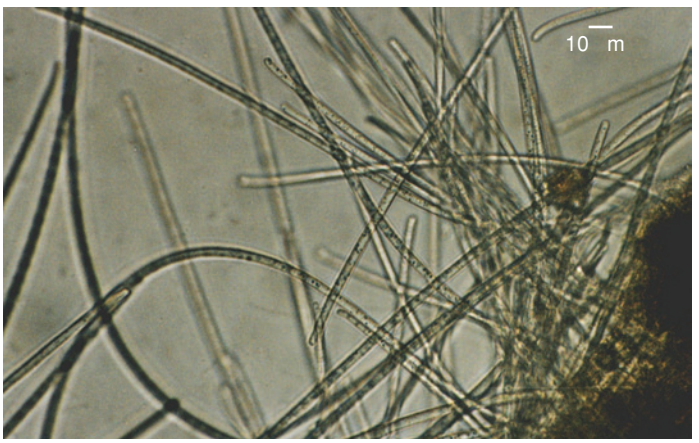

Figure 22.23 *Beggiatoa alba*. A light micrograph showing part of a colony (×400). Note the dark sulfur granules within many of the filaments.

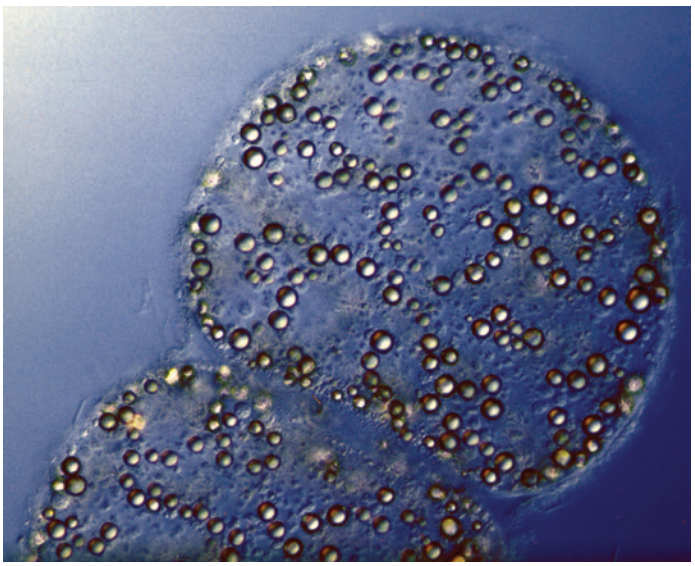

Figure 22.24 ***Thiomargarita namibiensis,* the World's Largest Known Bacterium.** This bacterium, usually 100–300 μm in diameter, occasionally reaches a size of 750 μm (larger than a period on this page), 100 times the size of a common bacterium. *T. namibiensis* uses sulfide from bottom sediments as an energy source and nitrate, which is found in the overlying waters, as an electron acceptor. Vacuoles that store high concentrations of nitrate appear beadlike in this image.

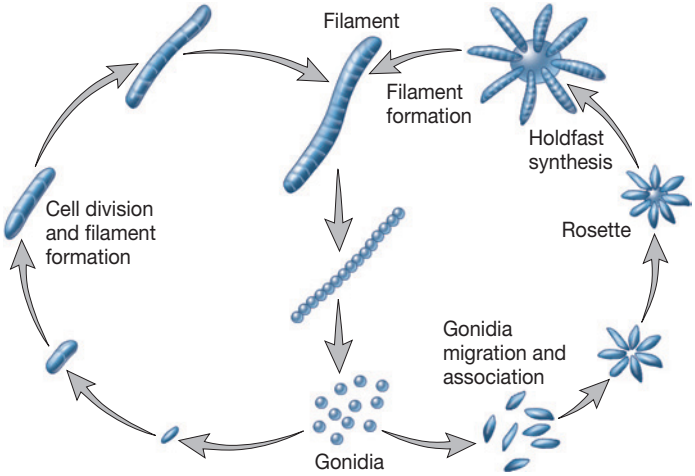

Figure 22.25 **Life Cycle and Morphology of *Leucothrix mucor.***

Leucothrix spp. are aerobic chemoorganotrophs that form filaments or trichomes up to 400 μm long. Most are marine, and attach to solid substrates by a holdfast, a microscopic root-like structure. These filamentous bacteria have a complex life cycle in which they are dispersed by the formation of small spherical cells called gonidia (**figure 22.25**). *Thiothrix* is a related genus whose members form sheathed filaments and release gonidia from the open end of the sheath. In contrast to *Leucothrix, Thiothrix* includes species that are facultatively autotrophic, chemoorganotrophic or mixotrophic, oxidizing hydrogen sulfide and depositing sulfur granules internally. *Thiothrix* spp. grow in sulfide-rich flowing water and activated sludge sewage systems.

The genus *Thiomicrospira,* family *Piscirickettsiaceae,* has an interesting history. Originally it included all marine, spiral-shaped, sulfur-oxidizing bacteria. Later 16S rRNA analysis showed that this group was not monophyletic, and members were split between γ- and ε-proteobacterial classes. For instance *Thiomicrospira denitrificans* is now known as *Sulfurimonas denitrificans* and is a member of ε-proteobacteria.

Figure 22.26 shows a cell model based on the annotated genome of *Thiomicrospira crunogena* XCL-2. This deep-sea microbe was isolated from a hydrothermal vent (*see figure 32.4*). This unique environment is characterized by the mixture of hot, anoxic, highly reduced vent fluid that rapidly mixes with cold, oxic bottom water. Of importance to this autotroph is the difference in dissolved CO_2 concentrations that it encounters: vent fluid is rich in CO_2, whereas bottom water is not. This has led to the evolution of a high affinity transporter for both HCO_3^- and CO_2. Also of note is the multienzyme complex capable of oxidizing a number of reduced sulfur compounds to sulfate. This "Sox" complex (for *s*ulfur *ox*idation) is conserved in a number of sulfur-dependent chemolithoautotrophs such as the β-proteobacteria *Thiobacillus* spp. Although *T. crunogena* can use a variety of reduced sulfur compounds as electron donors, it can use only oxygen as an electron acceptor. Interestingly, genome sequencing reveals the presence of what appears to be a complete prophage within the chromosome.

Order *Methylococcales* Consists of C1-Metabolizing Bacteria

The single family *Methylococcaceae* in the order *Methylococcales* includes the genera *Methylomonas, Methylobacter,* and *Methylococcus,* all of which are obligate methylotrophs that oxidize methane and other C1 compounds as their only carbon and energy source. Like the α-proteobacterial methanotrophs, these microbes also form extensive intracellular membranes; unlike α-proteobacteria, they form cysts instead of exospores (figure 22.5). They also differ in the use of the ribulose monophosphate pathway for the incorporation of C1 compounds (**figure 22.27**). ⏮ *Methanogens and methanotrophs (section 20.4)*

Order *Legionellales* Includes Intracellular Pathogens

Two families make up the order *Legionellales*. The first is *Legionellaceae,* with its single genus, *Legionella*. The second family is *Coxiellaceae,* which has two genera, *Coxiella* and *Rickettsiella* (not to be confused with the α-proteobacterial genus *Rickettsia*). All these microbes are intracellular pathogens that display a dimorphic (i.e., two cell types) lifestyle that is reminiscent of the chlamydial life cycle. ⏮ *Phylum* Chlamydiae *(section 21.6)*

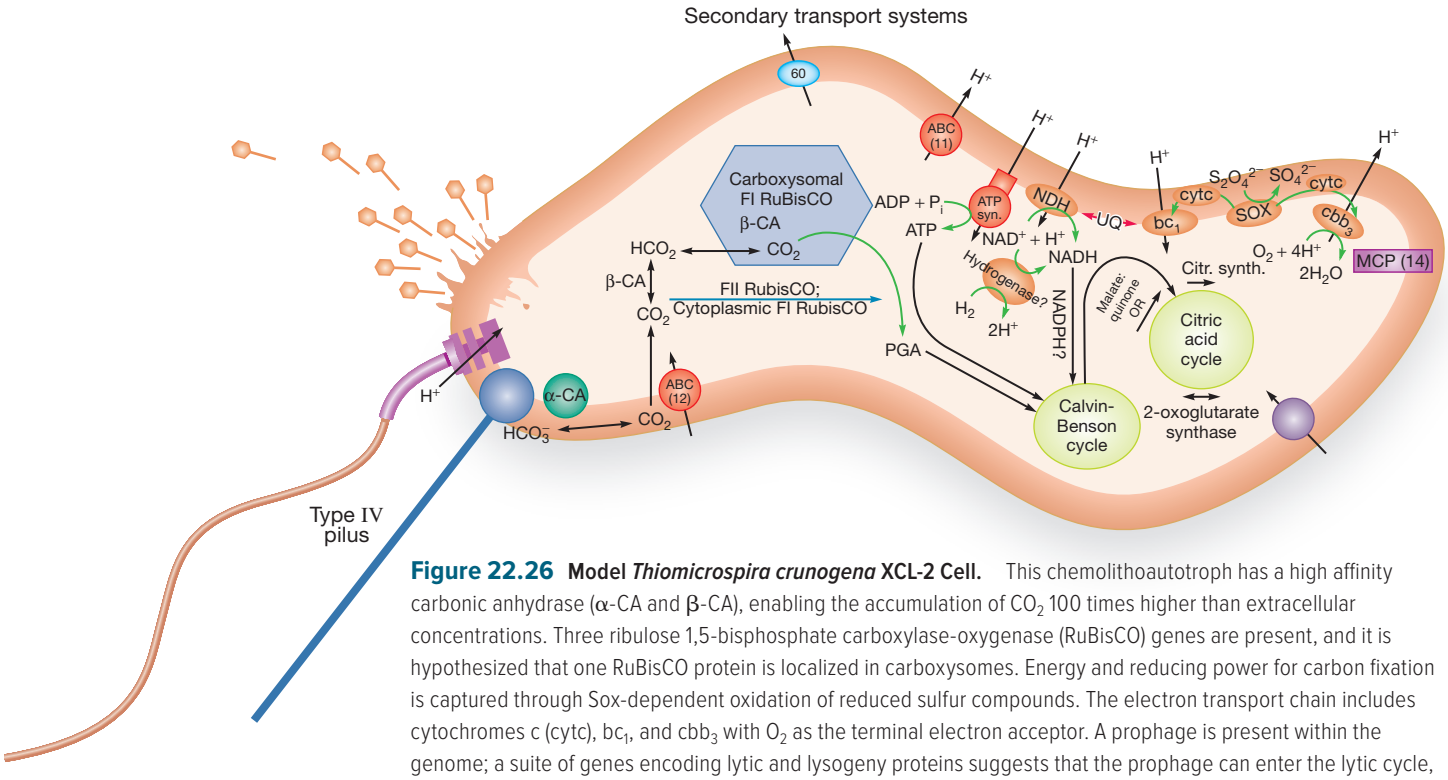

Figure 22.26 **Model *Thiomicrospira crunogena* XCL-2 Cell.** This chemolithoautotroph has a high affinity carbonic anhydrase (α-CA and β-CA), enabling the accumulation of CO_2 100 times higher than extracellular concentrations. Three ribulose 1,5-bisphosphate carboxylase-oxygenase (RuBisCO) genes are present, and it is hypothesized that one RuBisCO protein is localized in carboxysomes. Energy and reducing power for carbon fixation is captured through Sox-dependent oxidation of reduced sulfur compounds. The electron transport chain includes cytochromes c (cytc), bc_1, and cbb_3 with O_2 as the terminal electron acceptor. A prophage is present within the genome; a suite of genes encoding lytic and lysogeny proteins suggests that the prophage can enter the lytic cycle, as indicated by the release of phage on the left side of the image. Transporters include over 60 secondary transporters (light blue) for metal, inorganic, and organic compounds, as well as a dozen ATP-binding cassette (ABC) uptake proteins and 11 ABC exporters (red). Other membrane proteins include 14 methyl-accepting proteins (MCP, purple) that help mediate chemotaxis and 5 unclassified transporters (lavender).

Although there are over 40 species of *Legionella, L. pneumophila* has been most intensely studied because it causes a pneumonia in human hosts called Legionnaire's disease. In nature, *L. pneumophila* is an intracellular parasite of protozoa that live in moist soil and aquatic environments, including cooling towers, air conditioning units, and hot tubs. This explains why outbreaks of Legionnaire's disease occur in hotels, hospitals, and cruise ships—all of which have centralized cooling systems. In its protozoan hosts, as well as in some human cell cultures, *L. pneumophila* replicates by binary fission to produce slender, rod-shaped cells with a typical Gram-negative cell wall. The replicative forms (RFs) reside in a host vacuole called the replicative endosome. Late during infection, RFs differentiate into cystlike cells called *m*ature *i*ntracellular *f*orms (MIFs), which when released are nonreplicative; they exist only to infect the next host. MIFs are chubby rods that are metabolically dormant. They also have a distinct cell wall structure that includes a high concentration of the protein Hsp60. This is important because this protein acts as an invasin, that is, a protein required for host cell invasion. In addition, MIFs are heat tolerant and resistant to a variety of antibiotics. These features may help explain why *L. pneumophila* becomes more infective to human cells after it has grown within a protist. ▶▶| *Legionnaire's disease (section 39.1)*

Coxiella spp. also display two cell types within the host, although they have a much more impressive range of hosts, including insects, fish, birds, rodents, sheep, goats, and humans. As with *L. pneumophila,* humans become infected by inhaling contaminated aerosols, although in the case of the pathogen *C. burnetti,* the resulting Q fever is a flulike illness. The developmental life cycle of *C. burnetti* is similar to that of *L. pneumophila*. A small, infectious form called the *s*mall *c*ell *v*ariant (SCV, similar to MIFs and chlamydial elementary bodies) enters the host cell by phagocytosis. Once the phagosome has fused with a lysosome, the low pH triggers the SCV to become metabolically active. The resulting vacuole is called the parasitophorous (parasite-eating) vacuole. While they are in this vacuole, *C. burnetti* SCVs differentiate into the replicative form known as the *l*arge *c*ell *v*ariant (LCV). Both LCVs and SCVs undergo binary fission and infect host cells, so one might wonder why the microbe evolved the capacity to form SCVs. It is thought that SCVs, like MIFs, are responsible for long-term survival outside the host. This makes these pathogens distinct from chlamydiae and rickettsiae, which cannot survive outside

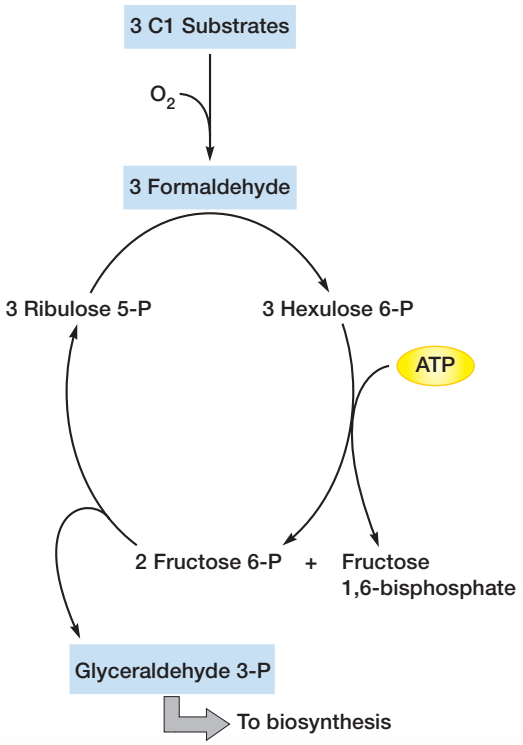

Figure 22.27 The Ribulose Monophosphate Pathway Is Used by γ-Proteobacterial Methylotrophs to Assimilate C1 Compounds.
The net yield of this pathway is a glyceraldehyde 3-P molecule that can be used in central metabolism.

MICRO INQUIRY *How does the ribulose monophosphate pathway compare to the serine pathway (figure 22.14) in terms of energy and reducing power used? What might be the ecological consequence of this difference?*

the host. In addition, it has been suggested that the compact and protected genome of SCVs makes these forms better suited for the initial respiratory burst and release of degradative enzymes when phagosomes and lysosomes initially fuse. ⏮ *Phylum* Chlamydiae *(section 21.6)* ⏭ *Phagocytosis (section 33.5); Q fever (section 39.5)*

Order *Pseudomonadales* Includes Important and Metabolically Diverse Bacteria

Pseudomonas is the most important genus in the order *Pseudomonadales,* family *Pseudomonaceae*. These bacteria are straight or slightly curved rods, and are motile by one or several polar flagella. They are chemoorganotrophs that usually carry out aerobic respiration, although some use nitrate as the terminal electron acceptor in anaerobic respiration. Most hexoses are degraded by the Entner-Doudoroff pathway; all pseudomonads have a functional tricarboxylic acid cycle. ⏮ *Glucose to pyruvate (section 11.4); Pyruvate to carbon dioxide (step 2) is accomplished by the tricarboxylic acid cycle (section 11.5)*

The genus *Pseudomonas* is an exceptionally heterogeneous taxon. Many of the 60 or so species can be placed in one of seven rRNA homology groups. The three best-characterized groups are subdivided according to properties such as the presence of poly-β-hydroxybutyrate (PHB), the production of a fluorescent pigment, pathogenicity, the presence of arginine dihydrolase, and glucose utilization. For example, the fluorescent subgroup does not accumulate PHB and produces a diffusible, water-soluble, yellow-green pigment that fluoresces under UV radiation. *P. aeruginosa, P. fluorescens, P. putida,* and *P. syringae* are members of this group.

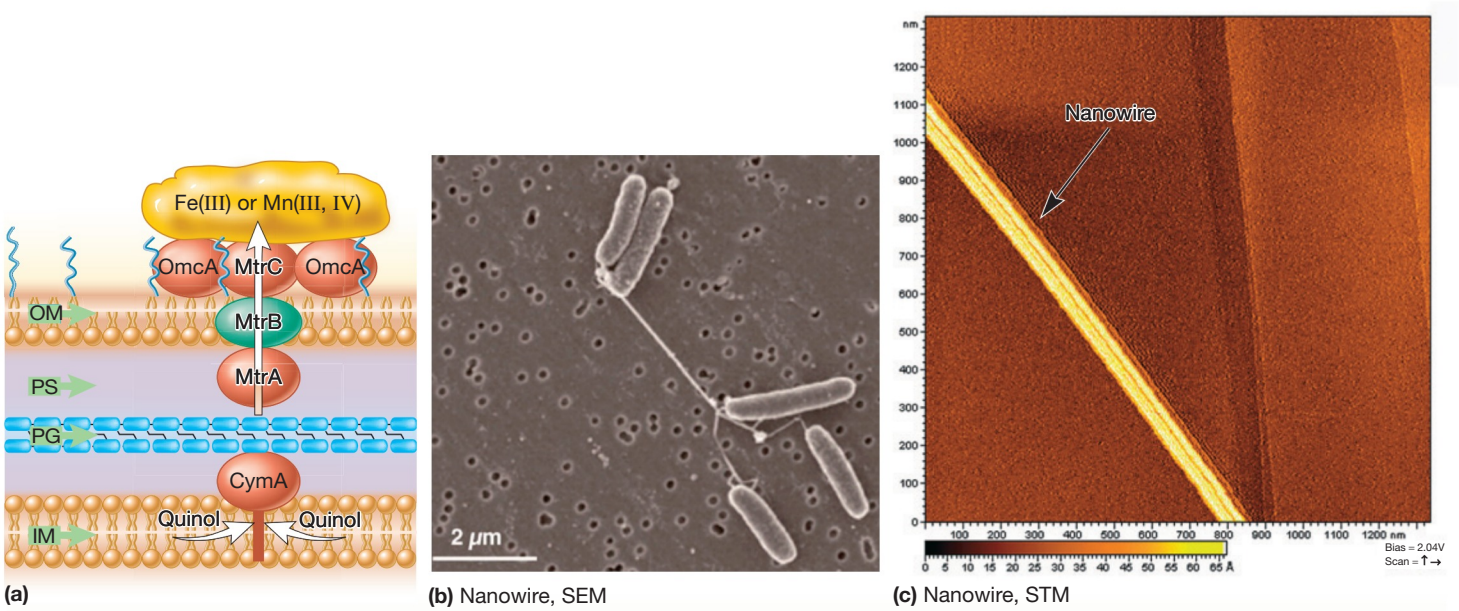
Pseudomonads have a number of practical impacts, including:

1. Many can degrade an exceptionally wide variety of organic molecules. Thus they are very important in the microbial breakdown of organic materials to inorganic substances (mineralization) in nature and in sewage treatment. The fluorescent pseudomonads can use approximately 80 different substances as their carbon and energy sources.
2. Several species (e.g., *P. aeruginosa*) are important experimental subjects. Many advances in microbial physiology and biochemistry have come from their study. For example, the study of *P. aeruginosa* has significantly advanced our understanding of how bacteria form biofilms and the role of extracellular signaling in bacterial communities and pathogenesis. The genome of *P. aeruginosa* has an unusually large number of genes for catabolism, nutrient transport, the efflux of organic molecules, and metabolic regulation, reflecting its ability to grow in many environments and resist antibiotics. ⏮ *Biofilms are common in nature (section 7.5); Cell-cell communication within microbial populations (section 7.5)*
3. Some pseudomonads are major animal and plant pathogens. *P. aeruginosa* is an opportunistic pathogen that infects cystic fibrosis patients. It also invades tissues that have been burned and causes urinary tract infections. *P. syringae* is an important plant pathogen.
4. Pseudomonads such as *P. fluorescens* are involved in the spoilage of refrigerated milk, meat, eggs, and seafood because they grow at 4°C and degrade lipids and proteins.

The genus *Azotobacter* also is in the family *Pseudomonaceae*. These bacteria are ovoid, and may be motile by peritrichous flagella. Cells are often pleomorphic, ranging from rods to coccoid shapes, and form cysts as the culture ages. They are aerobic and fix nitrogen nonsymbiotically. *Azotobacter* spp. are widespread in soil and water. ⏭ *Nitrogen-fixing bacteria are vital to agriculture (section 31.3)*

Order *Alteromonadales* Includes Anaerobes That Use a Range of Electron Acceptors

Many members of order *Alteromonadales,* including members of the genera *Marinomonas, Pseudoalteromonas,* and *Alteromonas,* are found in marine environments. *Shewanella* spp. have also been isolated from seawater, as well as lake sediments and



(a) **(b)** Nanowire, SEM **(c)** Nanowire, STM

Figure 22.28 External Terminal Electron Acceptors. (a) *Shewanella oneidensis* MR1 transfers electrons from the plasma membrane, through the outer membrane, to an insoluble metal. CymA is a quinol dehydrogenase that oxidizes quinol and passes the electrons to the c-type cytochrome MtrA. MtrB is not a cytochrome but helps move the electrons through the outer membrane to the surface-exposed c-type cytochromes, MtrC and OmcA. These redox proteins donate electrons to the oxidized, insoluble metals iron and manganese, which thereby serve as external, terminal electron acceptors. (b) When electron acceptors are in short supply, *S. oneidensis* MR1 makes nanowires along which electrons can travel to a terminal electron acceptor. This scanning electron micrograph shows the production of nanowires that occurs when cells are oxygen limited. (c) A scanning tunneling micrograph of a *S. oneidensis* MR1 nanowire with a diameter of 100 nm. Note the ridges and troughs that run along the axis of the nanowire. MICRO INQUIRY *Could a Gram-positive microbe use an insoluble metal as a terminal electron acceptor in the same way* S. oneidensis *does in (a)?*

salted foods. Bacteria in the genus *Shewanella* have generated much recent interest and are the focus of our discussion. This genus includes 48 facultatively anaerobic species that form straight or curved rods. It was first noted that *S. oneidensis* could use over 10 different electron acceptors and reduce thiosulfate and elemental sulfur to sulfide, a property usually seen only in strict anaerobes. Later it was discovered that all known *Shewanella* spp. show similar metabolic flexibility and can use a variety of metal electron acceptors, including uranium, chromium, iodate, technetium, neptunium, plutonium, selnite, tellurite, and vanadate, as well as nitroaromatic compounds. This wide range of metal electron acceptors makes *Shewanella* spp. excellent candidates as agents for bioremediation of environments contaminated with radionuclides. In addition, these bacteria can use a number of carbon substrates, and some can use H_2 as an energy and electron source. ▶▶| *Biodegradation and bioremediation (section 43.4)*

The use of metals as terminal electron acceptors is considered dissimilatory metal reduction because the metals are not incorporated into biomass. Dissimilatory metal reduction presents a problem for the microbe because many metals, such as iron and manganese, are insoluble in their oxidized forms, which is the form needed by the microbe for use as an electron acceptor. Dissimilatory metal-reducing bacteria have evolved several strategies that enable the use of solid metals such as Fe(III) or Mn(IV) as electron acceptors. The most direct approach is to localize cytochromes in the outer membrane, rather than the plasma membrane (**figure 22.28*a***). This enables the direct transfer of electrons from cytochromes to the extracellular metal. This approach is used by *Shewanella,* as well as by a number of Gram-negative dissimilatory metal-reducing bacteria such as the δ-proteobacterium *Geobacter sulfurreducens* (p. 531). Another strategy used by members of the genera *Shewanella* and *Pseudomonas* is to transfer electrons to the metal via external, intermediary compounds such as humic acids found in the environment or their own secreted metabolites. These compounds are collectively known as **electron shuttles** because they pass (shuttle) electrons from the last point on the electron transport chain (ETC) through the growth substrate to the mineral surface. Species of *Shewanella, Geobacter,* and some cyanobacteria have evolved a third strategy: the production of electrically conductive **nanowires.** These appendages measure about 100 nm in diameter and tens of μm in length. In *Shewanella* spp., nanowires are known to be thread-like extensions of plasma membrane. They transfer electrons from the terminal point in the ETC to a metal surface (figure 20.28*b,c*). Nanowires enable the transport of electrons to solid-phase acceptors

Table 22.6 Characteristics of Families of Facultatively Anaerobic Gram-Negative Rods

Characteristics	*Enterobacteriaceae*	*Vibrionaceae*	*Pasteurellaceae*
Cell dimensions	0.3–1.0 × 1.0–6.0 μm	0.3–1.3 × 1.0–3.5 μm	0.2–0.4 × 0.4–2.0 μm
Morphology	Straight rods; peritrichous flagella or nonmotile	Straight or curved rods; polar flagella; lateral flagella may be produced on solid media	Coccoid to rod-shaped cells, sometimes pleomorphic; nonmotile
Physiology	Oxidase negative	Oxidase positive; all can use D-glucose as sole or principal carbon source	Oxidase positive; heme and/or NAD^+ often required for growth; organic nitrogen source required
Symbiotic relationships	Some are parasitic on mammals and birds; some species are plant pathogens	Most are not pathogens; several inhabit light organs of marine organisms	Parasites of mammals and birds
Representative genera	*Escherichia, Shigella, Salmonella, Citrobacter, Klebsiella, Enterobacter, Erwinia, Serratia, Proteus, Yersinia*	*Vibrio, Photobacterium*	*Pasteurella, Haemophilus*

that are physically distant from the microbe. Interestingly, when near a redox active metal, *Shewanella* cells display electrokinesis—behavior that is analogous to chemotaxis. ◀◀ *Chemotaxis (section 3.8)* ▶▶ *Microbial fuel cells (section 43.3)*

Order *Vibrionales* Includes Aquatic Bioluminescent Bacteria and Pathogens

Three closely related orders of *Gammaproteobacteria* contain a number of important bacterial genera. Each order has only one family of facultatively anaerobic Gram-negative rods. **Table 22.6** summarizes the distinguishing properties of the families *Enterobacteriaceae, Vibrionaceae,* and *Pasteurellaceae*.

The order *Vibrionales* contains the family *Vibrionaceae*. Members of this family are straight or curved, flagellated rods. All use D-glucose as their sole or primary carbon and energy source (table 22.6). The majority are aquatic microorganisms, widespread in freshwater and the sea. The family has eight genera: *Vibrio, Photobacterium, Salinivibrio, Listonella, Allomonas, Enterovibrio, Catencoccus,* and *Grimontia*.

Several vibrios are important pathogens. *Vibrio cholerae* causes cholera, and *V. parahaemolyticus* can cause gastroenteritis in humans following consumption of contaminated seafood. *V. anguillarum* and others are responsible for fish diseases, which can be especially problematic in fish farms. ▶▶ *Cholera (section 39.4)*

Some members of *Vibrionaceae* are unusual in being bioluminescent. *Vibrio fischeri, V. harveyi,* and at least two species of *Photobacterium* are marine bacteria capable of bioluminescence. They emit a blue-green light catalyzed by the enzyme luciferase (**Microbial Diversity & Ecology 22.2**). The light is usually blue-green in color (472 to 505 nm), but one strain of *V. fischeri* emits yellow light with a major peak at 545 nm. Although many of these bacteria are free living, *V. fischeri, V. harveyi, P. phosphoreum,* and *P. leiognathi* live symbiotically in the luminous organs of fish (**figure 22.29**) and squid (*see figure 7.21*).

MICROBIAL DIVERSITY & ECOLOGY

22.2 Bacterial Bioluminescence

Several species in the genera *Vibrio* and *Photobacterium* can emit light of a blue-green color. The enzyme luciferase catalyzes the reaction and uses reduced flavin mononucleotide, molecular oxygen, and a long-chain aldehyde as substrates.

$$FMNH_2 + O_2 + RCHO \xrightarrow{\text{luciferase}} FMN + H_2O + RCOOH + \text{light}$$

Evidence suggests that an enzyme-bound, excited flavin intermediate is the direct source of luminescence. Because the electrons used in light generation are probably diverted from the electron transport chain and ATP synthesis, the bacteria expend considerable energy on luminescence. It follows that luminescence is regulated and can be turned off or on under the proper conditions.

There is much speculation about the role of bacterial luminescence and its value to bacteria, particularly because it is such an energetically expensive process. Luminescent bacteria do not emit light when they grow as free-living organisms in sea-water; the light emitted by a single cell would not be visible. When free-living luminescent bacteria infect the light organ of young fish or squid, they reproduce and reach densities where light emission is visible. Bacterial luminescence was the first example of density-dependent gene regulation by the quorum-sensing molecule autoinducer.

It remains unclear what advantage bacterial luminescence confers on some animal hosts. However, the mechanism by which autoinducer regulates light production in these marine bacteria is an important model for understanding quorum sensing in many Gram-negative bacteria, including a number of pathogens. ⏮ *Cell-cell communication within microbial populations (section 7.5); Quorum sensing by* Vibrio *spp. (section 14.5)*

Order *Enterobacteriales* Includes Pathogens and Mutualists

The order *Enterobacteriales* has only one family, *Enterobacteriaceae,* which contains 44 genera. This family is the largest listed in table 22.6. It contains peritrichously flagellated or nonmotile, facultatively anaerobic, straight rods with simple nutritional requirements.

The metabolic properties (particularly during anaerobic growth) of members of *Enterobacteriaceae* are very useful in characterizing its constituent genera. These bacteria, often called **enterobacteria** or **enteric bacteria** (Greek *enterikos,* pertaining to the intestine), all degrade sugars by means of the Embden-Meyerhof pathway. Under microaerobic or anoxic conditions, the enzyme **pyruvate formate-lyase** (**PFL**) catalyzes the cleavage of pyruvate to formate and acetyl-CoA. Those enteric bacteria that produce large amounts of gas during sugar fermentation, such as *Escherichia* spp., also have the enzyme **formate dehydrogenase** (**FDH**), which splits formic acid to H_2 and CO_2 (**figure 22.30**). This enzyme complex is crucial to survival during fermentation, when one-third of the carbon derived from glucose is converted to formate. If this intermediate were allowed to accumulate within the cell, the internal pH would become far too acidic to support viability. In fact, *E. coli* has three different FDH enzymes. FDH-H (H for hydrogen production) is synthesized only during fermentative conditions. FDH-N is produced under anoxic conditions when nitrate serves as the terminal electron acceptor. FDH-O is produced under microaerobic conditions as well as when nitrate is the terminal electron acceptor.

The family can be divided into two groups based on their fermentation products. The majority (e.g., the genera *Escherichia, Proteus, Salmonella,* and *Shigella*) carry out mixed acid fermentation and produce mainly lactate, acetate, succinate, ethanol, formate, H_2, and CO_2. In contrast, *Enterobacter, Serratia, Erwinia,* and *Klebsiella* spp. are butanediol fermenters, producing butanediol, ethanol, and CO_2. ⏮ *Fermentation does not involve an electron transport chain (section 11.8)*

Because enteric bacteria are so similar in morphology, biochemical tests are normally used to identify them after a preliminary examination of their morphology, motility, and growth responses (**figure 22.31** provides a simple example). Some more commonly used tests are those for the type of fermentation, lactose and citrate utilization, indole production from tryptophan, urea hydrolysis, and hydrogen sulfide production. For example, lactose fermentation occurs in some genera (e.g., *Escherichia*, *Klebsiella,* and *Enterobacter*) but not in others (e.g., *Shigella, Salmonella,* and *Proteus*). **Table 22.7** summarizes a few of the biochemical properties useful in distinguishing between genera of enteric bacteria. The mixed acid fermenters are located on the left in this table and the butanediol fermenters on the right. The two types of fermentations are distinguished by the methyl red and Voges-Proskauer tests, respectively. The usefulness of biochemical tests in identifying enteric bacteria is shown by the popularity of commercial identification systems, such as the Enterotube II and API 20E systems, that incorporate these tests. ⏭ *Identification of microorganisms from specimens (section 36.3)*

Members of *Enterobacteriaceae* are so widespread and important that they are probably seen more often in laboratories

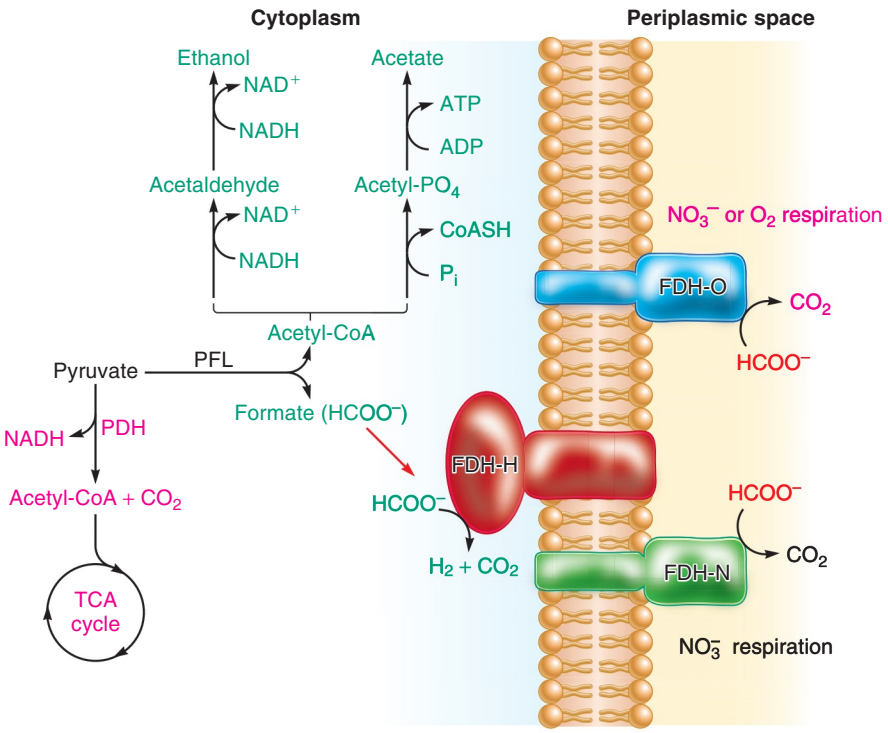

Figure 22.30 Metabolism of Pyruvate and Formate in *E. coli*. During aerobic growth, pyruvate is converted to CO_2 and acetyl-CoA by the pyruvate dehydrogenase complex (PDH) so that acetyl-CoA can enter the TCA cycle. Under low oxygen conditions, some pyruvate is also cleaved to formate and acetyl-CoA by pyruvate formate-lyase (PFL). Formate must then be converted into CO_2 and H_2 by one of three formate dehydrogenase (FDH) enzymes. FDH-O is active during aerobic respiration when oxygen levels are low. If respiration continues under anoxic conditions with nitrate as the terminal electron acceptor, both FDH-N and FDH-O split formate. These enzymes are located on the periplasmic face of the plasma membrane. During fermentative conditions, FDH-H is made, resulting in mixed acid fermentation: formate is cleaved to yield CO_2 and H_2, whereas acetyl-CoA is converted to ethanol and acetate. FDH-H is a peripheral membrane protein, with its active site exposed to the cytoplasm. Aerobic metabolism is shown in pink, fermentative metabolism in green.

MICRO INQUIRY *Why do you think FDH-O and FDH-N are on the periplasmic face of the plasma membrane while FDH-H is on the cytoplasmic face?*

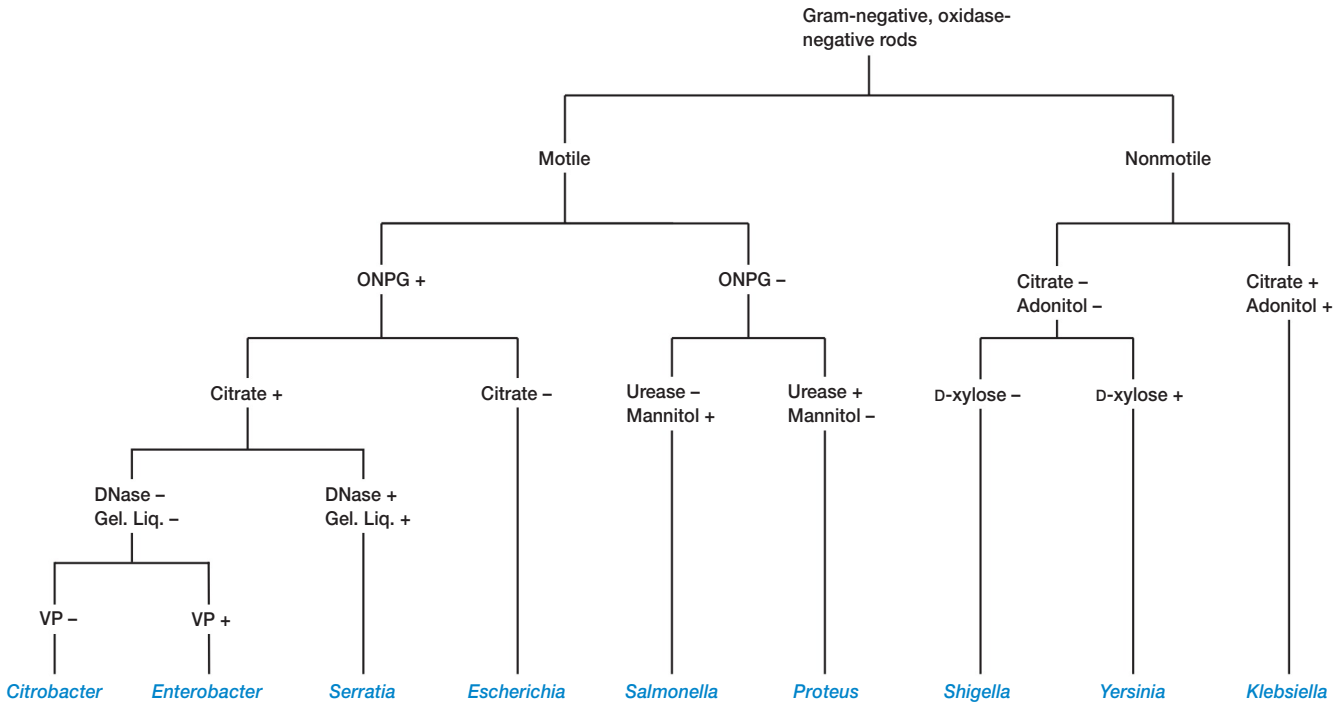

Figure 22.31 Identification of Enterobacterial Genera. A dichotomous key to selected genera of enteric bacteria based on motility and biochemical characteristics. The following abbreviations are used: ONPG, o-nitrophenyl-β-D-galactopyranoside (a test for β-galactosidase); DNase, deoxyribonuclease; Gel. Liq., gelatin liquefaction; and VP, Voges-Proskauer (a test for butanediol fermentation).

MICRO INQUIRY *What would be the identity of a motile microbe that synthesizes the enzyme β-galactosidase, assimilates citrate, produces DNase, and liquefies gelatin?*

than any other bacteria. *E. coli* is undoubtedly the best-studied bacterium and the experimental organism of choice for many microbiologists. It is an inhabitant of the colon of humans and other warm-blooded animals, and it is useful in the analysis of water for fecal contamination. Some strains cause gastroenteritis or urinary tract infections. Several other genera contain very important human pathogens responsible for a variety of diseases: *Salmonella,* typhoid fever and gastroenteritis; *Shigella,* bacillary dysentery; *Klebsiella,* pneumonia; and *Yersinia,* plague. Members of the genus *Erwinia* are major pathogens of crop plants and cause blights, wilts, and several other plant diseases.

Order *Pasteurellales* Includes Important Pathogens

Bacteria in the family *Pasteurellaceae* (order *Pasteurellales)* differs from those in *Vibrionales* and *Enterobacteriales* in several ways (table 22.6). Most notably, they are smaller, nonmotile, normally oxidase positive, have complex nutritional requirements, and are parasitic in vertebrates. The family contains seven genera: *Pasteurella, Haemophilus, Actinobacillus, Lonepinella, Mannheimia, Phocoenobacter,* and *Gallibacterium.*

Members of this family are best known for the diseases they cause in humans and many animals. *Pasteurella multocida* is responsible for fowl cholera, which kills many chickens, turkeys, ducks, and geese each year. *P. haemolytica* is at least partly responsible for pneumonia in cattle, sheep, and goats (e.g., "shipping fever" in cattle). *H. influenzae* serotype b is a major human pathogen that causes a variety of diseases, including meningitis, sinusitis, pneumonia, and bronchitis. Fortunately, a sharp reduction in the incidence of *H. influenzae* serotype b infections began in the mid-1980s due to administration of the *H. influenzae* type b ("Hib") vaccine. However, this bacterium still causes at least 3 million cases of serious disease and several hundreds of thousands of deaths each year globally.

22.4 Class *Deltaproteobacteria* Includes Chemoheterotrophic Anaerobes and Predators

After reading this section, you should be able to:

- Characterize the common physiological features of sulfate-reducing bacteria (SRB)
- Identify common carbon substrates used by SRB
- Draw an electron transport chain capable of dissimilatory sulfate reduction
- Relate the physiology of SRB to their common environmental niches
- Compare and contrast the physiology and ecology of *Shewanella* and *Geobacter* spp.
- Draw the life cycle of a bdellovibrio and explain why it is considered a bacterial predator
- Relate the life cycle of myxobacteria to their habitat and means of acquiring nutrients
- Describe the two types of gliding motility displayed by myxobacteria, and sketch their respective mechanistic models

Although **δ-proteobacteria** are not a large assemblage of genera, they show considerable morphological and physiological diversity. These bacteria can be divided into two general groups, all of them chemoorganoheterotrophs. Some are predators, such as bdellovibrios and myxobacteria. Others are anaerobes that use sulfate and sulfur as terminal electron acceptors while oxidizing organic nutrients. The class has eight orders and 20 families. **Figure 22.32** illustrates the phylogenetic relationships among major groups of δ-proteobacteria, and

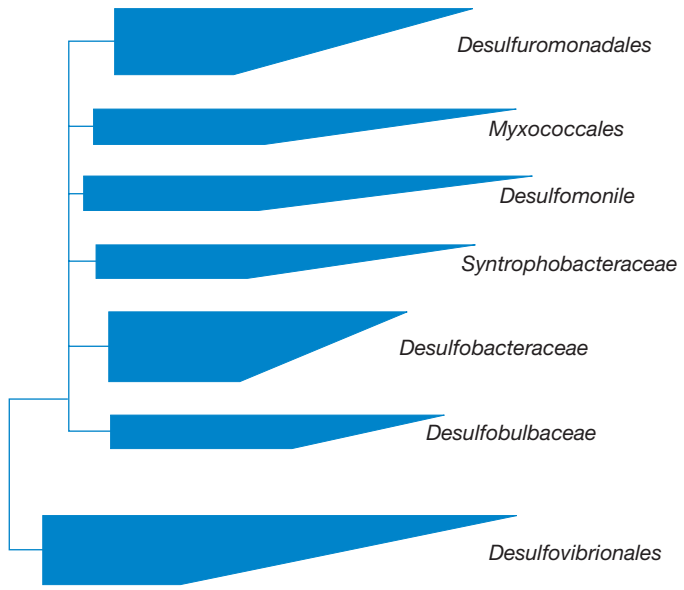

Figure 22.32 Phylogenetic Relationships Among Major Groups Within the δ-Proteobacteria. The relationships are based on 16S rRNA sequence.

Orders *Desulfovibrionales, Desulfobacterales,* and *Desulfuromonadales*: Anaerobic Sulfate/Sulfur Reducers

Desulfovibrionales, Desulfobacterales, and *Desulfuromonadales* are a diverse group of **sulfate-** or **sulfur-reducing bacteria** (**SRB**) that are united by their ability to reduce elemental sulfur or sulfate and other oxidized sulfur compounds to hydrogen sulfide during anaerobic respiration. Recall that anaerobic respiration is coupled with the oxidation of reduced organic compounds and in general the SRB can be grouped according to carbon metabolism. Many SRB oxidize lactate, formate, butyrate, propionate, pyruvate, and aromatic compounds to acetate, which is not further metabolized. Other SRBs oxidize acetate completely to CO_2. ◀◀ *Anaerobic respiration uses the same three steps as aerobic respiration (section 11.7)*

The use of sulfate as a terminal electron acceptor is a multistep process. Sulfate cannot be directly reduced. Because sulfate is a stable molecule, it must first be activated by reacting with ATP to form adenosine phosphosulfate, or APS (**figure 22.33**; figure 22.20b). The fate of APS during anaerobic respiration differs from that seen in sulfide-oxidizing chemolithoautotrophs (figure 22.20*a*). During sulfate reduction, APS accepts two electrons, which results in the production of sulfite (SO_3^{2-}) and adenosine monophosphate (AMP). Six additional electrons are needed to reduce sulfite completely to hydrogen sulfide. These are captured by a hydrogenase enzyme located on the periplasmic face of the plasma membrane. The hydrogenase donates the electrons from molecular hydrogen to cytochrome c_3, which in turn transfers

them to the integral membrane protein Hmc. Finally, an iron-sulfur protein delivers the electrons to sulfite reductase, and hydrogen sulfide is produced. Note that hydrogenase releases protons in the periplasm; the resulting proton motive force is sufficient to drive the synthesis of ATP.

SRB are very important in the cycling of sulfur within ecosystems. Because significant amounts of sulfate are present in almost all aquatic and terrestrial habitats, SRB are widespread and active in locations made anoxic by microbial digestion of organic materials. The SRB thrive in habitats such as muds and sediments of polluted lakes and streams, sewage lagoons and digesters, and waterlogged soils. *Desulfuromonas* spp. are most prevalent in anoxic marine and estuarine sediments. They also can be isolated from methane digesters and anoxic hydrogen sulfide–rich muds of freshwater habitats. Often sulfate and sulfur reduction are apparent from the smell of hydrogen sulfide (a "rotten egg" odor) and the blackening of water and sediment by iron sulfide. Hydrogen sulfide production in waterlogged soils can kill animals, plants, and microorganisms. SRB negatively impact industry because of their primary role in the anaerobic corrosion of iron in pipelines, heating systems, and other structures. ▶▶| *Sulfur cycle (section 28.1)*

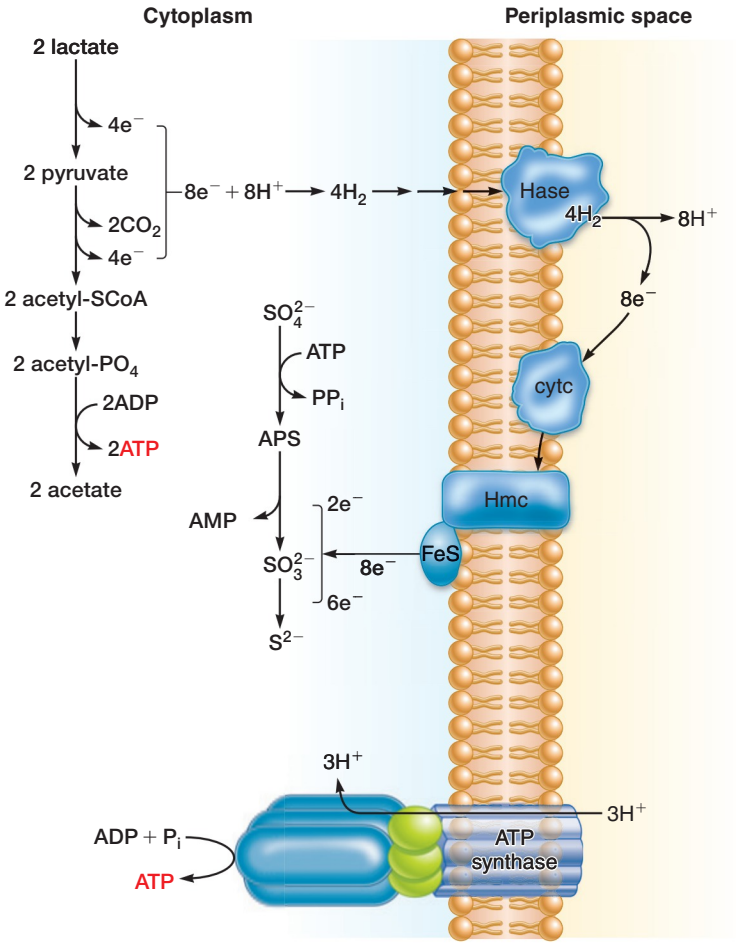
Order *Desulfuromonales* Includes Metabolically Flexible Anaerobes

The order *Desulfuromonales* encompasses three families, *Desulfuromonaceae, Geobacteraceae,* and *Pelobacteraceae*. All are strictly anaerobic with respiratory or fermentative metabolism. They can be chemolithoheterotrophs, obtaining electrons from reduced inorganic compounds, or chemoorganotrophs. They are mesophilic and have been isolated from anoxic marine and freshwater environments.

Geobacter metallireducens was the first microbe described to couple the oxidation of organic substrates such as acetate with the use of Fe(III) as a terminal electron acceptor. The capacity of *Geobacter* spp. to conserve energy from dissimilatory metal reduction is of great interest to environmental microbiologists.

Table 22.8 Characteristics of Selected δ- and ε-Proteobacteria

Class Genus	Dimensions (μm) and Morphology	Oxygen Requirement	Other Distinctive Characteristics
δ-Proteobacteria			
Bdellovibrio	0.2–0.5 × 0.5–1.4; comma-shaped rods with a sheathed polar flagellum; also capable of gliding motility	Aerobic	Prey on other Gram-negative bacteria and grow in the periplasm; alternate between predatory and intracellular reproductive phases
Desulfovibrio	0.5–1.5 × 2.5–10; curved or sometimes straight rods, motile by polar flagella	Anaerobic	Oxidize organic compounds to acetate and reduce sulfate or sulfur to H_2S
Desulfuromonas	0.4–0.9 × 1.0–4.0; straight or slightly curved or ovoid rods, lateral or subpolar flagella	Anaerobic	Reduce sulfur to H_2S, oxidize acetate to CO_2; form pink or peach-colored colonies
Myxococcus	0.4–0.7 × 2–8; slender rods with tapering ends, gliding motility	Aerobic	Form fruiting bodies with microcysts not enclosed in a sporangium
Stigmatella	0.7–0.8 × 4–8; straight rods with tapered ends, gliding motility	Aerobic	Stalked fruiting bodies with sporangioles containing myxospores (0.9–1.2 × 2–4 μm)
ε-Proteobacteria			
Campylobacter	0.2–0.8 × 0.5–5; spirally curved cells with a single polar flagellum at one or both ends	Microaerophilic	Carbohydrates not fermented or respired; oxidase positive and urease negative; found in intestinal tract, reproductive organs, and oral cavity of animals
Helicobacter	0.2–1.2 × 1.5–10; helical, curved, or straight cells with rounded ends; multiple, sheathed flagella	Microaerophilic	Catalase and oxidase positive; urea rapidly hydrolyzed; found in the gastric mucosa of humans and other animals

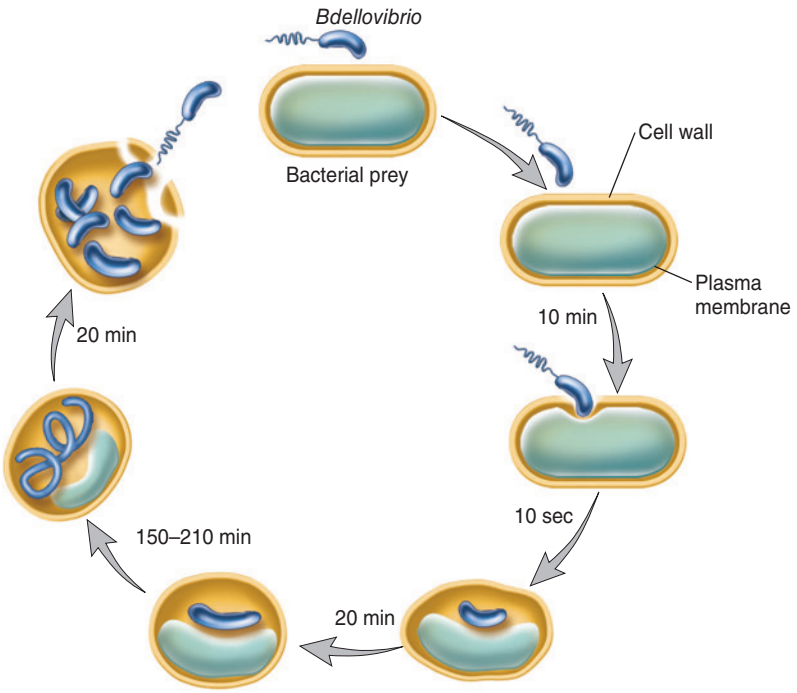


They have discovered that these bacteria, like γ-proteobacteria in the genus *Shewanella,* can reduce a number of toxic and radioactive metals. In addition, when *Geobacter* spp. oxidize organic substrates, they can transfer the electrons directly to an electrode. Like *Shewanella, Geobacter* spp. have an outer membrane reductase that transfers electrons they receive from the plasma membrane-bound ETC to an external, insoluble acceptor. They also synthesize nanowires (figure 22.28). However, they do not use external electron shuttles, as do *Shewanella* spp. There is great interest in using members of both genera in bioremediation and to generate electricity with microbial fuel cells. ▶▶| *Microbial fuel cells (section 43.3)*

Order *Bdellovibrionales* Includes Predators That Invade Other Gram-Negative Bacteria

The order *Bdellovibrionales* has only the family *Bdellovibrionaceae* and four genera. The genus *Bdellovibrio* (Greek *bdella,*

Figure 22.33 Dissimilatory Sulfate Reduction by *Desulfovibrio*. These microbes make ATP by substrate-level phosphorylation during acetate fermentation and by ATP synthase. Synthesis of ATP by ATP synthase is driven by a proton motive force generated by a periplasmic hydrogenase, which oxidizes H_2 to protons and electrons. The electrons are passed back into the cell, where they are used to reduce sulfate completely to sulfide. As detailed in the text, the oxidation of sulfate to sulfide requires eight electrons and the activation of sulfate by its covalent attachment to AMP to form APS.



(a)

(b)

Figure 22.34 The Life Cycle of *Bdellovibrio*. (a) A general diagram showing the complete life cycle. (b) *Bdellovibrio bacteriovorus* encapsulated in the periplasm of *E. coli*.

leech) contains aerobic, Gram-negative, curved rods with polar flagella. The flagellum is unusually thick due to the presence of a sheath that is continuous with the cell wall. Bdellovibrios have a distinctive lifestyle: they prey on other Gram-negative bacteria and alternate between a nongrowing predatory phase and an intracellular reproductive phase.

The life cycle of a bdellovibrio is complex, although it requires only 1 to 3 hours for completion (**figure 22.34**). The free bacterium swims along very rapidly (about 100 cell lengths per second) until it collides violently with its prey. It attaches to the prey bacterium's surface, begins to rotate as fast as 100 revolutions per second, and bores a hole through the host cell wall in a process involving type IV pili and the release of several hydrolytic enzymes. Its flagellum is lost during penetration of the cell. These bacteria can also scout for bacterial prey by gliding slowly over solid substrates. ⏮ *Bacterial pili and fimbriae (section 3.7)*

After entry, the bdellovibrio cell takes control of the host cell and grows in the periplasm while the host cell loses its shape and rounds up. The predator quickly inhibits host DNA, RNA, and protein synthesis, and disrupts the host's plasma membrane so that cytoplasmic constituents leak out of the cell. The growing bdellovibrio uses host amino acids as its carbon, nitrogen, and energy source. It employs host fatty acids and nucleotides directly in biosynthesis, thus saving carbon and energy. The bdellovibrio rapidly grows into a long filament and then divides into many smaller, flagellated progeny, which escape upon host cell lysis. Such multiple fission is rare in bacteria and archaea. *Bdellovibrio*

Order *Myxococcales*: Bacteria with Morphological Complexity and Multicellularity

Myxobacteria are Gram-negative, aerobic soil bacteria characterized by gliding motility and a complex life cycle that includes production of multicellular structures called fruiting bodies and the formation of spores called myxospores. Myxobacterial cells are rods, which may be either slender with tapered ends or stout with rounded, blunt ends. The order *Myxococcales* is divided into six families based on the shape of vegetative cells, myxospores, and sporangia.

Most myxobacteria are predators of other microbes but, unlike bdellovibrios, do not depend on predation for reproduction. Myxobacteria secrete lytic enzymes and antibiotics to kill their prey. The digestion products, primarily small peptides, are absorbed. Most myxobacteria use amino acids as their major source of carbon, nitrogen, and energy. All are aerobic chemoorganotrophs with respiratory metabolism.

The myxobacterial life cycle is quite distinctive and in many ways resembles that of cellular slime molds (**figure 22.35**). In the presence of a food supply, myxobacteria glide along a solid surface, feeding and leaving slime trails. During this stage, the cells often form a swarm and move in a coordinated fashion. Some species congregate to produce a sheet of cells that moves rhythmically to generate waves or ripples. When their nutrient supply is exhausted, the myxobacteria aggregate and differentiate into a fruiting body, a structure that is largely made up of individual cells that have differentiated into exospores called myxospores. The life cycle of the species *Myxococcus xanthus* serves as a model system for bacterial differentiation and behavior. Development in this microbe is induced by nutrient limitation and requires at least five different extracellular signaling molecules that allow the cells to communicate with one another. ⏮ *Bacteria move in response to environmental conditions (section 3.8)*

Fruiting bodies range in height from 50 to 500 μm and often are colored red, yellow, or brown by carotenoid pigments. Each species forms a characteristic fruiting body. They vary in complexity from simple globular objects made of about 100,000 cells (*Myxococcus*) to the elaborate, branching, treelike structures formed by members of the genera *Stigmatella* and *Chondromyces*. In some species, cells develop into dormant myxospores enclosed in walled structures called sporangioles or

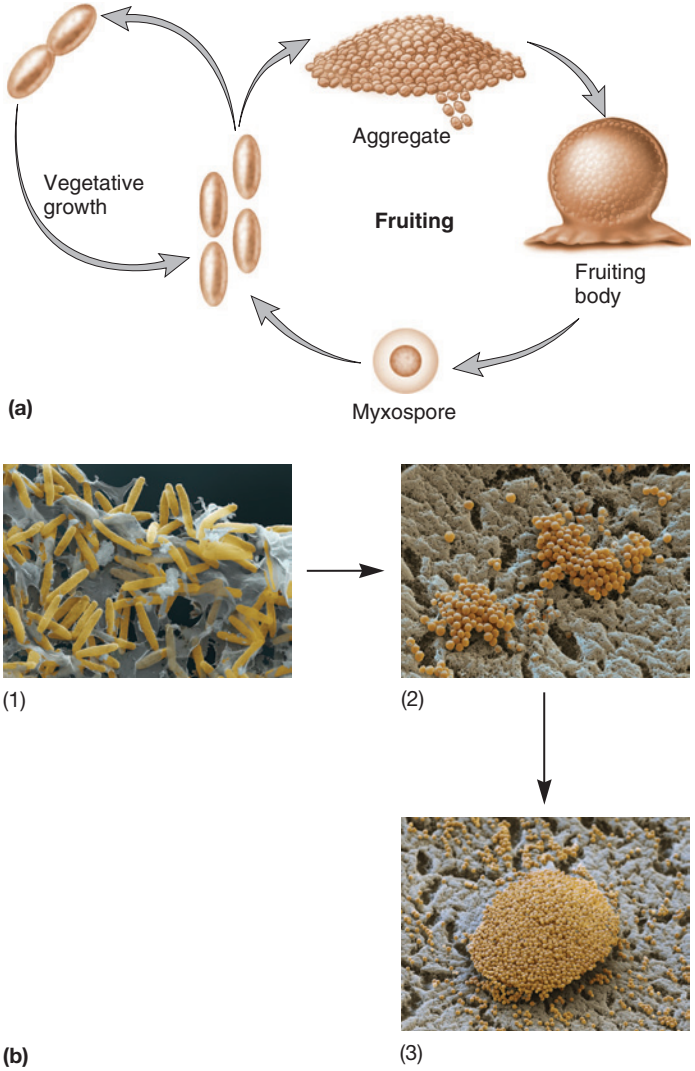


Figure 22.35 **Life Cycle of *Myxococcus xanthus*.** (a) When nutrients are plentiful, *M. xanthus* grows vegetatively. However, when nutrients are depleted, the exchange of extracellular signaling molecules triggers cells to aggregate and form fruiting bodies. Most of the cells within a fruiting body become resting myxospores that will not germinate until nutrients are available. (b) Scanning electron micrographs taken during (1) vegetative growth (2), aggregation, and (3) fruiting body formation.

sporangia. As might be expected for such complex structures, a variety of new proteins are synthesized during fruiting body formation, and *Myxococcus xanthus* has one of the largest bacterial genomes sequenced to date.

Myxospores are dormant and desiccation-resistant; they may survive up to 10 years under adverse conditions (compare this with thousands of years for Gram-positive endospores). The use of fruiting bodies provides further protection for the myxospores and assists in their dispersal. Because myxospores are kept together within the fruiting body, a colony of myxobacteria automatically develops when the myxospores are released and germinate. This communal organization may be advantageous because myxobacteria obtain nutrients by secreting hydrolytic enzymes and absorbing soluble digestive products. A mass of myxobacteria can produce enzyme concentrations sufficient to digest their prey more easily than can an individual cell.

Fruiting body development requires gliding motility. Gliding motility in *M. xanthus* is much slower (2–4 mm/min) than in flavobacteria (*see figure 21.21*). Two types of motility have been characterized in *M. xanthus*. Social (S) motility is a kind of twitching that is governed by the production of retractable type IV pili from the front end of the cell (**figure 22.36*a***). When the pili retract, the cell creeps forward. This type of motility was originally called social motility because it is only observed when cells are in a group. It is now known that cell-to-cell contact is required for S motility because cells share outer membrane lipoproteins involved in pili secretion. The second type of motility is called adventurous (A) motility because it is exhibited by single cells that leave the group, perhaps scouting for prey.

The mechanism mediating adventurous motility in *M. xanthus* remained a mystery for many decades. It is now known that A motility requires a multiprotein motility "machine" (figure 22.36*b*). The molecular motor is made up of Agl proteins, which have several functions. Agl proteins couple the translocation of protons with gliding motility, much like Mot proteins in the flagellar basal body in swimming bacteria (*see figure 3.45*). When gliding, the Agl proteins move in a continuous looped path lengthwise along the cell surface. The cytoskeletal protein MreB may be involved with the helical movement of the Agl proteins. The mechanical work of the Agl motor proteins is converted to movement by the Glt (*gl*iding *t*ransducer) proteins located in the cell wall. Because the Glt proteins contact one of the Agl proteins, they too are moved along the cell surface. Critically, Glt proteins use this movement to produce thrust when the entire multiprotein complex comes into contact with the substrate at specific areas in the cell envelope called focal adhesions. Although it is not known how Glt proteins contact the substrate, it is clear that this is facilitated by slime secreted by the bacterium.

It is intriguing that a single microbe has evolved two motility systems, and while S motility appears to be similar to twitching motility in *Pseudomonas aeruginosa,* neither system seems to be similar to the mechanism by which *Bacteroidetes,* cyanobacteria, or *Mycoplasma* species glide. This suggests that gliding motility has evolved independently multiple times. ⏮ *Bacterial cytoskeleton (section 3.6); Twitching and gliding motility (section 3.8); Class* Mollicutes, *Phylum* Tenericutes *(section 21.3); Phylum* Bacteroidetes *includes important gut microbiota (section 21.9)*

Myxobacteria are found in soils worldwide. They are most commonly isolated from neutral soils or decaying plant material such as leaves and tree bark, and from animal dung. Although they grow in habitats as diverse as tropical rain forests and the Arctic tundra, they are most abundant in warm areas.

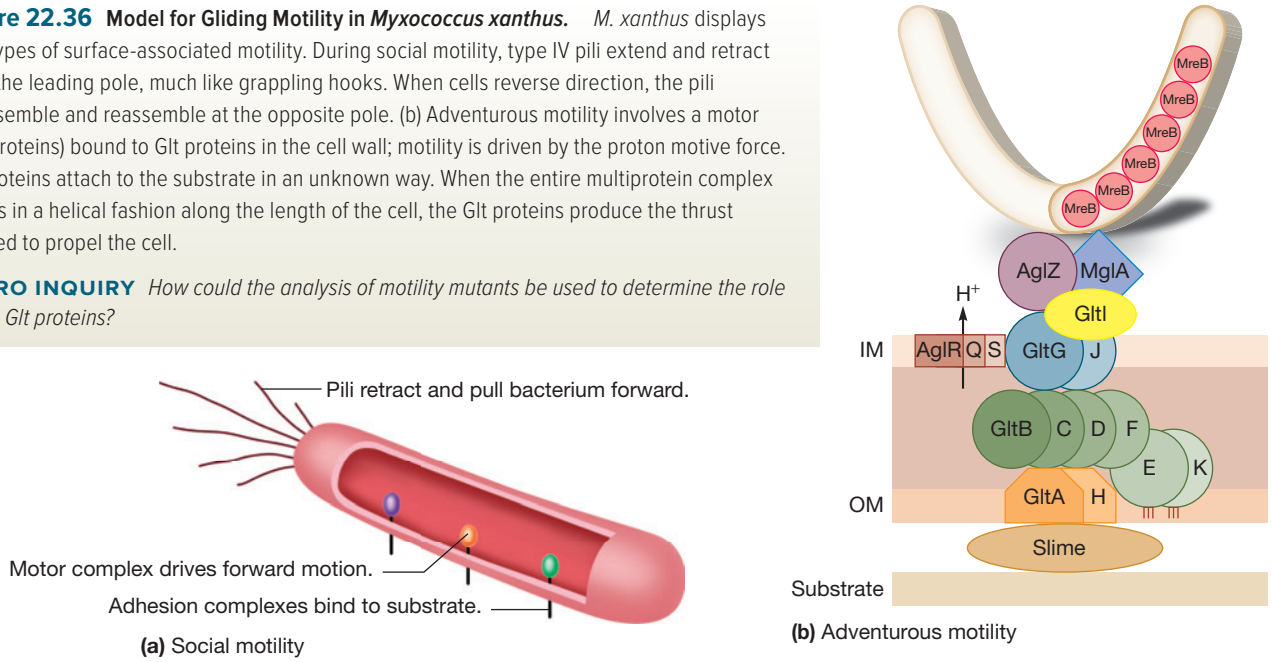

Figure 22.36 Model for Gliding Motility in *Myxococcus xanthus*. *M. xanthus* displays two types of surface-associated motility. During social motility, type IV pili extend and retract from the leading pole, much like grappling hooks. When cells reverse direction, the pili disassemble and reassemble at the opposite pole. (b) Adventurous motility involves a motor (Agl proteins) bound to Glt proteins in the cell wall; motility is driven by the proton motive force. Glt proteins attach to the substrate in an unknown way. When the entire multiprotein complex moves in a helical fashion along the length of the cell, the Glt proteins produce the thrust needed to propel the cell.

MICRO INQUIRY *How could the analysis of motility mutants be used to determine the role of the Glt proteins?*

22.5 Class *Epsilonproteobacteria* Ranges from Pathogens to Deep-Sea Bacteria

After reading this section, you should be able to:

- List two common human illnesses caused by ε-proteobacteria
- Describe the unusual metabolism of *Helicobacter* spp. and explain how *H. pylori* can tolerate the acidic conditions within the stomach
- Describe some of the unusual habitats that recently discovered ε-proteobacteria inhabit

ε-proteobacteria make up the smallest of the five proteobacterial classes. They all are slender, Gram-negative rods, which can be straight, curved, or helical. Although *Bergey's Manual* places ε-proteobacteria in one order, *Campylobacterales* (families *Campylobacteraceae, Helicobacteraceae,* and *Hydrogenimonaceae*), recent phylogenetic analysis that includes SSU rRNA sequences from newly cultured and uncultured organisms identifies an additional order called *Nautiliales*. Although ε-proteobacteria are physiologically and ecologically diverse, most inhabit extreme environments such as the acidic gastric mucosa, hydrothermal vents, and sulfidic caves. Two genera, *Campylobacter* and *Helicobacter,* contain members that are microaerophilic, motile, helical or vibrioid, Gram-negative rods. Table 22.8 summarizes some of the characteristics of these two genera.

The genus *Campylobacter* contains both nonpathogens and species pathogenic for humans and other animals. *C. foetus* causes reproductive disease and abortions in cattle and sheep. Other campylobacters are associated with conditions in humans ranging from septicemia (pathogens or their toxins in the blood) to enteritis (inflammation of the intestinal tract). Infection with some species frequently precedes the development of Guillain-Barré syndrome (GBS), the most common form of flaccid paralysis. It is thought that these bacteria trigger GBS by a phenomenon known as molecular mimicry. In this case, the structure of *Campylobacter* spp. lipopolysaccharide resembles components found on nerve cells. This causes the immune system to mistakenly attack the host's peripheral nervous system even after infection has cleared.

C. jejuni is a slender, Gram-negative, motile, curved rod found in the intestinal tract of animals. It causes an estimated 2 million human cases of *Campylobacter* gastroenteritis—inflammation of the stomach and intestine with subsequent diarrhea—in the United States each year. Studies with chickens, turkeys, and cattle have shown that as much as 50 to 100% of a flock or herd of these birds or other animals excrete *C. jejuni*. Campylobacteria are transmitted to humans by contaminated

food and water, contact with infected animals, or anal-oral sexual activity.

The other ε-proteobacterial genus that contains pathogens is *Helicobacter.* There are at least 23 species of *Helicobacter,* all isolated from the stomachs and upper intestines of humans, dogs, cats, and other mammals. In developing countries, 70 to 90% of the population is infected; the rate in developed countries ranges from 25 to 50%. The major human pathogen is *Helicobacter pylori,* which causes gastritis, peptic ulcer disease, and gastric cancer. *H. pylori* is an obligate microaerophile. The only carbohydrate the bacterium can use is glucose, which it metabolizes by both respiratory and fermentative pathways. It uses the pentose phosphate pathway, which provides NADPH for biosynthesis, and the Entner-Doudoroff pathway to produce pyruvate. The microbe does not have a complete TCA cycle and appears to run the cycle "forward" (i.e., oxidatively) from oxaloacetate to α-ketoglutarate and "backward" (i.e., in the reductive direction) from oxaloacetate to succinate. Fumarate may act as the terminal electron acceptor during anaerobic respiration. It can also carry out aerobic respiration. Pyruvate is fermented to lactate, acetate, and formate during fermentation. As a resident of the gastric mucosa, it would seem that *H. pylori* is exposed to very acidic conditions, yet in the laboratory, it cannot be cultured below pH 4.5. The presence of urease enzymes in the cytoplasm and the cell surface helps explain this paradox. *H. pylori* burrows within the gastric mucosa, which is not as acidic as the lumen. There it depends on urease activity to convert urea to CO_2 and NH_3. The ammonia drives the local pH up while the microbe uses chemotaxis to maintain its position within the mucous membranes. Indeed, motility is required for colonization of the host.

Figure 22.37 ε-Proteobacteria Dominate Filamentous Microbial Mats in a Wyoming Sulfidic Cave Spring.

ε-proteobacteria are also found in a variety of unusual ecosystems. For instance, filamentous microbial mats in anoxic, sulfide-rich cave springs are dominated by ε-proteobacteria (**figure 22.37**). Many have been cultured from marine hydrothermal vents; terrestrial forms have been isolated from groundwater, oil-field brines, limestone caves, and sulfidic springs. These include thermophilic, chemolithoautotrophic, chemoorganotrophic, and chemolithoheterotrophic species (**table 22.9**).

Chemolithoheterotrophic organisms use organic carbon for biosynthesis but inorganic compounds, such as sulfide and molecular hydrogen, as electron donors for energy conservation. The autotrophic species use the reductive TCA cycle for CO_2 fixation (*see figure 12.5*). Many ε-proteobacteria that

Table 22.9 Some Recently Isolated ε-Proteobacteria

Species	Isolation Site	Optimum Growth Temperature	Carbon Metabolism	Electron Donor	Electron Acceptor	Sulfur/Nitrogen Reduction Product

Key Concepts

22.1 Class *Alphaproteobacteria* Includes Many Oligotrophs

- The purple nonsulfur bacteria can grow anaerobically as photoorganoheterotrophs and aerobically as chemoorganoheterotrophs. When growing photosynthetically, purple bacteria localize the light-harvesting proteins and reaction centers on intracytoplasmic membranes (**figure 22.3**).
- Rickettsias are obligate intracellular parasites. They have numerous transport proteins in their plasma membranes and make extensive use of host cell nutrients, coenzymes, and ATP.
- Many proteobacteria have prosthecae or stalks or reproduce by budding. Two examples of budding or appendaged bacteria are *Hyphomicrobium* spp. (budding bacteria that produce swarmer cells) and *Caulobacter* spp. (bacteria with prosthecae and holdfasts) (**figures 22.7–22.10**).
- *Rhizobium* spp. carry out nitrogen fixation, whereas agrobacteria cause the development of plant tumors. Both are in the family *Rhizobiaceae* (**figures 22.11** and **22.12**).
- Proteobacteria that use 1-carbon compounds for carbon and energy are called methylotrophs; some of these microbes can use methane and are called methanotrophs. In bacteria, this is an aerobic process that produces the intermediate formaldehyde, which is either oxidized for energy or assimilated for anabolic purposes (**figures 22.13, 22.14,** and **22.28**).
- Nitrifying bacteria are chemolithotrophic aerobes that oxidize either ammonia to nitrite or nitrite to nitrate and are responsible for nitrification (**figure 22.15** and **table 22.2**).
- *Magnetococcus marinus* is the only cultured representative of a new order of magnetotacatic bacteria. These marine microbes are facultatively chemolithoautotrophic and microaerophilic.
- Members of the globally distributed marine SAR11 clade are the most abundant microorganisms on Earth. They are uniquely adapted to life in oligotrophic waters.

22.2 Class *Betaproteobacteria* Includes Chemoheterotrophs and Chemolithotrophs

- The genus *Neisseria* contains nonmotile, aerobic, Gram-negative cocci that usually occur in pairs. They colonize mucous membranes and cause several human diseases, including meningitis and gonorrhea.
- *Sphaerotilus, Leptothrix,* and several other genera contain species with sheaths, hollow tubelike structures that surround chains of cells without being in intimate contact with the cells.
- The order *Nitrosomonadales* includes two genera of nitrifying bacteria, including the ammonia-oxidizing microbe *Nitrosomonas europaea* (**table 22.2; figure 22.19**).
- Colorless sulfur bacteria such as *Thiobacillus* spp. oxidize elemental sulfur, hydrogen sulfide, and thiosulfate to sulfate while generating energy chemolithotrophically (**figure 22.20**).

22.3 Class *Gammaproteobacteria* Is the Largest Bacterial Class

- γ-proteobacteria are the largest subgroup of proteobacteria and have great variety in physiological types (**table 22.5**).
- Purple sulfur bacteria are anaerobes and usually photolithoautotrophs. They oxidize hydrogen sulfide to sulfur and deposit the granules internally (**figure 22.22**).
- Bacteria such as *Beggiatoa* and *Leucothrix* spp. grow in long filaments or trichomes. They have gliding motility. *Beggiatoa* spp. are primarily chemolithotrophs and *Leucothrix* spp. are chemoorganotrophs.
- Marine *Beggiatoa, Thioploca,* and *Thiomargarita* spp. are among the largest microbes. Members of the genus *Thiomargarita* form large intracellular vacuoles in which nitrate is stored (**figure 22.24**).
- The marine bacterium *Thiomicrospira crunogena* is a chemolithoautotroph that uses reduced sulfur compounds as a source of energy and electrons and O_2 as the terminal electron acceptor (**figure 22.26**).
- Members of the genus *Pseudomonas* are straight or slightly curved, Gram-negative, aerobic rods that are motile by one or several polar flagella and do not have prosthecae or sheaths.
- Pseudomonads participate in natural mineralization processes, are major experimental subjects, cause many diseases, and often spoil refrigerated food.
- The genus *Shewanella* is notable for species with metabolic flexibility and the ability to use extracellular, insoluble metals as terminal electron acceptors. They are among several microbes that have evolved strategies to accomplish this, including the use of electron shuttles and formation of nanowires (**figure 22.28**).

- The most important facultatively anaerobic, Gram-negative rods are found in three families: *Vibrionaceae, Enterobacteriaceae,* and *Pasteurellaceae* (**table 22.6**).
- *Enterobacteriaceae,* often called enterobacteria or enteric bacteria, are peritrichously flagellated or nonmotile, facultatively anaerobic, straight rods with simple nutritional requirements (**table 22.7**).
- Enteric bacteria are usually identified by a variety of physiological tests. *E. coli* performs a mixed acid fermentation, which depends on the enzymes pyruvate formate-lyase and formate dehydrogenase (**figure 22.30**).

22.4 Class *Deltaproteobacteria* Includes Chemoheterotrophic Anaerobes and Predators

- δ-proteobacteria are aerobic chemoorganotrophic bacteria that can use elemental sulfur and oxidized sulfur compounds as electron acceptors in anaerobic respiration. Other δ-proteobacteria are predatory aerobes (**table 22.8**).
- Sulfate-reducing bacteria are very important in sulfur cycling in ecosystems. *Desulfovibrio* spp. conserve energy by fermentation and a proton motive force (**figure 22.33**).
- *Bdellovibrio* spp. are aerobic curved rods with a sheathed polar flagellum that consume other Gram-negative bacteria and grow within the periplasmic space of their prey (**figure 22.34**).
- *Myxobacteria* spp. are Gram-negative, aerobic soil bacteria with gliding motility and a complex life cycle that leads to the production of dormant myxospores held within fruiting bodies (**figures 22.35** and **22.36**).

22.5 Class *Epsilonproteobacteria* Ranges from Pathogens to Deep-Sea Bacteria

- ε-proteobacteria are the smallest of the proteobacterial classes and include two important genera with pathogenic species: *Campylobacter* and *Helicobacter.* These bacteria are microaerophilic, motile, helical or vibrioid, Gram-negative rods (**table 22.8**).
- Recently the order *Nautiliaceae* has been added. Many of these bacteria are chemolithoautotrophs from deep-sea hydrothermal vent ecosystems (**table 22.9**).

Compare, Hypothesize, Invent

1. The advantages of metabolic flexibility in *Rhodospirillum rubrum* must offset the energetic burden of carrying all the structural and regulatory genes involved in these processes. What makes this trade-off possible?
2. Compare nitrification with denitrification: which is found in heterotrophs and which is found in autotrophs? Are they both dissimilatory processes?
3. Why might the ability to form dormant cysts be of great advantage to an agrobacterium but not as much to a rhizobium?
4. Examine figures 22.20 and 22.33. Note that in both cases APS is formed, but in the case of *T. ferrooxidans*, it is involved in sulfide oxidation, whereas for *Desulfovibrio*, it is used during sulfate reduction. What other similarities and differences are present? Why must APS be used in both cases?
5. How might electron shuttles facilitate growth of bacteria in a biofilm that has become anoxic in the interior?
6. Intercellular communication has been studied in detail in *Myxococcus xanthus.* Review the life cycle of this developmentally complex microbe and indicate at what points during this process intercellular signaling molecules might be exchanged and the message they would convey.
7. The γ-proteobacterium *Congregibacter litoralis* is one of several cultured aerobic anoxygenic phototrophs (AAnPs). AAnPs are also found among α- and β-proteobacteria. These microbes are photoheterotrophs that contain Bchl *a*. They cannot grow photoautotrophically or anaerobically; *C. litoralis* is a microaerophile. It possesses the genes needed for the oxidation of reduced sulfur compounds, but the addition of reduced, inorganic sulfur to the media does not enhance growth. Compare the distribution of the AAnPs among the proteobacterial classes with that of the purple sulfur and nonsulfur bacteria. How would you determine if the AAnPs and the purple bacteria evolved from a single photosynthetic ancestor or have acquired the capacity to grow phototrophically by horizontal gene transfer? Finally, if *C. litoralis* does not use reduced sulfur compounds as a source of electrons, what do you think is the electron donor?

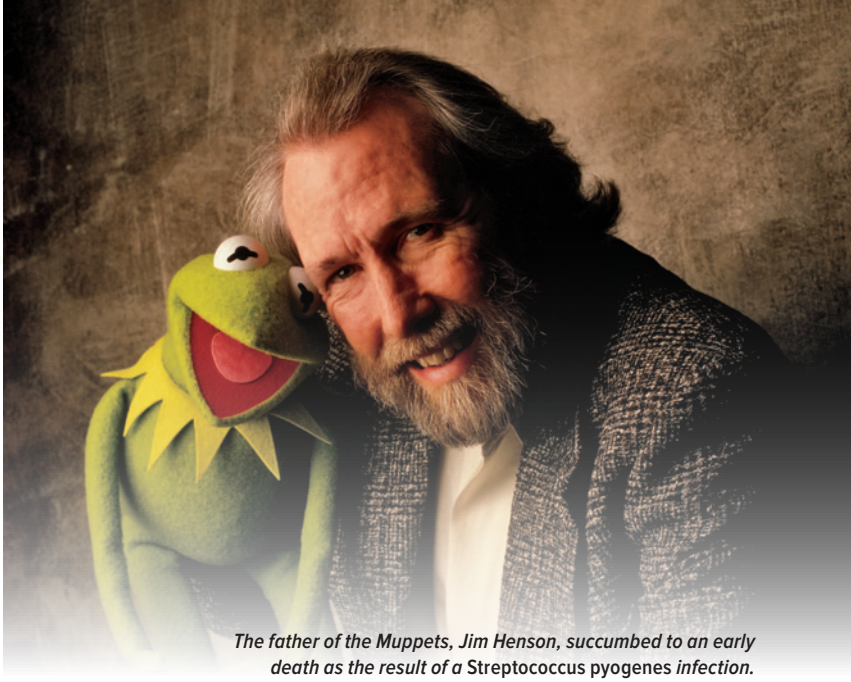
Firmicutes: The Low G + C Gram-Positive Bacteria



The father of the Muppets, Jim Henson, succumbed to an early death as the result of a Streptococcus pyogenes *infection.*

Invasive Strep Strikes Young, Old, and Famous

In 1990 the world mourned the untimely death of a genius. At the age of 53, Jim Henson, the creator of the Muppets, succumbed to pneumonia. Big Bird, Elmo, Bert, Ernie, children, and grown-ups were shocked to hear that a man in his prime could die from a disease thought to be fatal only among the very young and very old. How could this be?

You might be surprised to learn that the same bacterium that causes strep throat in schoolchildren caused Henson's death. In fact, up to 20% of kids carry *Streptococcus pyogenes* asymptomatically. How can a single bacterial species have no effect on children but kill an adult? The short answer is it depends on the strain, but the long answer is more interesting. *S. pyogenes* is a member of group A streptococci, called GAS for short. It was first described in 1874, when it was cultured from infected wounds. Later named *S. pyogenes* (pyogenic means pus producing), it has also been named *S. hemolyticus* (reflecting its ability to lyse red blood cells), *S. erysipelatos* (referring to reddened inflammation), and *S. scarlatinae*, as it is also the cause of scarlet fever. As this changeable but descriptive nomenclature suggests, *S. pyogenes* infection should not be ignored.

S. pyogenes is transmitted by direct contact with contaminated mucus or wounds. Strep throat is easily treated with antibiotics; but in cases where the microbe gains access to the blood, muscle, or lungs, this is not the case. Such "invasive strep" bacteria produce a suite of toxins and other virulence factors that make their treatment difficult. Some invasive streptococci have been dubbed "flesh-eating bacteria" because they cause necrotizing fasciitis, which results in the rapid destruction of muscle, skin, and fat. The pneumonia that killed Jim Henson was caused by an invasive strain that secretes a toxin that causes streptococcal toxic shock syndrome (STSS). This is not the same toxic shock syndrome associated with tampon use; that is caused by *Staphylococcus aureus*, a different firmicute. The *S. pyogenes* toxin is a superantigen (*see section 34.5*) that leads to a rapid plunge in blood pressure and organ failure. Once a lethal concentration of toxin has been released into the bloodstream, antibiotics cannot reverse the course of disease.

The firmicutes discussed in this chapter may sometimes seem like a hit parade of pathogens. However, we also rely on firmicutes for fermented dairy products, including yogurt and cheese. In fact, these so-called lactic acid bacteria are so similar to streptococci, they were once placed in a single genus. Both lactic acid bacteria and the present-day streptococci are fermenters. They lack oxidative phosphorylation, but despite their limited metabolic flexibility, they have remarkable, if sometimes very sad, capabilities.

Phylogenetic relationships among Gram-positive bacteria show that they can be divided into a low G + C group (**figure 23.1**) and a high G + C group, which is covered in chapter 24. The low G + C Gram-positive bacteria are placed in the phylum *Firmicutes* and divided into three classes: *Clostridia, Bacilli*, and the recently added *Negativicutes*. **Figure 23.2** shows the phylogenetic relationships among some of the bacteria reviewed in this chapter, but it does not illustrate the *Negativicutes*. This class includes many newly discovered species as well as some that were previously considered *Clostridia*.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Draw a Gram-positive cell wall and list its constituent parts (section 3.4)
- ✔ Differentiate between swimming and gliding motility (section 3.8)
- ✔ Outline the process of endospore formation and germination (section 3.9)
- ✔ Distinguish heterotrophy from autotrophy (section 11.1)
- ✔ List environmental factors that influence microbial growth (section 7.4)
- ✔ Compare and contrast the growth and physiology of obligate aerobes, facultative anaerobes, microaerophiles, and strict anaerobes (section 7.4)
- ✔ Explain how biofilms form and why they are important (section 7.5)
- ✔ Compare and contrast anaerobic and aerobic respiration, oxygenic and anoxygenic phototrophy, and substrate-level phosphorylation and oxidative phosphorylation (sections 11.4, 11.5, and 11.11)
- ✔ Draw an electron transport chain indicating the relative standard reduction potentials of the electron donor, acceptor, and electron transporters (sections 10.4 and 11.6)
- ✔ Summarize the generation of ATP and the fate of pyruvate in fermentation (section 11.8)

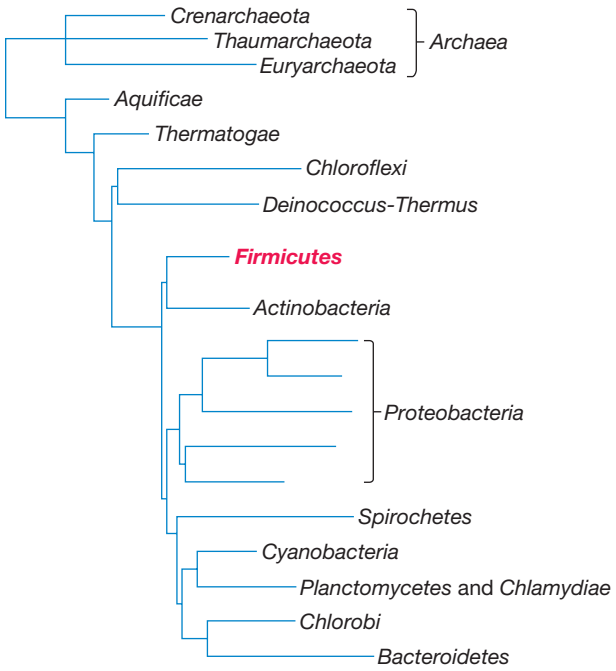


Figure 23.1 **Phylogenetic Relationships Among *Bacteria* and *Archaea*.** The phylum *Firmicutes* is highlighted.

23.1 Class *Clostridia:* Anaerobic Endospore-Forming Bacteria

After reading this section, you should be able to:

- Identify several *Clostridia* spp. that form endospores
- Outline the reaction by which some clostridia ferment amino acids, and relate this carbon substrate to their environmental distribution and pathogenic potential
- Identify the terminal electron acceptors used by *Desulfotomaculum* spp.
- Distinguish phototrophy in heliobacteria from that of other anoxygenic phototrophic bacteria
- Discuss the importance of *Veillonella* spp. to human disease

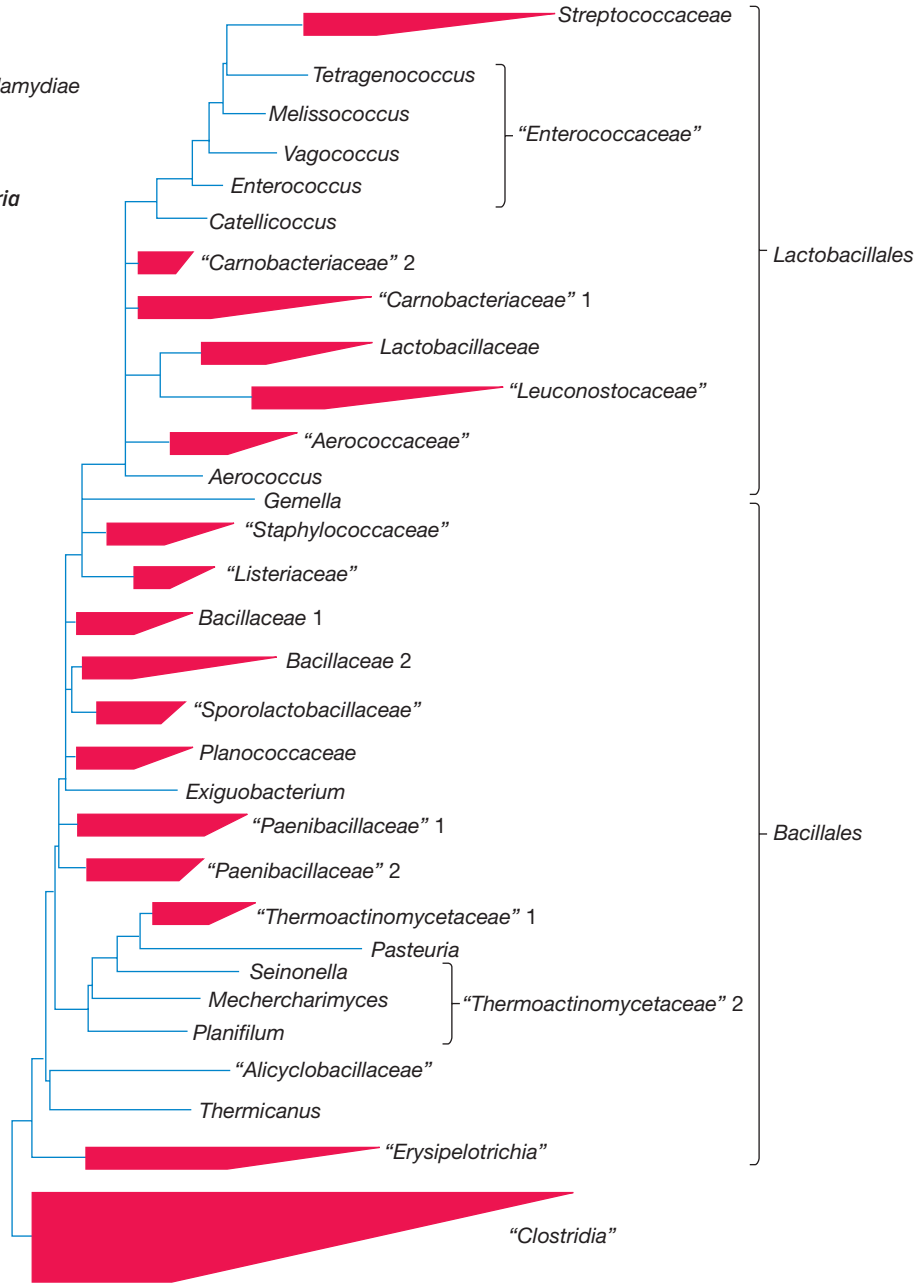

Figure 23.2 **Phylogenetic Relationships in the Phylum *Firmicutes* (Low G + C Gram Positives).** The major phylogenetic groups are shown. Each tetrahedron in the tree represents a group of related organisms; its horizontal edges show the shortest and longest branches in the group. Multiple branching at the same level indicates that the relative branching order of the groups cannot be determined from the data.

Table 23.1 Characteristics of Selected Members of the Class *Clostridia*

Genus	Dimensions (μm), Morphology, and Motility	Genome Size (Mb)	Oxygen Relationship	Other Distinctive Characteristics
Clostridium	0.3–2.0 × 1.5–20; rod-shaped, often pleomorphic, nonmotile or peritrichous flagella	Most species 3.0–4.0	Anaerobic	Usually chemoorganotrophic, fermentative, and catalase negative; form oval or spherical endospores
Desulfotomaculum	0.3–1.5 × 3–9; straight or curved rods, peritrichous or polar flagella	2.7–3.9	Anaerobic	Reduce sulfate to H_2S, form subterminal to terminal endospores; stain Gram negative but have Gram-positive wall; catalase negative
Heliobacterium	1.0 × 4–10; rods that are frequently bent, gliding motility	3.1	Anaerobic	Photoheterotrophic with bacteriochlorophyll *g;* stain Gram negative but have Gram-positive wall; some form endospores

There are two classes of low G + C bacteria that form endospores: *Clostridia* and *Bacilli*. Recall that endospores are made within the mother cell upon nutrient deprivation. Once released, these **spores** are remarkably resistant to environmental stresses, sometimes surviving thousands of years. ◀◀ *Bacterial endospores are a survival strategy (section 3.9)*

The class *Clostridia* contains a diverse group of bacteria. The characteristics of some of the more important genera are summarized in **table 23.1**. With over 100 species, *Clostridium* is the largest genus in the class. It includes obligately anaerobic, fermentative, Gram-positive bacteria that form endospores (**figure 23.3**). Members of this genus have great practical impact. Because they are anaerobic and form heat-resistant endospores, they are responsible for many cases of food spoilage, even in canned foods. Clostridia often can ferment amino acids via the **Stickland reaction** (**figure 23.4**). In this process, one amino acid is oxidized to produce pyruvate, which then is fermented to yield acetate and ATP. A different amino acid serves as an electron acceptor, so it is reduced, thereby reoxidizing NADH to NAD^+ and forming an additional two acetate molecules. This reaction also generates ammonia, hydrogen sulfide, and fatty acids during the anaerobic decomposition of proteins. These products are responsible for many unpleasant odors arising during putrefaction.

Although some clostridia are industrially valuable (e.g., *C. acetobutylicum* is used to manufacture butanol), the pathogenic

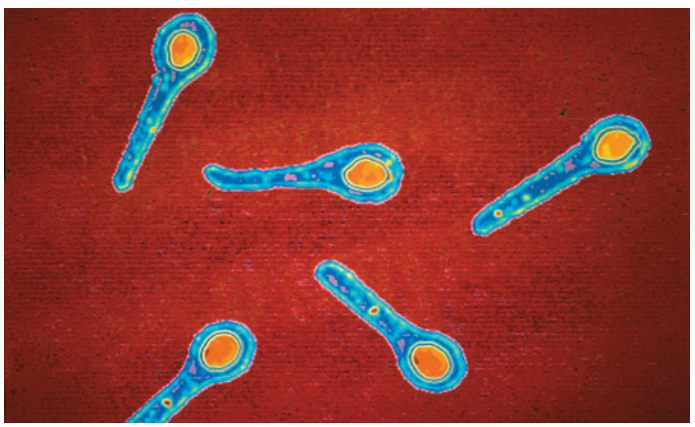

Figure 23.3 ***Clostridium tetani.*** This pathogen makes endospores that are round and terminal. When the mother cell surrounding each endospore lyses, the released spores remain viable for hundreds, if not thousands of years (×3,000)

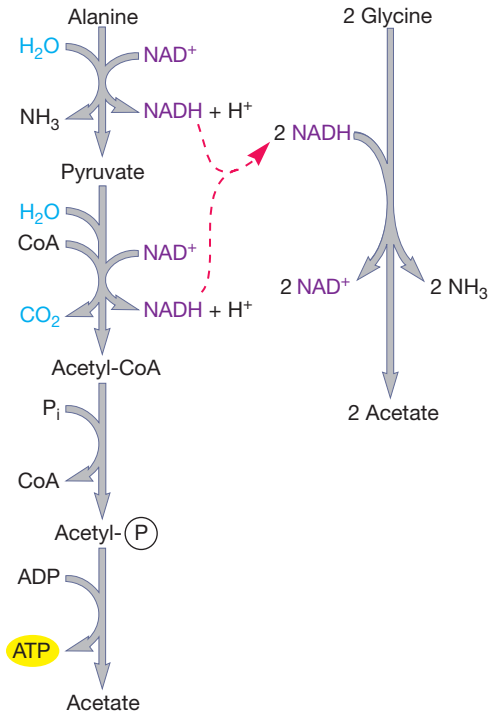

Figure 23.4 The Stickland Reaction. Alanine is oxidized to acetate, and glycine is used to reoxidize the NADH generated during alanine fermentation. The fermentation also produces some ATP.

species produce well-known toxins. For instance, *C. botulinum* produces the botulism toxin and *C. tetani* causes tetanus through the release of tetanus toxin. *C. perfringens* secretes a variety of protein toxins and, depending on the strain, causes gas gangrene and food poisoning. Although it lacks a TCA cycle and makes ATP only by fermentation, it has an extraordinary doubling time of only 8 to 10 minutes when in the human host. This is presumably due to the ready supply and assimilation of host macromolecules. ▶▶| *Botulism (section 39.4); Tetanus (section 39.3)*

C. tetani ferments a number of amino acids to lactate, butyrate, and H_2 (**figure 23.5**). It lacks the genes to catabolize

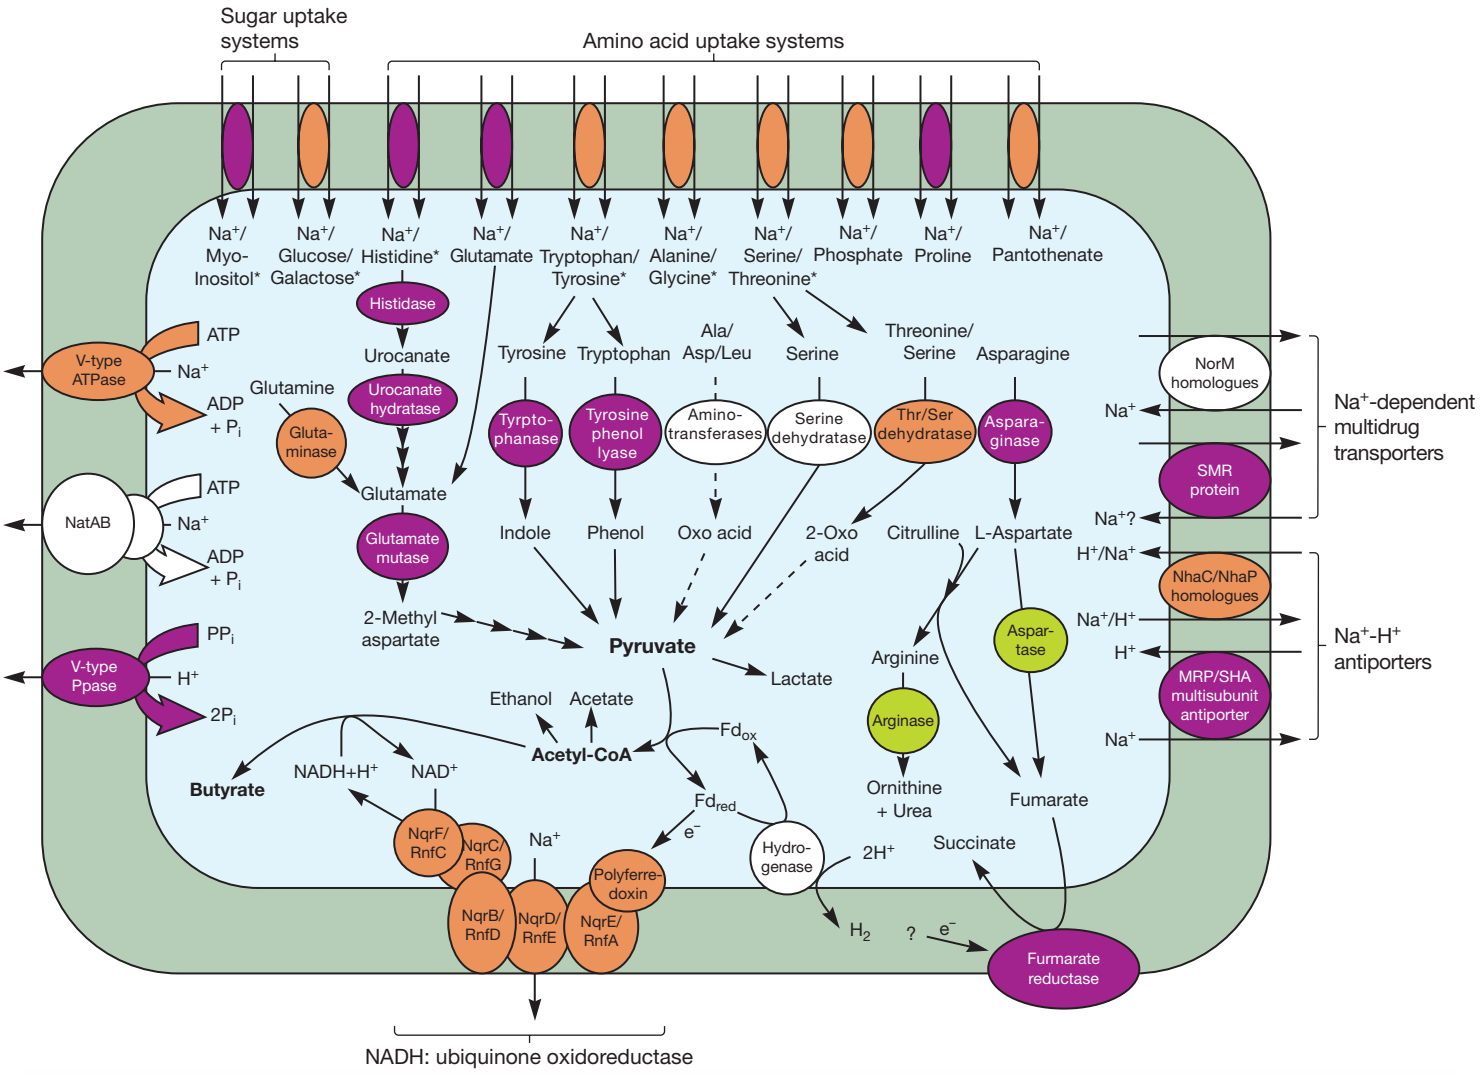

Figure 23.5 Amino Acid Fermentation and Na^+ Flux in *Clostridium tetani*. The fermentation of amino acids and the generation of a Na^+ motive force is central to survival of this pathogen. Note that amino acids are transported into the cell by Na^+-dependent uptake systems. Sugars are also transported in this manner but are used in anabolic reactions only. Several Na^+-dependent transporters with unknown substrates are present. A V-type ATPase and an ATP-binding cassette transporter (NatAB) pump Na^+ out of the cell at the expense of ATP hydrolysis. A proton translocating pyrophosphatase (V-type Ppase) is used to export H^+. Components of a membrane-bound electron transport chain are present, but it is thought that the NADH dehydrogenase participates in amino acid fermentation. The lack of quinones suggests that the ETC is not used to establish a proton motive force.

MICRO INQUIRY *The presence of an electron transport chain in a strictly fermentative microbe is unusual. Describe how this microbe uses its ETC and how this differs from a respiratory microbe.*

sugars. By contrast, *C. acetobutylicum* and *C. perfringens* can catabolize both carbohydrates and amino acids. *C. tetani* uses an ATP-binding cassette transporter and a V-type ATPase to couple ATP hydrolysis to the flow of sodium ions out of the cell. V-type ATPases pump protons, or in this case sodium ions, out of the cell at the expense of ATP made by substrate-level phosphorylation during fermentation. This is not a futile exercise, because it creates a sodium motive force, which in turn drives amino acid and sugar uptake systems. Although *C. tetani* also exports protons via a pyrophosphatase, external protons seem to serve only as the counter ion in Na^+-H^+ antiport. Surprisingly, *C. tetani* possesses genes for a membrane-bound electron transport chain; microbes that make ATP exclusively by fermentation do not generally possess electron transport chains. In this case, it appears that this chain links Na^+-extrusion with oxidation of NADH generated during fermentation. ⏮ *Primary and secondary active transport (section 3.3)*

Desulfotomaculum is a genus that contains endospore-forming species that reduce sulfate and sulfite to hydrogen sulfide during anaerobic respiration (**figure 23.6**). Although they stain Gram negative, electron microscopy studies show that these bacteria have Gram-positive cell walls, and phylogenetic studies place the genus with the low G + C Gram positives.

Heliobacteria further illustrate the diversity of this class. The genera *Heliobacterium* and *Heliophilum* contain unusual anaerobic, phototrophic species characterized by the presence of bacteriochlorophyll *g*. They have a photosystem I–type reaction center like green sulfur bacteria but have no intracytoplasmic photosynthetic membranes; pigments are contained in the plasma membrane (**figure 23.7**). They also differ from many other anoxygenic phototrophic bacteria because they cannot grow autotrophically. Pyruvate is used during photoheterotrophic growth in light; it is fermented in dark, anoxic conditions. Like the clostridia, heliobacteria are capable of nitrogen fixation. Although they have a Gram-positive cell wall, they have a low peptidoglycan content, and they stain Gram negative. Some heliobacteria form endospores. ⏮ *Light reactions in anoxygenic photosynthesis (section 11.11); Photosynthetic bacteria are diverse (section 21.4)*

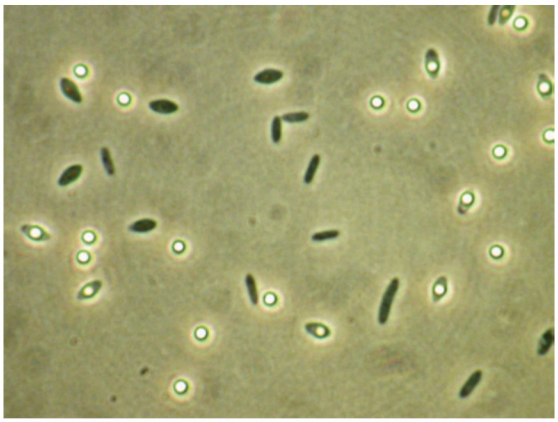

Figure 23.6 ***Desulfotomaculum.*** *Desulfotomaculum acetoxidans* with endospores (bright spheres); phase contrast.

MICRO INQUIRY *In addition to its Gram-staining characteristics, why do you think* Desulfotomaculum *spp. were originally thought to be Gram-negative microbes?*

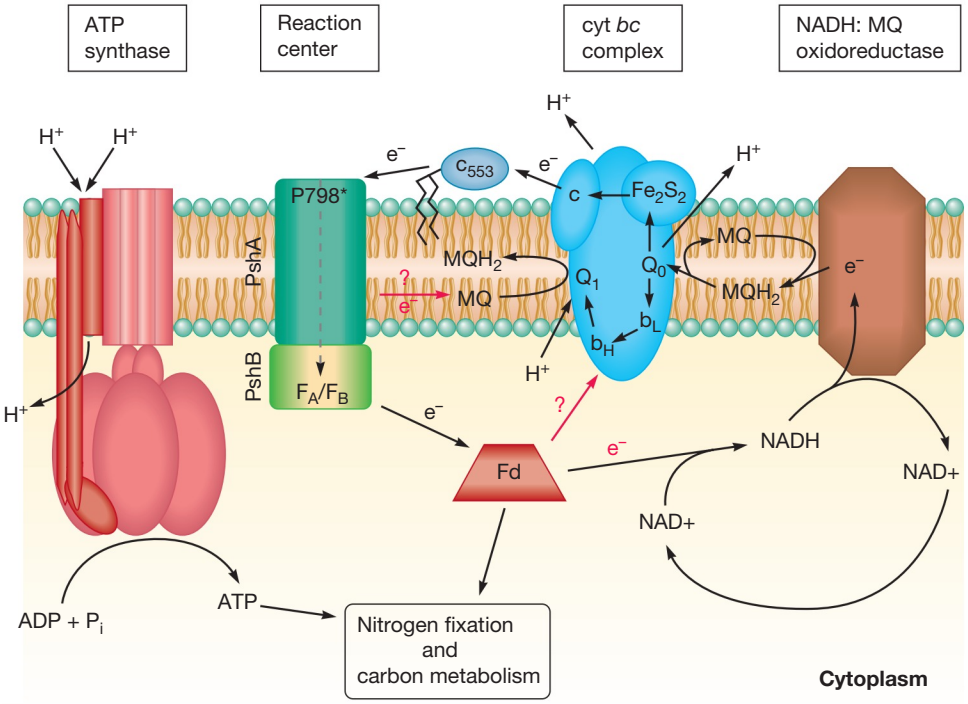

Figure 23.7 **Electron Transfer in *Heliobacterium modesticaldum*.** Genes encoding all subunits of NADH:quinone oxidoreductase are present on the *H. modesticaldum* genome. This suggests that electrons flow from NADH to the NADH:menaquinonone (MQ) oxidoreductase, to cytochrome (cyt) *bc* complex, which in turn reduces a 2Fe-2S subunit and cytochrome b_L. Electrons from cyt *bc* can be transferred via cyt c_{553} to the reaction center (RC) primary electron donor P798. Based on similarities between the heliobacterial RC and photosystem I in other anoxygenic photosynthetic bacteria, it is hypothesized that a proton motive force is generated by cyclic electron flow.

MICRO INQUIRY *What are the two sources of electrons for the* H. modesticaldum *electron transport chain?*

23.2 Class *Negativicutes*: Gram-Positive Bacteria with Outer Membranes

After reading this section, you should be able to:

- Explain why these bacteria are considered Gram positive despite possessing outer membranes.
- Discuss why new taxonomic ranks must be developed
- Identify the location where *Veillonella* sp. might be found on your body

In 2010 three bacterial isolates were cultured from human skin and soft-tissue wounds. What happened next illustrates the ever-changing world of microbial taxonomy and systematics. Further investigation of these bacteria revealed that although they had an inner and outer membrane, like Gram-negative bacteria, 16S rRNA sequences showed that they were closely related to microbes in the Gram-positive family *Veillonellaceae*. Because the three isolates were distinct from any other bacteria in this family, they were assigned to a new genus and species: *Negativicoccus succinicivorans*. The name reflects their unusual cell envelope and the fermentation of succinate.

The discovery of *N. succinicivorans* triggered a reexamination of the class *Clostridia*. It was determined that bacteria that have peptidoglycan between the inner and outer membranes and therefore stain Gram-negative, but are otherwise genetically *Firmicutes,* require their own class. Therefore the new class *Negativicutes* and order *Selenomonadales* were approved (**table 23.2**). Two existing families, *Acidaminococcaceae* and *Veillonellaceae,* were then assigned to this new order. Such changes are always controversial, and this one is no exception.

Members of the genus *Veillonella* are anaerobic, chemoheterotrophic cocci. Usually they are diplococci, but they may exist as single cells, clusters, or chains. All have complex nutritional requirements and ferment carbohydrates, organic acids, and amino acids to produce gas (CO_2 and often H_2) plus a mixture of volatile fatty acids. They are parasites of homeothermic (warm-blooded) animals. Some species are part of the normal biota of the mouth, the gastrointestinal tract, and the urogenital tract of humans and other animals.

Retrieve, Infer, Apply

1. List three species of *Clostridium* and why they are notable.
2. Suggest why *C. tetani* uses a sodium motive force rather than a proton motive force.
3. What is the evolutionary significance of the discovery of a phototrophic bacterium within the low G + C Gram-positive bacteria? Do you think the phototrophic apparatus in *Heliobacterium* spp. evolved independently of those found in Gram-negative anoxygenic phototrophs? Explain.
4. What kind of genetic evidence, in addition to 16S rRNA sequences, might have demonstrated that *Negativicutes* should be considered Gram positive?

23.3 Class *Bacilli:* Aerobic Endospore-Forming Bacteria

After reading this section, you should be able to:

- List terminal electron acceptors and fermentation products produced by *Bacillus* spp. and staphylococci
- Discuss reasons that make *Bacillus subtilis* an important model organism
- List three reasons *Bacillus* spp. are of practical importance
- Summarize the evolution and emergence of MRSA, and list at least two diseases caused by *Staphylococcus aureus*
- Describe the structure and medical importance of *Listeria monocytogenes*
- Identify the genera considered lactic acid bacteria, and discuss their importance in the food industry
- Distinguish between enterococci and streptococci
- Name bacterial genera with species capable of hemolysis, and differentiate between α-hemolysis and β-hemolysis

The class *Bacilli* is very large but includes only two orders, *Bacillales* and *Lactobacillales*. These include genera representing cocci, endospore-forming rods and cocci, and nonsporing rods. We first describe the biology of some members of the order *Bacillales* and then important representatives of the order *Lactobacillales*. The phylogenetic relationships between some of these organisms are shown in figure 23.2, and the characteristics of selected genera are summarized in **table 23.3**.

Table 23.2 Characteristics of Selected Members of the Class *Negativicutes*

Genus	Dimension (μm), Morphology, Motility	Genome Size (Mb)	Oxygen Relationship	Other Distinctive Characteristics
Veillonella	0.3–0.5; cocci in pairs, short chains, and masses; nonmotile	2.8	Anaerobic	Pyruvate and lactate fermented but not carbohydrates; parasitic in mouths, intestines, and respiratory tracts of animals.
Megasphaera	1.7–2.6, cocci, nonmotile	1.8–2.6	Anaerobic	Ferment a variety of carbohydrates, including lactate; isolated from mouths, intestines of animals, and spoiled beer
Negativicoccus	0.4, cocci; nonmotile	1.45	Anaerobic and microaerophilic	Isolated from human skin and soft-tissue wounds; ferments succinate to acetate and propionate

Table 23.3 Characteristics of Members of the Class *Bacilli*

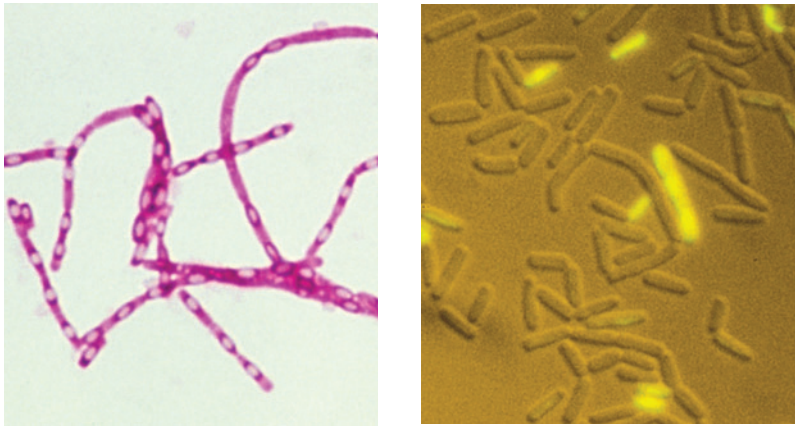
Genus	Dimensions (μm), Morphology, and Motility	Genome Size (Mb)	Oxygen Relationship	Other Distinctive Characteristics
Bacillus	0.5–2.5 × 1.2–10; straight rods, peritrichous flagella, spore-forming	4.2–5.4	Aerobic or facultative	Catalase positive; chemoorganotrophic
Caryophanon	1.5–3.0 × 10–20; multicellular rods with rounded ends, peritrichous flagella, nonsporing	Nd[1]	Aerobic	Acetate only major carbon source; catalase positive; trichome cells have greater width than length; trichomes can be in short chains
Enterococcus	0.6–2.0 × 0.6–2.5; spherical or ovoid cells in pairs or short chains, nonsporing, sometimes motile	3.2	Aerotolerant	Ferment carbohydrates to lactate with no gas; complex nutritional requirements; catalase negative; occur widely, particularly in fecal material
Lactobacillus	0.5–1.2 × 1.0–10; usually long, regular rods, nonsporing, rarely motile	1.9–3.3	Facultative or microaerophilic	Fermentative, at least half the end product is lactate; require rich, complex media; catalase and cytochrome negative
Lactococcus	0.5–1.2 × 0.5–1.5; spherical or ovoid cells in pairs or short chains, nonsporing, nonmotile	2.4	Aerotolerant	Chemoorganotrophic with fermentative metabolism; lactate without gas produced; catalase negative; complex nutritional requirements; in dairy and plant products
Leuconostoc	0.5–0.7 × 0.7–1.2; cells spherical or ovoid, in pairs or chains; nonmotile and nonsporing	1.7–3.2	Facultative	Require fermentable carbohydrate and nutritionally rich medium for growth; fermentation produces lactate, ethanol, and gas; catalase and cytochrome negative
Staphylococcus	0.9–1.3; spherical cells occurring singly and in irregular clusters, nonmotile and nonsporing	2.5–2.8	Facultative	Chemoorganotrophic with both respiratory and fermentative metabolism; usually catalase positive; associated with skin and mucous membranes of vertebrates
Streptococcus	0.5–2.0; spherical or ovoid cells in pairs or chains, nonmotile and nonsporing	1.8–2.2	Aerotolerant	Fermentative, producing mainly lactate and no gas; catalase negative; commonly attack red blood cells (α- or β-hemolysis); complex nutritional requirements; commensals or parasites on animals
Thermoactinomyces	0.4–1.0 in diameter; branched, septate mycelium resembles those of actinomycetes	3.4	Aerobic	Usually thermophilic; true endospores form singly on hyphae; numerous in decaying hay, vegetable matter, and compost

1 Nd: Not determined; genome not yet sequenced.

Order *Bacillales*

The genus *Bacillus,* family *Bacillaceae,* is the largest in the order *Bacillales.* The genus contains endospore-forming, chemoheterotrophic rods that are usually motile with peritrichous flagella (**figure 23.8**). Members of this genus are aerobic or facultative, and catalase positive. *Bacillus subtilis,* the type species *(see page 445)* for the genus, is the most well-studied Gram-positive bacterium. It is a facultative anaerobe that can use nitrate as a terminal electron acceptor or perform mixed acid fermentation with lactate, acetate, and acetoin as major end products. It is nonpathogenic and a terrific model organism for the study of gene regulation, cell division, quorum sensing, and cellular differentiation. Its 4.2-Mb genome was one of the first genomes to be completely sequenced and reveals a number of interesting elements. For instance, several families of genes have been expanded by gene duplication; the largest such family encodes ABC transporters—the most abundant class of protein in *B. subtilis.* There are 18 genes that encode sigma factors. Recall that the use of alternative sigma subunits of RNA polymerase is one way in which bacteria regulate gene expression. In this case, many of the sigma factors govern spore formation and other responses to stressful conditions. ⏮ *Bacterial endospores are a survival strategy (section 3.9); Protein maturation and secretion (section 13.8); Sporulation in* Bacillus subtilis *(section 14.5)*

B. subtilis is a soil-dwelling microbe whose spores are easily extracted from diverse soil types. Interestingly, it is often found in its vegetative state (i.e., not as a spore) when



(a) *Bacillus anthracis* **(b)** *B. cereus*

Figure 23.8 ***Bacillus.*** (a) *B. anthracis endo*spores are elliptical and central (×1,600). (b) *B. cereus* stained with SYTOX Green nucleic acid stain and viewed by epifluorescence and differential interference contrast microscopy. The cells that glow yellow are dead.

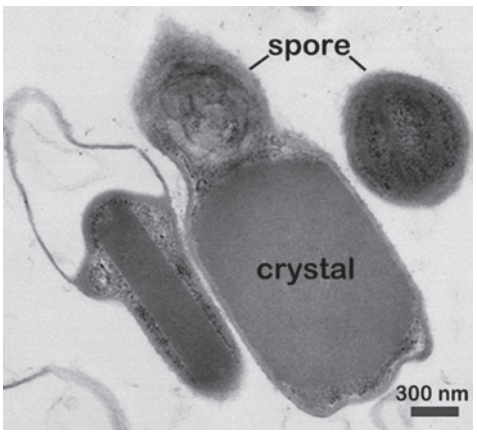


Figure 23.10 **The Parasporal Body.** An electron micrograph of a *B. thuringiensis* sporulating cell containing a parasporal crystal just beneath the endospore. A free spore is also shown.

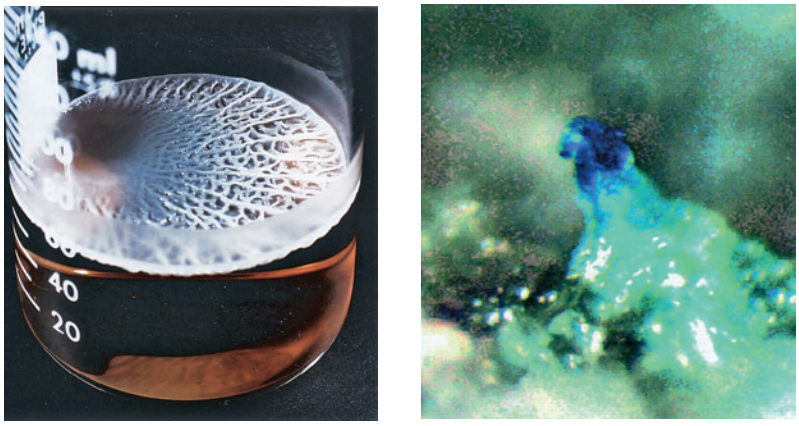


(a) Biofilm formation **(b)** Fruiting body formation

Figure 23.9 **Biofilm Formation by *Bacillus subtilis.*** (a) When grown for several days without agitation in nutrient-limiting medium, *B. subtilis* forms a hydrophobic biofilm at the aqueous-air interface. (b) *B. subtilis* forms multicellular structures called fruiting bodies, when grown on minimal-salts agar for several days. These cells are labeled so that spores turn blue, demonstrating that spores are abundant at the tips of these structures.

MICRO INQUIRY *What growth or survival advantage might this type of multicellular behavior confer to* B. subtilis?

growing in association with actively decaying material and in close association with plant roots. In addition to forming spores, *B. subtilis* also develops biofilms made up of vegetative cells at the base and differentiated structures containing spores at the tip (**figure 23.9**). ◀◀ *Biofilms are common in nature (section 7.5)*

Many species of *Bacillus* are of considerable importance. They produce the antibiotics bacitracin, gramicidin, and polymyxin. *B. cereus* (figure 23.8*b*) can cause food poisoning. Several species are used as insecticides. For example, *B. thuringiensis* and *B. sphaericus* form a solid protein crystal, the **parasporal body,** next to their endospores during endospore formation (**figure 23.10**). As discussed in chapter 42, the *B. thuringiensis* parasporal body contains protein toxins that kill over 100 species of moths when activated in the alkaline gut of caterpillars thereby destroying the epithelium. The *B. sphaericus* parasporal body contains proteins toxic for mosquito larvae and may be useful in controlling the mosquitoes that carry the malaria parasite *Plasmodium*. *B. anthracis* is the causative agent of the disease anthrax, which can kill both farm animals and humans. ▶▶ *Anthrax (section 39.5); Agricultural biotechnology relies on a plant pathogen (section 42.5)*

Members of the genus *Thermoactinomyces* historically were classified as actinomycetes because, like these microbes, their soil-associated substrate hyphae (filamentous cells) differentiate into upwardly growing aerial hyphae. However, phylogenetic analysis places them with low G + C bacteria in the order *Bacillales,* family *Thermoactinomycetaceae*. Their G + C content (52–55 mol%) is considerably lower than that of actinobacteria. Also unlike actinobacteria, *Thermoactinomyces* species form true endospores within both the aerial and substrate hyphae. These bacteria are thermophilic and grow between 45 and 60°C. *Thermoactinomyces* spp. are commonly found in damp haystacks and compost piles. In fact, *T. vulgaris* from haystacks, grain storage silos, and compost piles is a causative agent of farmer's lung, an allergic disease of the respiratory system. Spores from *T. vulgaris* recovered from the mud of a Minnesota lake were found to be viable after about 7,500 years of dormancy.

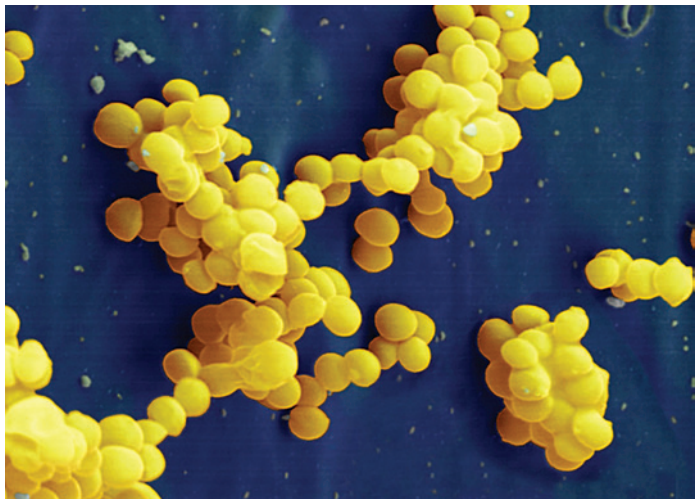
One other genus within the order *Bacillales* bears mentioning: *Sporosarcina.* This genus is one of five genera in the family *Panococcaceae,* and it contains the only known endospore-forming bacterium that has a coccoid rather than

rod shape. *S. ureae* is particularly interesting because it is tolerant of very alkaline conditions (up to pH 10), which it creates when it degrades urea to CO_2 and NH_3. Interestingly, it is easily isolated from agricultural soils on which animals frequently urinate.

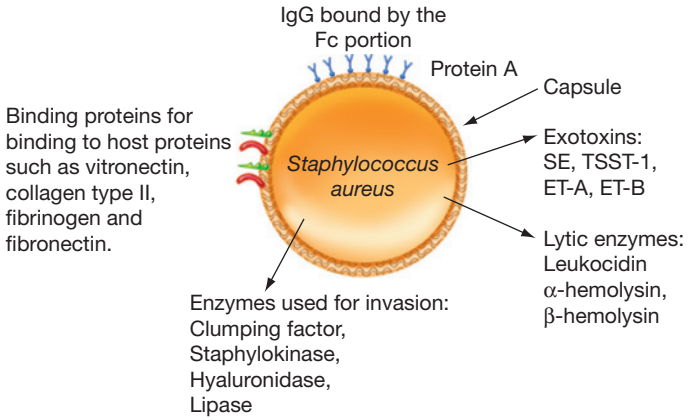
Family *Staphylococcaceae*

The family *Staphylococcaceae* contains five genera, the most important of which is *Staphylococcus.* Members of this genus are facultatively anaerobic, nonmotile cocci, 0.5 to 1.5 μm in diameter, occurring singly, in pairs, and in tetrads, and characteristically dividing in more than one plane to form irregular clusters (**figure 23.11**). They are usually catalase positive and oxidase negative. They respire using oxygen as the terminal electron acceptor, although some can reduce nitrate to nitrite. They are also capable of fermentation and convert glucose principally to lactate.

Staphylococci are normally associated with the skin and mucous membranes of warm-blooded animals. They are responsible for many human diseases. *S. aureus* has an impressive collection of virulence factors to evade and subvert the host (figure 23.11*b*). These include Protein A, which binds host antibodies by the conserved Fc region, rendering them ineffective. Two types of proteins aid in colonization and dissemination; clumping factors enable bacteria to attach to platelets and wounded tissue, thereby promoting initial colonization. By contrast, the protein staphylokinase dissolves fibrin clots that would otherwise keep the bacterium from invading beyond the site of initial colonization. The enzyme coagulase, which causes blood plasma to clot, is used as a marker for the identification of *S. aureus* but has no clear role in pathogenesis. Growth and hemolysis patterns on blood agar are also useful in identifying these staphylococci. The staphylococcal β-hemolysin lyses cells by forming solvent-filled channels in target plasma membranes. ▶▶| *Staphylococcal diseases (section 39.3); Staphylococcal food poinsoning (section 39.4)*



(a)



(b)

Figure 23.11 ***Staphylococcus.*** (a) *S. aureus* cocci arranged in grape-like clusters; color-enhanced scanning electron micrograph. Each cell is about 1 μm in diameter. (b) *S. aureus* produces many virulence factors that account for its success as a pathogen. Staphylokinase catalyzes the degradation of host fibrin, facilitating microbial invasion. Hyaluronidase degrades hyaluronic acid, which is found in connective and epithelial tissues. See chapter 39 for further discussion of staphylococcal diseases.

Family *Listeriaceae*

The family *Listeriaceae* includes two genera: *Brochothrix* and *Listeria*. *Brochothrix* spp. are most commonly found in meat but are not pathogenic. *Listeria* is the medically important genus in this family. It contains short rods that are facultatively anaerobic, catalase positive, and motile by peritrichous flagella. In addition to aerobic respiration, these microbes ferment glucose mainly to lactate. *Listeria* spp. are widely distributed in nature, particularly in decaying matter. *L. monocytogenes* is a pathogen of humans and other animals, and causes listeriosis, an important food-borne infection. ▶▶| *Food-borne disease outbreaks (section 41.3)*

Order *Lactobacillales*

Streptococcus, Enterococcus, Lactococcus, Lactobacillus, and *Leuconostoc* are all genera in the order *Lactobacillales.* These bacteria do not form endospores and are usually nonmotile. They are strictly fermentative, depending on sugars for carbon and energy. They lack cytochromes and an electron transport chain so they obtain energy only by substrate-level phosphorylation. Those that produce lactic acid as their major or sole fermentation product are sometimes collectively called **lactic acid bacteria** (**LAB**). Nutritionally, they are fastidious, and many vitamins, amino acids, purines, and pyrimidines must be supplied because of their limited biosynthetic capabilities. Members of this order usually are categorized as facultative anaerobes but can be considered aerotolerant. |◀◀ *Oxygen concentration (section 7.4); Fermentation does not involve an electron transport chain (section 11.8)*

The largest genus in this order is *Lactobacillus,* with about 100 species. Lactobacilli include rods and some coccobacilli. All lack catalase and cytochromes, and produce lactic acid as their

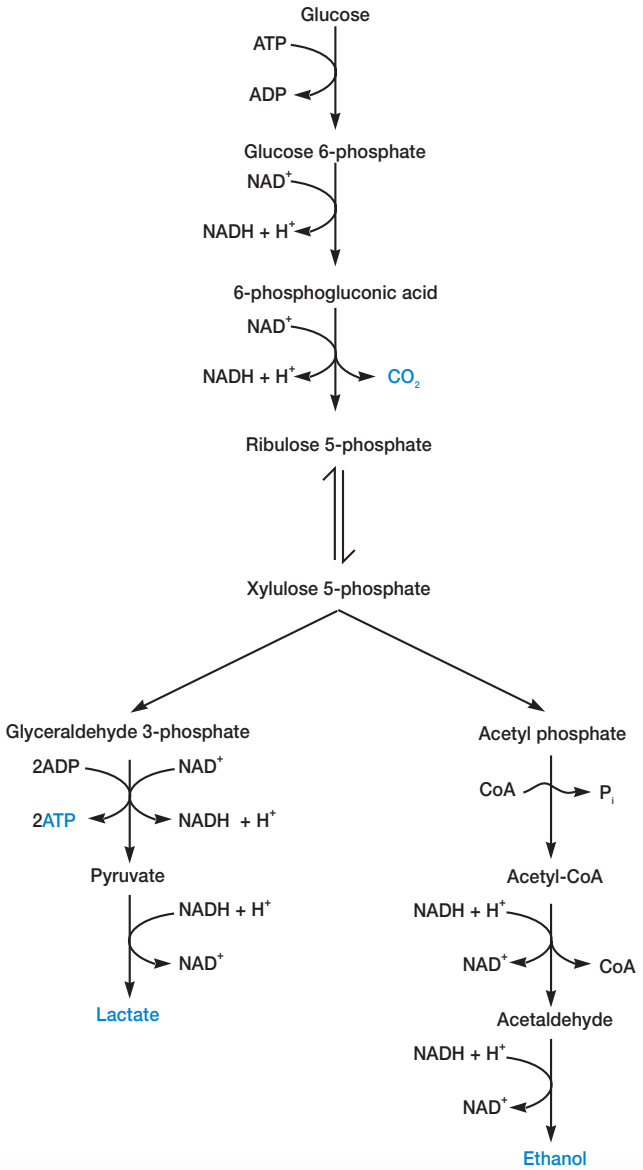


Figure 23.12 Heterolactic Fermentation and the Phosphoketolase Pathway. The phosphoketolase pathway converts glucose to lactate, ethanol, and CO_2.

MICRO INQUIRY *What is the net yield of ATP for each glucose that enters the phosphoketolase pathway?*

main or sole fermentation product (*see figure 11.20*). They carry out either **homolactic fermentation** using the Embden-Meyerhof pathway or **heterolactic fermentation** with the phosphoketolase pathway (**figure 23.12**). They grow optimally under slightly acidic conditions, at a pH between 4.5 and 6.4, and are found in dairy products, meat, water, sewage, beer, fruits, and many other materials. Lactobacilli also are part of the normal flora of the human body; in particular they are important normal vaginal flora.

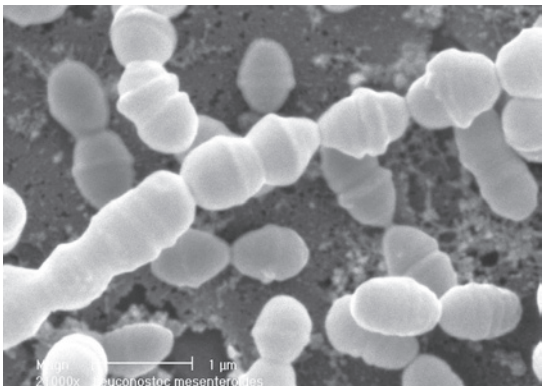

Figure 23.13 *Leuconostoc.* *Leuconostoc mesenteroides;* scanning electron micrograph.

Lactobacillus species are indispensable to the food and dairy industry. They are used in the production of fermented vegetable foods (e.g., sauerkraut, pickles), sourdough bread, Swiss and other hard cheeses, yogurt, and sausage. Yogurt is probably the most popular fermented milk product in the United States, and *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subspecies *bulgaricus* are used in its production. At least one species, *L. acidophilus,* is sold commercially as a probiotic agent that may provide some health benefits for the consumer. On the other hand, some lactobacilli are problematic. They can be responsible for spoilage of beer, wine, milk, and meat. ▶▶| *Fermented milks (section 41.5); Probiotics (section 41.6)*

Leuconostoc, family *Leuconostocaceae,* contains facultative Gram-positive cocci, which may be elongated or elliptical and arranged in pairs or chains (**figure 23.13**). Leuconostocs carry out heterolactic fermentation by converting glucose to D-lactate and ethanol or acetic acid by means of the phosphoketolase pathway (figure 23.12). They can be isolated from plants, silage, and milk. They are used in wine production, in the fermentation of vegetables, and in the manufacture of buttermilk, butter, and cheese. *L. mesenteroides* synthesizes dextrans from sucrose and is important in industrial dextran production. *Leuconostoc* species are involved in food spoilage and tolerate high sugar concentrations so well that they grow in syrup and can be a major problem in sugar refineries.

Bacteria in the important families *Enterococcaceae* and *Streptococcaceae* occur in pairs or chains when grown in liquid media (**figure 23.14** and **table 23.4**). They are unable to respire and have a strictly fermentative metabolism. They ferment sugars to produce lactic acid but no gas; that is, they carry out homolactic fermentation. A few species are strict anaerobes rather than aerotolerant. Enterococci such as *E. faecalis* are normal residents of the intestinal tracts of humans and most other animals. *E. faecalis* is an opportunistic pathogen that can cause urinary tract infections and endocarditis. Enterococci are major agents in the horizontal transfer of antibiotic-resistance genes.

The family *Streptococcaceae* includes only two genera: *Lactococcus* and *Streptococcus. Lactococcus* spp. ferment sugars to lactic acid and can grow at 10°C but not at 45°C. *L. lactis* is widely used in the production of buttermilk and cheese because it can

curdle milk and add flavor through the synthesis of diacetyl and other products.

The genus *Streptococcus* is large and complex. All species in the genus are facultatively anaerobic and catalase negative. Many characteristics are used to identify these cocci. One of the most important is the ability to lyse red blood cells when grown on blood agar, an agar medium containing 5% sheep or horse blood (**figure 23.15**). In **α-hemolysis,** a 1- to 3-mm greenish zone of incomplete hemolysis forms around the colony; **β-hemolysis** is characterized by a clear zone of complete lysis. Serological studies are also very important in identification because streptococci often have distinctive cell wall antigens. These bacteria produce a surface protein, the M protein, that is important in pathogenesis and species identification. The **Lancefield grouping system,** used for many years, was based on structural variations in M protein structure. This system has largely been replaced by sequence analysis of the *eem* gene, which encodes the M protein *(see figure 39.5).* Biochemical and physiological tests, and sensitivity to bacitracin, sulfa drugs, and optochin (a quinine analogue) also are used to identify particular species. ▶▶| *Clinical microbiology and immunology (chapter 36)*

The streptococci have been divided into three groups: pyogenic streptococci, oral streptococci, and other streptococci. Pyogenic streptococci are pathogens associated with pus formation. Most species are β-hemolytic on blood agar and form chains of cells. The major human pathogen in this group is *S. pyogenes,* which causes streptococcal sore throat, acute glomerulonephritis, and rheumatic fever. The normal habitat of oral streptococci is the oral cavity and upper respiratory tract of humans and other animals. In other respects, oral streptococci are not necessarily similar. *S. mutans* is associated with the formation of dental caries. *S. pneumoniae* is α-hemolytic and grows as pairs of cocci. It is associated with lobar pneumonia and otitis media (inflammation of the middle ear) in young children. ▶▶| *Streptococcal diseases (sections 39.1* and *39.3)*

MICRO INQUIRY *Why is there a green zone around α-hemolytic colonies?*

Retrieve, Infer, Apply

1. You are studying what you think is a new *Bacillus* isolate. Without performing molecular analyses, what morphological and physiological traits would you assay?
2. What makes the genus *Thermoactinomyces* unique? What disease does *T. vulgaris* cause?
3. List three environments where you would find *Staphylococcus* spp. On what basis are pathogenic and nonpathogenic species and strains distinguished?
4. List the major properties that define the genus *Lactobacillus*. In what ways are species in this genus important in the food and dairy industries?
5. How are various species of *Streptococcus* identified?
6. Of what practical importance are leuconostocs? What are lactic acid bacteria?
7. What is the difference between α-hemolysis and β-hemolysis?

Key Concepts

23.1 Class *Clostridia*: Anaerobic Endospore-Forming Bacteria

- Members of the genus *Clostridium* are anaerobic, Gram-positive rods that form endospores and do not carry out dissimilatory sulfate reduction. They are responsible for food spoilage, botulism, tetanus, and gas gangrene. They have a fermentative metabolism (**figures 23.3–23.5**).
- *Desulfotomaculum* contains anaerobic, endospore-forming species that reduce sulfate to sulfide during anaerobic respiration.
- Heliobacteria are anaerobic, phototrophic bacteria with bacteriochlorophyll *g*. Some form endospores (**figure 23.7**).

23.2 Class *Negativicutes*: Gram-Positive Bacteria with Outer Membranes

- The discovery of several new Gram-negative staining bacteria that are phylogenetically *Firmicutes* led to the development of the class *Negativicutes*.
- The class has two families previously considered *Clostridia: Acidaminococcacaea* and *Veillonellaceae*. All members have an outer membrane and are fermentative; many are residents of warm-blooded animals (**table 23.2**).

23.3 Class *Bacilli*: Aerobic Endospore-Forming Bacteria

- The class *Bacilli* is divided into two orders: *Bacillales* and *Lactobacillales*.
- The genus *Bacillus* contains aerobic and facultative, catalase-positive, endospore-forming, chemoorganotrophic rods that are usually motile with peritrichous flagella. *Bacillus subtilis* is a model organism that forms endospores and multicellular structures such as biofilms and fruiting bodies (**figures 23.8** and **23.9**).
- *Thermoactinomyces* spp. are thermophilic and form a mycelium and true endospores. *T. vulgaris* causes allergic reactions that lead to farmer's lung.

- Members of the genus *Staphylococcus* are facultatively anaerobic, nonmotile, Gram-positive cocci that form irregular clusters. They carry out aerobic respiration; some also ferment and use nitrate as a terminal electron acceptor. *S. aureus* is a pathogen that possesses an array of virulence factors (**figure 23.11**).
- Several important genera such as *Lactobacillus* and *Listeria* contain regular, nonsporing rods. *Lactobacillus* spp. carry out lactic acid fermentation and are extensively used in the food and dairy industries. *Listeria monocytogenes* is an important agent in food poisoning. *Leuconostoc* spp. carry out heterolactic fermentation using the phosphoketolase pathway (**figure 23.12**); they are involved in the production of fermented vegetable and dairy products.
- The genera *Streptococcus, Enterococcus,* and *Lactococcus* contain cocci arranged in pairs and chains that are usually facultative anaerobes that carry out fermentation (**table 23.4**). Some important species are the pyogenic coccus *S. pyogenes, S. pneumoniae,* the enterococcus *E. faecalis,* and the lactococcus *L. lactis.*

Compare, Hypothesize, Invent

1. Some species of *Clostridium* demonstrate much faster doubling times when in the host than when grown in vitro. Design an experiment that would explore this phenomenon.
2. What physiological properties might account for the ease with which anaerobic clostridia can be isolated from soil and other generally aerobic niches.
3. *S. aureus* strains that are resistant to methicillin (MRSA) are also resistant to many other antibiotics and are more virulent than non-MRSA strains. Refer to chapters 16 and 18, and develop a testable hypothesis that predicts how these many traits came to be in a single group of strains.
4. Cells of *Bacillus subtilis* that are committed to sporulate secrete a signaling protein that prevents sister cells from entering sporulation and a killing factor that causes these sisters to lyse. The nutrients released by these cells are consumed by the "killer" cells, providing the nutrients needed to complete spore formation. It has been proposed that this provides evidence that sporulation is a "last resort" for survival by this microbe. Do you agree that the capacity to cannibalize sister cells is evidence that the *B. subtilis* uses spore formation as last resort? Explain your answer, being careful not to project human terms onto the microbes (i.e., anthropomorphize).

Actinobacteria: High G + C Gram-Positive Bacteria

If this pharmacist is dispensing an antibiotic, odds are, it was made by a streptomycete. Members of the genus Streptomyces *synthesize the majority of antibiotics used in medicine today. They also produce other bioactive compounds that have important medicinal and industrial uses.*

Antibiotic Production: Is It Actually Bacterial Chit-Chat?

Among bacteria, it is hard to find a genus whose constituents have given more to humankind than *Streptomyces*. When growing in their natural soil habitat, streptomycetes are key players in a microbial community that eats decaying plant and animal material. And like diners in a crowded restaurant, these microbes are "talking" up a storm, using a vocabulary of small molecules.

In fact, some microbiologists hypothesize that antibiotics are the language of inter- and intraspecies communication. If this is the case, then streptomycetes are very talkative indeed. About two-thirds of all antibiotics prescribed are made by these bacteria, including tetracycline, vancomycin, and neomycin. Noting that streptomycetes produce and secrete such a wide range of natural products, pharmaceutical companies have screened countless isolates, discovering that they also make anticancer compounds (e.g., doxorubicin), antifungals (e.g., nystatin), and ivermectin, used to treat parasitic infections in humans and to prevent heartworm in dogs. All told, *Streptomyces* species produce about 10,000 bioactive products, but models suggest there may be 990,000 yet undiscovered!

How can it be that after 60 years of research, so few streptomycete compounds are known? And how do we know this? One stark piece of evidence was revealed in 2002 when the *S. coelicolor* genome was published. This species was known to make four antibiotics, yet the genes for the production of 20 additional compounds were found. These genes are tightly regulated; to find and test new antibiotics, their regulatory "off" switch must be unlocked. This is where the ability of streptomycetes to communicate gets interesting. About 60 years ago, streptomycin, the first drug to treat tuberculosis, was found to be made by *S. griseus*. Ten years later, researchers discovered that streptomycin production depended on the release of tiny amounts of a small molecule called A-factor, a gamma-butyrolactone. If *S. griseus* cells fail to exchange A-factor, no streptomycin is produced. Much later it was discovered that a different group of chemicals, 2-alkyl-4-hydroxymethylfuran-3-carboxylic acids (or AHFCAs), controls the release of other antibiotics. And studies with natural isolates show that when cultured alone, many *Streptomyces* spp. lack discernible antibiotic activity. But when grown in the company of other streptomycetes, and allowed to exchange secreted molecules, new antibiotics are released.

What does all this bacterial chitchat mean? To the microbes it probably provides a way to ensure that enough of their kind are present. After all, the amount of antibiotic secreted by an individual isn't a very effective defense. To the world of drug discovery, it means that screening for new natural products is more complicated than simply growing a *Streptomyces* isolate in pure culture. New and creative methods of culturing and screening must be developed.

By definition, high G + C Gram-positive bacteria have a DNA base composition above approximately 50 mol% G + C; these bacteria belong to the phylum *Actinobacteria* (**figure 24.1**). Based on 16S rRNA sequence data,

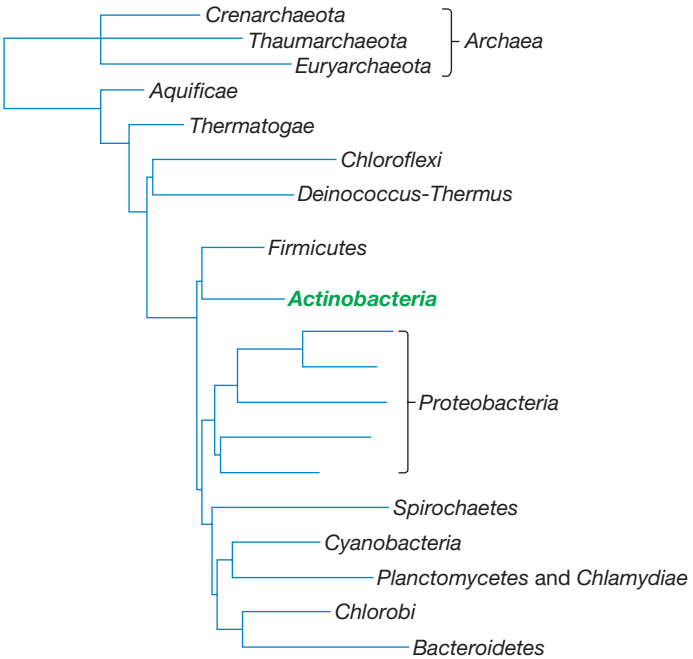

Figure 24.1 Phylogenetic Relationships Among *Bacteria* and *Archaea*. The phylum *Actinobacteria* is highlighted.

Table 24.1 Characteristics of Actinobacteria

Genus	Dimensions (μm), Morphology and Motility	Genome Size Range (Mb)	Oxygen Relationship	Other Distinctive Characteristics
Actinoplanes	Nonfragmenting, branching mycelium with little aerial growth; sporangia formed; motile spores with polar flagella	8.7–9.4	Aerobic	Hyphae often in palisade arrangement; highly colored; type II cell walls; found in soil and decaying plant material
Arthrobacter	0.8–1.2 × 1.0–8.0; young cells are irregular rods, older cells are small cocci; usually nonmotile	3.9–5.2	Aerobic	Have rod-coccus growth cycle; respiratory metabolism; catalase positive; mainly in soil
Bifidobacterium	0.5–1.3 × 1.5–8; rods of varied shape, usually curved; nonmotile	1.9–2.8	Anaerobic	Cells can be clubbed or branched, pairs often in V arrangement; ferment carbohydrates to acetate and lactate but no CO_2; catalase negative
Corynebacterium	0.3–0.8 × 1.5–8.0; straight or slightly curved rods with tapered or clubbed ends; nonmotile	2.3–3.4	Facultatively anaerobic	Cells often arranged in a V formation or in palisades of parallel cells; catalase positive and fermentative; polyphosphate granules
Frankia	0.5–2.0 in diameter; vegetative hyphae with limited-to-extensive branching and no aerial mycelium; multilocular sporangia formed	5.3–9.0	Aerobic to microaerophilic	Sporangiospores nonmotile; usually fix nitrogen; type III cell walls; most strains are symbiotic with angiosperm plants and induce nodules
Micrococcus	0.5–2.0 diameter; cocci in pairs, tetrads, or irregular clusters; usually nonmotile	2.3–2.6	Aerobic	Colonies usually yellow or red; catalase positive with respiratory metabolism; primarily on mammalian skin and in soil
Mycobacterium	0.2–0.6 × 1.0–10; straight or slightly curved rods, sometimes branched; acid-fast; nonmotile and nonsporing	3.3–7.0	Aerobic	Catalase positive; can form filaments that are readily fragmented; walls have high lipid content; in soil and water; some parasitic
Nocardia	0.5–1.2 in diameter; rudimentary to extensive vegetative hyphae that can fragment into rod-shaped and coccoid forms	6.2–9.4	Aerobic	Aerial hyphae formed; catalase positive; type IV cell walls; widely distributed in soil
Propionibacterium	0.5–0.8 × 1–5; pleomorphic nonmotile rods, may be forked or branched; nonsporing	2.5–2.6	Anaerobic to aerotolerant	Fermentation produces propionate and acetate, and often gas; catalase positive
Streptomyces	0.5–2.0 in diameter; vegetative mycelium extensively branched; aerial mycelium forms chains of three to many spores	8.5–10.1	Aerobic	Form discrete lichenoid or leathery colonies that often are pigmented; respiratory metabolism; use many organic compounds as nutrients; soil organisms

there are six classes in the phylum. In this chapter, we cover members of the class ***Actinobacteria.*** Many actinobacteria are also called actinomycetes. **Actinomycetes** are aerobic bacteria that are distinctive because most have filamentous cells called hyphae that differentiate to produce asexual spores. A summary of the actinobacteria discussed in this chapter is presented in **table 24.1.**

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Draw a Gram-positive cell wall and list its constituent parts (section 3.4)
- ✔ Compare and contrast the growth and physiology of obligate aerobes, facultative anaerobes, microaerophiles, and strict anaerobes (section 7.4)
- ✔ List environmental factors that influence microbial growth (section 7.4)
- ✔ Explain how biofilms form and why they are important (section 7.5)
- ✔ Discriminate between substrate-level phosphorylation and oxidative phosphorylation (sections 11.4 and 11.6)
- ✔ Draw an electron transport chain indicating the relative standard reduction potentials of the electron donor, acceptor, and electron transporters (sections 10.4 and 11.6)
- ✔ Compare anaerobic and aerobic respiration (sections 11.3 and 11.7)
- ✔ Summarize the generation of ATP and the fate of pyruvate in fermentation (section 11.8)

24.1 Class *Actinobacteria*

After reading this section, you should be able to:

- Draw the life cycle of at least two different actinobacteria
- Distinguish an exospore from an endospore
- Discuss the taxonomic importance of cell wall structure
- List common environments in which these microbes can be found
- List one veterinary and two human diseases caused by actinobacteria
- Explain snapping division and how this results in the palisade arrangement of cells
- Relate the structure of mycolic acids to the properties of mycobacterial cell walls
- Relate the unusual carbon and energy substrates used by bacteria in the family *Nocardiaceae* to their importance in bioremediation
- Describe the unusual morphology of actinoplanete spores
- Name two reasons propionibacteria are important to humans
- Explain how streptomycete morphology helps this group thrive in soils
- Discuss the origin of the antibiotic streptomycin and list five other medicinal agents made by streptomycetes
- Describe the morphology of *Frankia* spp., relate this to their colonization of plants, and explain the advantage these bacterial symbionts confer to plants such as alder trees
- Describe the morphology of members of *Bifidobacteriaceae*
- Differentiate between the human pathogenic and nonpathogenic members of class *Actinobacteria*

Actinobacteria are fascinating microorganisms. Although all are chemoorganoheterotrophs, recently several have been discovered to use atmospheric H_2 as an electron donor to maintain electron flow into the electron transport chain when growing in nutrient-depleted aerobic conditions. As described in the chapter opening story, they also produce metabolites used as antibiotics, anticancer drugs, antihelminthics, and drugs that suppress the immune system in patients who have received organ transplants. This practical aspect of actinobacteria is linked very closely to their mode of growth, which in many cases involves a complex life cycle. Many actinobacteria make filaments, called **hyphae,** instead of more familiar, smaller rods or cocci. Septae (crosswalls) usually divide the hyphae into long cells (20 μm and longer), each containing several nucleoids. When growing on a solid substratum such as soil or agar, filamentous actinobacteria develop a branching network of hyphae (**figure 24.2**). Hyphae grow on and into the substratum to form a dense hyphal mat called a **substrate mycelium.** In nature, the substratum is soil or other sediments. In the laboratory, substrate hyphae grow into agar, where the tangle of substrate hyphae imparts a leathery texture to the colonies of many actinomycetes. In many actinobacteria, substrate hyphae go on to differentiate into upwardly growing hyphae to form an **aerial mycelium** that gives the colony a fuzzy appearance. It is at this time that medically useful compounds are formed. Because the physiology of the

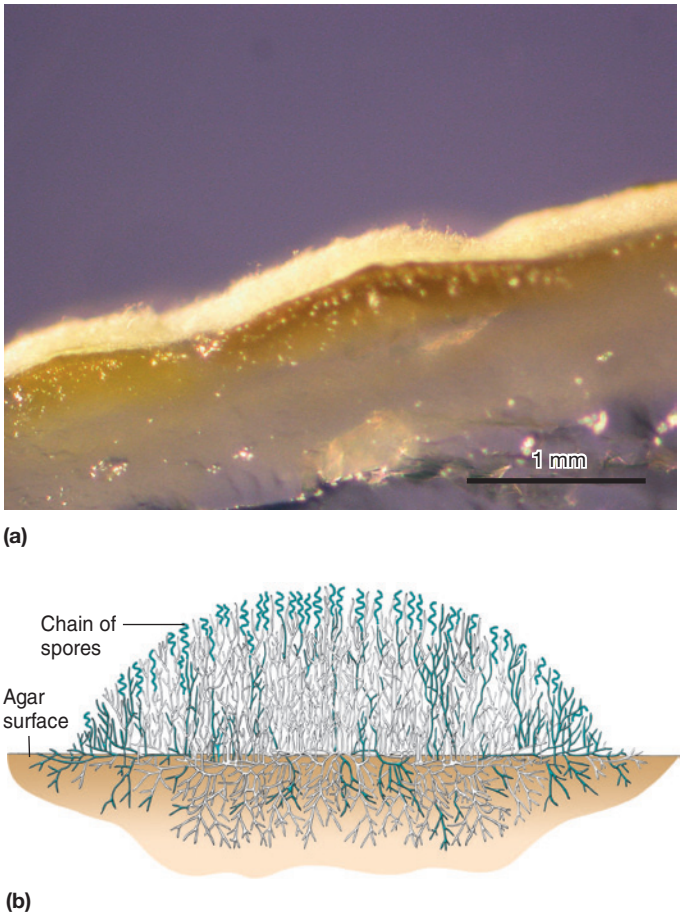

Figure 24.2 Cross Section of an Actinobacterial Colony. (a) This photomicrograph shows *Streptomyces griseus* substrate hyphae (yellow) growing into the agar and the white aerial hyphae growing away from the colony surface. (b) The colony consists of actively growing aerial hyphae that cannibalize the substrate hyphae to obtain nutrients. Live hyphae are blue; dead are white.

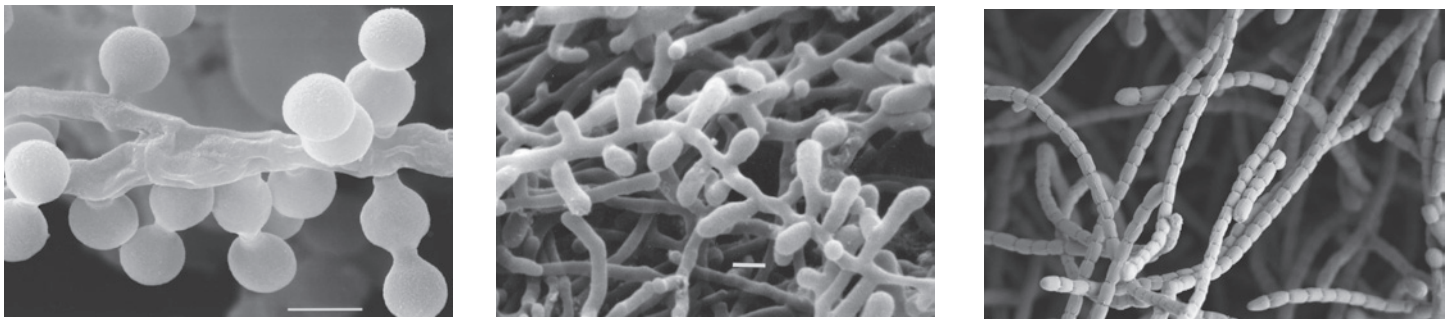
actinobacteria has switched from actively growing vegetative cells into this special, secondary cell type, these compounds are often called **secondary metabolites.**

Over time, aerial hyphae septate to form chains of spores. When the septum completes constriction, individual exospores are released into the environment. These spores are considered **exospores** because they do not develop within a mother cell as do the endospores of *Bacillus* and *Clostridium* spp. If the spores are located in a sporangium (a sheathlike structure), they may be called **sporangiospores.** The spores can vary greatly in shape (**figure 24.3**). Like spore formation in other bacteria, actinobacterial sporulation is in response to nutrient deprivation and chemical signaling between microbes. In general, actinobacterial spores are not particularly heat resistant but withstand desiccation well, so they are well suited to the sediment environment. Most actinobacteria are nonmotile, and spores dispersed by wind or animals may find a new habitat to provide needed nutrients. Interestingly, among the few motile actinobacteria, movement is confined to flagellated spores.



(a) (b) (c)

Figure 24.3 Examples of Actinomycete Spores as Seen in the Scanning Electron Microscope. (a) Spores of *Pseudonocardia yunnanensis* (bar = 1 μm). (b) Single spores of *Saccharomonospora viridis* are closely spaced along aerial hyphae. This organism causes farmer's lung. (c) Spore chain of *Streptomyces venezuelae*, which produces the antibiotic chloramphenicol.

Actinobacterial cell wall composition varies greatly among different groups and remains of taxonomic importance, despite the ubiquity of 16S rRNA analysis. Four major cell wall types can be distinguished based on the structure of the peptidoglycan and the cell wall sugar content (**figure 24.4** and **table 24.2**; *also see figure 3.17*). Peptidoglycan containing unusual other sugars can be used to categorize actinomycetes. Two aspects of amino acid content are also helpful: the amino acid in position 3 of the tetrapeptide side chain and the presence of glycine in interpeptide bridges. Some other taxonomically valuable properties include the color of the mycelium and sporangia, the surface features and arrangement of spores, the phospholipid composition of cell membranes, and spore heat resistance. ◀◀ *Peptidoglycan structure (section 3.4)*

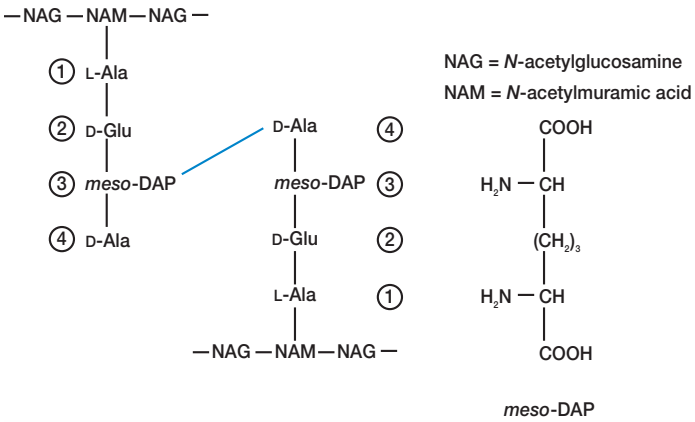


Figure 24.4 Actinobacterial Peptidoglycan Structure. Peptidoglycan with *meso*-diaminopimelic acid in position 3 and a direct cross-linkage between positions 3 and 4 of the peptide subunits is shown here. This is found in a variety of bacteria, including actinobacteria containing type III and IV cell walls (e.g., *Frankia* and *Nocardia*). Other actinobacteria have a glycine residue linking tetrapeptides.

MICRO INQUIRY *Refer to table 24.2 and determine how the cell walls of* Streptomyces *and* Actinoplanes *species differ from that shown here.*

Order *Actinomycetales*

The order *Actinomycetales* includes the genera *Actinomyces, Actinobaculum, Arcanobacterium,* and *Mobiluncus.* Most are irregularly shaped, nonsporing, Gram-positive rods with aerobic, facultative, or microaerophilic metabolism. The rods may be straight or slightly curved, and usually have swellings, club shapes, or other deviations from normal rod-shape morphology.

Members of the genus *Actinomyces* are either straight or slightly curved rods, or slender filaments with true branching (**figure 24.5**). The rods and filaments may have swollen or clubbed ends. They are either facultative or strict anaerobes that require CO_2 for optimal growth. *Actinomyces* species are normal inhabitants of mucosal surfaces of humans and other warm-blooded animals; the oral cavity is their preferred habitat. *A. bovis* causes lumpy jaw in cattle. *A. israelii* is most commonly responsible for actinomycoses, ocular infections, and lumpy jaw in humans.

Order *Micrococcales*

Of the wide variety of genera within the order *Micrococcales*, two of the best known are *Micrococcus* and *Arthrobacter.* The genus *Micrococcus* contains aerobic, catalase-positive cocci that occur mainly in pairs, tetrads, or irregular clusters and are usu-

Table 24.2 Actinobacterial Cell Wall Types and Whole Cell Sugar Patterns

Cell Wall Type	Diaminopimelic Acid Isomer	Glycine in Interpeptide Bridge	Characteristic Sugars	Representative Genera
I	L, L	+	NA[1]	*Nocardioides, Streptomyces*
II	*meso*	+	NA	*Micromonospora, Pilimelia, Actinoplanes*
III	*meso*	–	NA	*Actinomadura, Frankia*
IV	*meso*	–	Arabinose, galactose	*Saccharomonospora, Nocardia*

Whole Cell Sugar Patterns[2]	Characteristic Sugars	Representative Genera
A	Arabinose, galactose	*Nocardia, Rhodococcus, Saccharomonospora*
B	Madurose[3]	*Actinomadura, Streptosporangium, Dermatophilus*
C	None	*Thermomonospora, Actinosynnema, Geodermatophilus*
D	Arabinose, xylose	*Micromonospora, Actinoplanes*

1 NA, either not applicable or no diagnostic sugars.
2 Characteristic sugar patterns are present only in wall types II–IV, those actinobacteria with *meso*-diaminopimelic acid.
3 Madurose is 3-*O*-methyl-D-galactose.

ally nonmotile (**figure 24.6**). Unlike many other actinobacteria, micrococci do not undergo morphological differentiation. Their colonies often are yellow, orange, or red. They are widespread in soil, water, and on mammalian skin.

The genus *Arthrobacter* contains aerobic, catalase-positive rods with respiratory metabolism. Their most distinctive feature is a rod-coccus growth cycle (**figure 24.7**). When in exponential phase, these bacteria are irregular, branched rods that undergo snapping division (p. 557). As they enter stationary phase, the cells change to a coccoid form. Upon transfer to fresh medium, the coccoid cells differentiate to form actively growing rods. Although arthrobacters often are isolated from fish, sewage, and plant surfaces, like many other actinobacteria, their most important habitat is soil, where they constitute a significant component of the culturable microbial community. They are well adapted to this niche because they are resistant to desiccation and nutrient deprivation, even though they do not form spores. Arthrobacters are unusually flexible nutritionally and can even degrade some herbicides and pesticides.

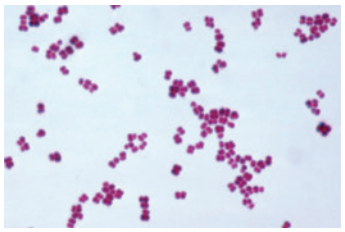

Figure 24.6 *Micrococcus.* *Micrococcus luteus*, Gram stain.

MICRO INQUIRY *What makes the morphology of* M. luteus *distinct from most other* actinobacteria *discussed in this chapter?*

Retrieve, Infer, Apply

1. Describe the function of the substrate mycelium, aerial mycelium, and exospore. Explain how these structures confer a survival advantage.
2. How can cell wall structure and sugar content be used to classify actinobacteria?
3. Why are actinobacteria of such practical interest?
4. List two genera that are commonly associated with humans.

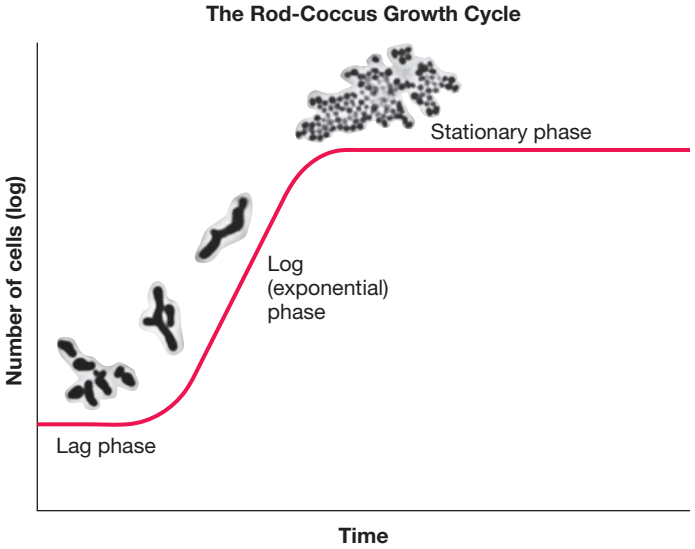

Figure 24.7 The Rod-Coccus Growth Cycle of *Arthrobacter* spp. When grown at 25°C, coccoid cells of about 1 μm in diameter (like those in stationary phase) swell and elongate to form branching rods of about 7–10 μm in length in exponential phase. As nutrients are depleted and cells enter stationary phase, the cells become spherical and form clusters.

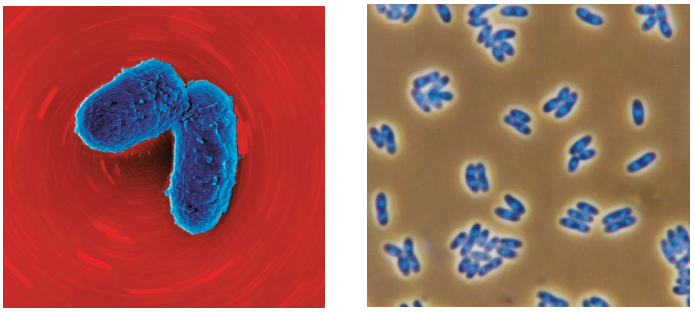

(a) (b)

Figure 24.8 ***Corynebacterium diphtheriae* Undergoes Snapping Division, Giving Rise to Cells in Palisades.** (a) Following snapping division, daughter cells remain attached and at an angle (×28,000). (b) This angular association of pairs of cells results in a palisade arrangement (×1,000).

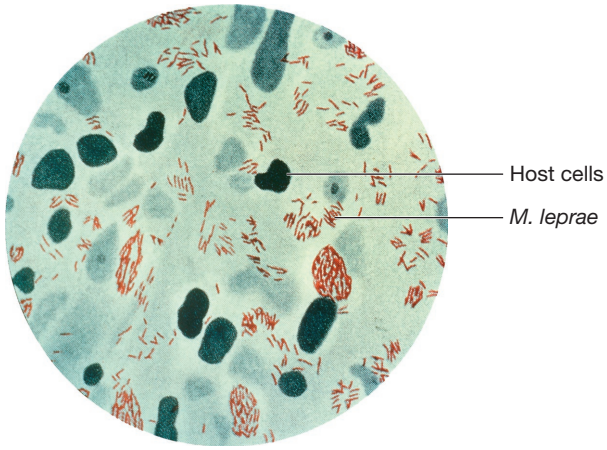

Figure 24.9 **Mycobacteria.** *Mycobacterium leprae* from a leprosy skin lesion, acid-fast stain (×1,000).

Order *Corynebacteriales* Includes Important Human Pathogens

The order *Corynebacteriales* includes three very important genera: *Corynebacterium, Mycobacterium,* and *Nocardia*. Species in these genera produce long-chain fatty acids, called mycolic acids. These lipids are a virulence factor and are essential for viability only in mycobacteria.

The family *Corynebacteriaceae* has one genus, *Corynebacterium,* which includes aerobic and facultative, catalase-positive, straight to slightly curved rods. Club-shaped cells are common. Both corynebacteria and arthrobacters have a two-layered cell wall that leads to **snapping division** (**figure 24.8*a***). This occurs because during cell division, only the inner layer grows inward to generate a septum dividing new cells. As the septum thickens, tension rises on the outer wall layer, which still holds the two cells together. Eventually increasing tension ruptures the outer layer at its weakest point, and a snapping movement tears the outer layer apart around most of its circumference. The new cells now rest at an angle to each other and are held together by the remaining portion of the outer layer, which acts as a hinge. This results in angular arrangements of the cells or a **palisade arrangement** in which rows of cells are lined up side by side (figure 24.8*b*). Although some species are harmless saprophytes, many corynebacteria are plant or animal pathogens. For example, *C. diphtheriae* is the causative agent of diphtheria in humans. ▶▶| *Diphtheria (section 39.1)*

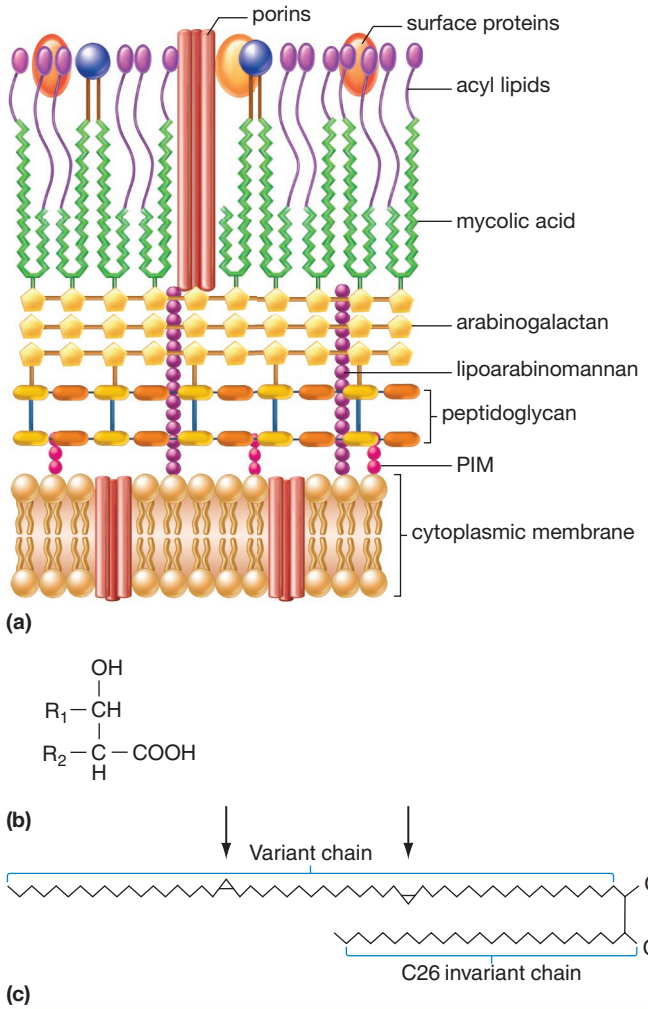

Figure 24.10 **Mycobacterial Cell Wall.** (a) The peptidoglycan layer is tethered to the plasma membrane by the glycolipids lipoarabinomannan and phosphatidylinositol mannosides (PIM). Arabinogalactan (D-arabinose and D-galactose), which is linked to mycolic acids, is also attached to the peptidoglycan, and is covered by a lipid bilayer. Like Gram-negative bacteria, mycobacteria have porins to regulate the passage of small molecules across the outer membrane. (b) The generic structure of mycolic acids, a family that includes over 500 different types. (c) An example mycolic acid with two cyclopropane rings.

MICRO INQUIRY *Why do* Mycobacterium *spp. have porins?*

The family *Mycobacteriaceae* contains the genus *Mycobacterium,* which is composed of slightly curved or straight rods that sometimes branch or form filaments (**figure 24.9**). Mycobacterial filaments readily fragment into rods and coccoid bodies. They are aerobic and catalase positive. Mycobacteria grow very slowly and must be incubated for 2 to 40 days after inoculation on a complex medium to form a visible colony.

Although mycobacteria are considered Gram positive, their cell walls possess an outer membrane, and their peptidoglycan is held within the periplasm (**figure 24.10*a***). The outer membrane is constructed of tightly packed, covalently linked **mycolic acids** and noncovalently attached shorter lipids. Mycolic acids are complex fatty acids with an invariant C26 fatty acid that is attached to a

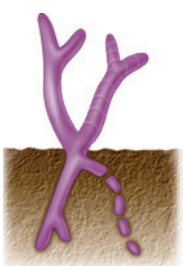
longer, variable fatty acid (figure 24.10*b*). Mycolic acids in the outer membrane are covalently linked to the peptidoglycan by arabinogalactan, a polysaccharide made of arabinose and galactose subunits. The cell wall is extremely hydrophobic and impenetrable to most organic molecules, including antibiotics. In fact, mycobacteria have evolved porins that enable the entry of small molecules (*see figure 3.26*). In addition, the mycobacterial outer membrane possesses a recently discovered mechanism for protein secretion called the type VII secretion system. The lipid content makes the cell wall **acid-fast** (basic fuchsin dye cannot be removed from the cell by acid alcohol treatment). ⏮ *Differential staining (section 2.3); Protein maturation and secretion (section 13.8)*

Although some mycobacteria are free-living saprophytes, they are best known as animal pathogens. *M. bovis* causes tuberculosis in cattle, other ruminants, and primates. Because this bacterium can produce tuberculosis (TB) in humans, dairy cattle are tested for the disease yearly; milk pasteurization kills the pathogen. Prior to widespread milk pasteurization, contaminated milk was a significant source of transmission. Today *M. tuberculosis* is the chief source of tuberculosis in humans. It is estimated that about one-third of the world's population is infected with *M. tuberculosis* (*see figure 39.4*). Leprosy is also a mycobacterial human disease; it is caused by *M. leprae* (figure 24.9). Finally, *M. avium* and the related species *M. intracellulare* comprise *M. avium* complex (MAC), which has become a common mycobacterial disease in developed countries, particularly among individuals with compromised immunity. ⏮ *Comparative genomics (section 18.7)* ⏭ Mycobacterium *infections (section 39.1); Mycobacterial skin infections (section 39.3)*

The family *Nocardiaceae* is composed of two genera, *Nocardia* and *Rhodococcus.* These bacteria develop a substrate mycelium that readily breaks into rods and coccoid fragments (**figure 24.11**). They also form an aerial mycelium that may produce conidia. Almost all are strict aerobes. These and related bacteria that resemble members of the genus *Nocardia* (named after Edmond Nocard [1850–1903], French bacteriologist and veterinary pathologist) are collectively called **nocardioforms.**

Nocardia bacteria are distributed worldwide in soil and aquatic habitats. They are involved in the degradation of hydrocarbons and waxes, and can contribute to the biodeterioration of rubber joints in water and sewage pipes. Although most are free-living saprophytes, some species, particularly *N. asteroides,* are opportunistic pathogens that cause nocardiosis in humans and other animals. People with low resistance due to other health problems, such as individuals with HIV-AIDS, are most at risk. The lungs are typically infected; other organs and the central nervous system may be invaded as well.

Rhodococcus contains species that are widely distributed in soils and aquatic habitats. They are of considerable interest because they can degrade an enormous variety of molecules such as petroleum hydrocarbons, detergents, benzene, polychlorinated biphenyls (PCBs), and various pesticides.



Nocardia

Figure 24.11 Nocardioforms. These bacteria form substrate hyphae that fragment as well as aerial hyphae that differentiate into spores.

Retrieve, Infer, Apply

1. Compare the morphology and cell wall structure of corynebacteria with that of mycobacteria.
2. What is snapping division? How does it lead to palisade formation?
3. What implications does the complex hydrophobic mycobacterial cell wall have in terms of treating diseases caused by these bacteria?
4. What is a nocardioform? List two reasons these microbes are relevant to humans.

Order *Micromonosporales* Includes Bacteria That Produce Morphologically Diverse Spores

The order *Micromonosporales* contains the genera *Micromonospora, Dactylosporangium, Pilimelia,* and *Actinoplanes.* These bacteria are often called actinoplanetes (Greek *actinos,* a ray or beam, and *planes,* a wanderer). They have an extensive substrate mycelium but usually lack all but a rudimentary aerial mycelium. Often the hyphae are highly colored, and diffusible pigments may be produced. Spores are usually formed within a sporangium raised above the surface of the substratum at the end of a special hypha called a sporangiophore. The spores are quite unusual because in some species, they demonstrate flagellated motility. Flagella attach to a new substrate, where spores remain until triggered to germinate. The morphology and arrangement of spores is also variable. For instance, *Actinoplanes* and *Pilimelia* spp. have sporangia that may have only a few spores, while other species produce thousands of spores per sporangium (**figure 24.12**). The spores are arranged in coiled or parallel chains. *Dactylosporangium* spp. form club-shaped, fingerlike, or pyriform sporangia with one to six spores (figure 24.12*c*). *Micromonospora* bacteria bear single spores, which often occur in branched clusters of sporophores.

Actinoplanetes grow in almost all soil habitats, ranging from forest litter to beach sand. Some flourish in freshwater, particularly in streams and rivers (probably because of abundant oxygen and plant debris), others are marine. Actinoplanes is the source of the drug acarbose used to treat type 2 diabetes. The soil-dwelling species may have an important role in the decomposition of plant and animal material. *Pilimelia* bacteria grow in association with keratin. *Micromonospora* spp. actively degrade chitin and cellulose, and produce antibiotics such as gentamicin.

Order *Propionibacteriales*

The order *Propionibacteriales* contains the genus *Propionibacterium,* pleomorphic, nonmotile, nonsporing rods that are often club-shaped with one end tapered and the other end rounded. The most famous members of this genus are used to produce Swiss cheese, where its gaseous products of fermentation are responsible for the holes. Cells also may be coccoid or branched. They can be single, in short chains, or in clumps. They are facultatively anaerobic or aerotolerant; lactate and sugars are fermented to produce large quantities of propionic and acetic acids, and often carbon dioxide. In animals, these bacteria are found growing in

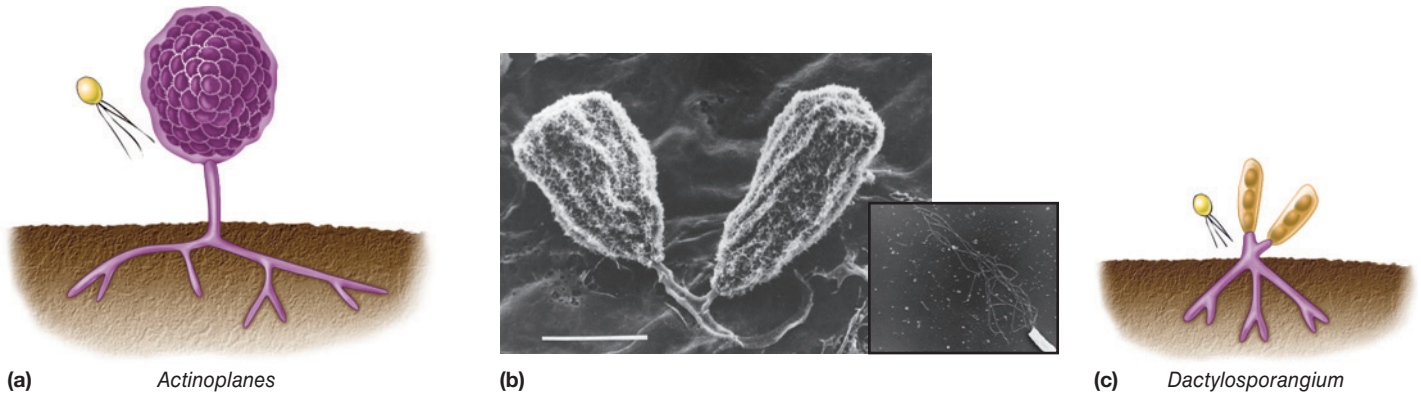


Figure 24.12 ***Micromonosporaceae.*** Actinoplanete morphology. (a) *Actinoplanes* structure. (b) A scanning electron micrograph of mature *Actinoplanes capillaceus* sporangia; inset shows a motile spore. (c) *Dactylosporangium* structure.

the digestive tract and on the skin. *P. acnes* is involved with the development of body odor and is thought to cause acne vulgaris.

Order *Streptomycetales:* An Important Source of Antibiotics

The order *Streptomycetales* has only one family, *Streptomycetaceae,* and three genera, the most important of which is *Streptomyces.* This is a large genus; there are about 150 species. All are considered strict aerobes. Members of this family and similar bacteria are often called **streptomycetes** (Greek *streptos,* bent or twisted, and *myces,* fungus).

Like Gram-negative myxobacteria, streptomycetes are a good example of true multicellularity among bacteria. This is illustrated by their life cycle (**figure 24.13**). Single, nonmotile exospores germinate to produce long substrate hyphae. These form a dense substrate mycelium. Upon receipt of cues that indicate nutrient limitation and intercellular signals, the substrate hyphae grow up into the air to form aerial hyphae. Aerial hyphae obtain nutrients by cannibalizing the filaments within the substrate mycelium. It is at this point in the life cycle that the stressed but still surviving substrate hyphae produce antibiotics and other secondary metabolites. As aerial hyphae continue to grow, they curl and septate in regular intervals. Ultimately the aerial hyphae become chains of spores that pinch off into single exospores to begin the cycle anew. Interestingly, the process of exospore formation is dependent on the cytoskeletal proteins FtsZ and MreB, but vegetative growth is not, because substrate hyphae grow by extending their tips rather than by binary fission. This results in long filaments with only occasional septae. Because multiple nucleoids are enclosed in the same cell, this is called syncytial growth. ◀◀ *Cytokinesis (section 7.2)* ▶▶ *Antibiotics (section 42.1)*

Streptomycetes are very important both ecologically and medically. The natural habitat of most streptomycetes is the soil, where they may constitute from 1 to 20% of the culturable population. In fact, the odor of moist earth is largely the result of streptomycete production of volatile substances such as geosmin. Streptomycetes play a major role in mineralization—the degradation of organic matter to inorganic elements. As substrate hyphae grow into the earth, they secrete a variety of exoenzymes enabling the degradation of resistant substances such as pectin, lignin, chitin, keratin, latex, agar, and aromatic compounds. ▶▶ *Diverse microorganisms inhabit soil (section 31.2)*

Selman Waksman's discovery that *S. griseus* (**figure 24.14*a***) produces streptomycin, the first drug to cure TB, set off a massive search resulting in the isolation of new *Streptomyces* species

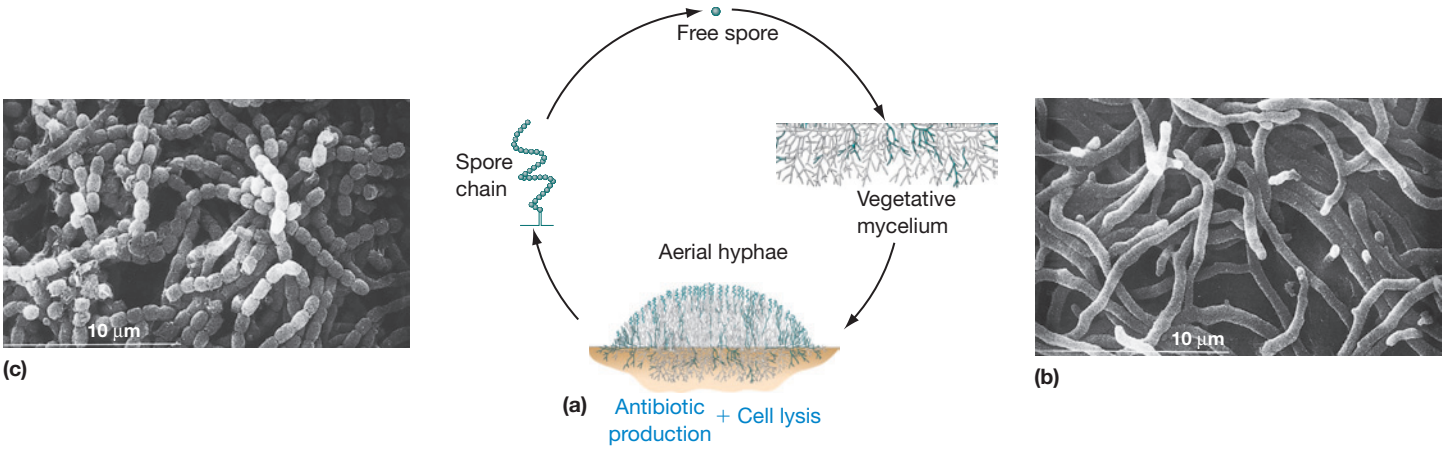

Figure 24.13 ***Streptomyces*** **Life Cycle.** (a) Streptomycetes form three types of cells: exospores germinate to produce vegetative (also called substrate) hyphae, which then differentiate into aerial hyphae. These give rise to chains of exospores. Scanning electron micrographs are shown of (b) *S. coelicolor* vegetative hyphae and (c) chains of exospores.

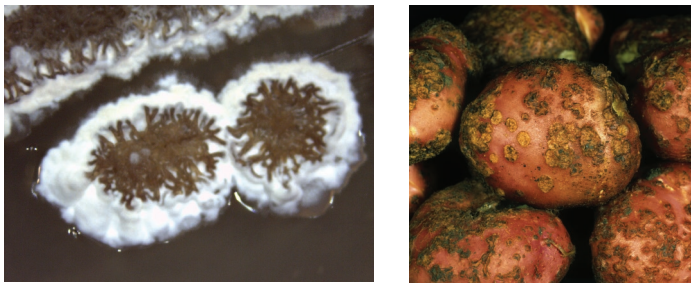

(a) (b)

that produce other compounds of medicinal importance. Since that time, streptomycetes have been found to produce over 10,000 bioactive compounds; a few are listed in **table 24.3**. Hundreds of these natural products are now used in medicine and industry; about two-thirds of the antimicrobial agents used in human and veterinary medicine are derived from streptomycetes. Antibiotic-producing bacteria have "immunity" genes that encode proteins (or small noncoding RNA) that make them resistant to the antibiotics they synthesize. ⏮ *Antimicrobial chemotherapy (chapter 9)*

The genome of *Streptomyces coelicolor,* which produces four antibiotics, is one of the largest bacterial genomes (8.67 Mbp). Its large number of genes (7,825) no doubt reflects the number of proteins required to undergo a complex life cycle. Many genes are devoted to regulation, with an astonishing 65 predicted RNA polymerase sigma transcription factors and about 80 two-component regulatory systems. The ability to exploit a variety of soil nutrients is also demonstrated by the presence of a large number of ABC transporters, the Sec and two Tat protein translocation systems, and over 50 secreted degradative enzymes. ⏮ *Protein maturation and secretion (section 13.8); Regulation of transcription initiation saves considerable energy and materials (section 14.2)*

Although most streptomycetes are nonpathogenic saprophytes, a few are associated with plant and animal diseases. *Streptomyces scabies* causes scab disease in potatoes and beets (figure 24.14*b*). *S. somaliensis* is the only streptomycete known to be pathogenic to humans. It is associated with actinomycetoma, an unusual infection of subcutaneous tissues that produces lesions that lead to swelling, abscesses, and even bone destruction if untreated. *S. albus* and other species have been isolated from patients with various ailments and may be pathogenic.

Order *Streptosporangiales*

The order *Streptosporangiales* includes maduromycetes, so named because they produce the sugar derivative **madurose** (3-*O*-methyl-D-galactose). Aerial hyphae bear pairs or short chains of spores, and the substrate hyphae are branched (**figure 24.15**). Members of some genera form sporangia; spores are not heat resistant. *Thermomonospora* bacteria

Table 24.3 Examples of Natural Products Made by Streptomycetes

Microbe	Natural Product	Application
Streptomyces orientalis	Vancomycin	Antibiotic: cell wall inhibitor
S. mediterranei	Rifamycin	Antibiotic: transcription inhibitor
S. rimosus	Tetracycline	Antibiotic: protein synthesis inhibitor
S. venezuelae	Chloramphenicol	Antibiotic: protein synthesis inhibitor

produce single spores on the aerial hyphae or on both the aerial and substrate hyphae. They have been isolated from moderately high-temperature habitats such as compost piles and hay and can grow at 40 to 48°C.

Order *Frankiales:* Bacteria That Fix N_2 in Trees

The order *Frankiales* includes the genera *Frankia* and *Geodermatophilus.* Species in both form multilocular sporangia, characterized by clusters of spores when hyphae divide both transversely and longitudinally. (Multilocular means having many cells or compartments.) *Geodermatophilus* spp. have motile spores and are aerobic soil organisms. *Frankia* spp. form nonmotile spores in a sporogenous body (**figure 24.16**). They grow in symbiotic association with the roots of at least eight families of higher nonleguminous plants (e.g., alder trees). They are microaerophilic and can fix atmospheric nitrogen.

Frankia bacteria fix nitrogen so efficiently that a plant such as an alder can grow in the absence of combined nitrogen (e.g., NO_3^-) (figure 24.16*b*). Within the nodule, these bacteria form branching hyphae with globular vesicles at their ends, which may be the sites of nitrogen fixation. Their nitrogenase resembles that of rhizobia in that it is oxygen sensitive and requires molybdenum and cobalt. ▶▶| *Nitrogen-fixing bacteria are vital to agriculture (section 31.3)*

Order *Bifidobacteriales:* Pathogens and Probiotics

The order *Bifidobacteriales* includes members of the genera *Falcivibrio* and *Gardnerella,* which are found in the human genital/urinary tract. *Gardnerella* spp. are thought to be a major cause of bacterial vaginitis. Bifidobacteria have gained recent attention as more is learned about the importance of human gut microflora. They are nonmotile, nonsporing, Gram-positive rods of varied shapes that are slightly curved and clubbed; often they are branched (**figure 24.17**). The rods can be single or in clusters and V-shaped pairs. They are anaerobic and actively ferment carbohydrates to produce acetic and lactic acids but not carbon dioxide. They are found in the mouth and intestinal tract of warm-blooded vertebrates, in sewage, and in insects. *B. bifidum* is a pioneer colonizer of the human intestinal tract, especially when babies are breast fed. *Bifidobacterium* species are sold as probiotic agents (particularly in yogurt) because they are thought to impart a health benefit. ▶▶| *Normal microbiota of the human body adapt to many sites (section 32.3); Probiotics (section 41.6)*

Retrieve, Infer, Apply

1. List the distinguishing properties of actinoplanetes. What other actinomycetes form motile spores?
2. Where would you most likely find a member of the genus *Propionibacterium* in your home or dormitory?
3. List three types of natural products made by members of the genus *Streptomyces.*
4. Describe three ways in which *Streptomyces* spp. are of ecological importance.
5. Briefly describe the defining properties of genera in the order *Streptosporangiales.* What is madurose?
6. Why are *Frankia* spp. considered ecologically important?
7. Examine the ingredients list on a commercial yogurt cup; are bifidobacteria present?

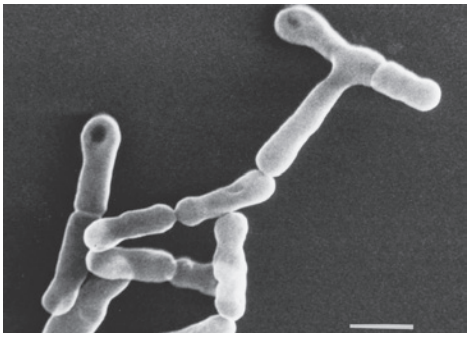

Figure 24.17 ***Bifidobacterium.*** *Bifidobacterium bifidum*; scanning electron photomicrograph.

Key Concepts

24.1 Class *Actinobacteria*

- Members of this class that form branching, usually nonfragmenting hyphae and asexual spores are collectively called actinobacteria or actinomycetes (**figure 24.2**).
- The asexual spores borne on aerial hyphae are called exospores because they do not develop within a mother cell. Some produce sporangiospores.
- Actinobacteria have several distinctively different types of cell walls and often also vary in terms of the sugars present in cell extracts. Properties such as color and morphology are also taxonomically useful (**tables 24.1** and **24.2; figure 24.4**).
- Members of the genus *Actinomyces* are irregularly shaped, nonsporing rods that can cause disease in cattle and humans.
- Members of the genus *Micrococcus* are unusual members of this class because they form simple coccoid cells. Some species are normal inhabitants on human skin.
- Arthrobacters have an unusual rod-coccus growth cycle and, like corynebacteria, carry out snapping division (**figures 24.7**).
- Corynebacteria form irregular and club-shaped cells that are often arranged in palisades. *C. diphtheriae* is the cause of diphtheria (**figure 24.8**).
- Mycobacteria form either rods or filaments that readily fragment. Their cell walls have a high lipid content and mycolic acids, which makes them acid-fast (**figures 24.9** and **24.10**).
- Nocardioform actinobacteria have hyphae that readily fragment into rods and coccoid elements, and often form aerial mycelia with spores (**figure 24.11**).
- *Micromonospora* and *Actinoplanes* spp. have an extensive substrate mycelium and form aerial sporangia and are present in soil, freshwater, and the ocean (**figure 24.12**).
- Members of the genus *Propionibacterium* are common skin and intestinal inhabitants, and are important in cheese manufacture and the development of acne vulgaris.
- The order *Streptomycetales* includes the genus *Streptomyces*. Members of this genus produce substrate hyphae that differentiate into aerial hyphae-bearing chains of 3 to 50 or more exospores (**figure 24.13**).
- Streptomycetes are important in the degradation of resistant organic material in the soil and produce many useful antibiotics. A few cause diseases in plants and animals. However, they are most notable for the variety of antibiotics and other medically and industrially important compounds they produce (**table 24.3**).
- The genera *Frankia* and *Geodermatophilus* are placed in the order *Frankiales*. *Frankia* spp. grow in symbiotic association with nonleguminous plants and fix nitrogen (**figure 24.16**).
- The genus *Bifidobacterium* is placed in the order *Bifidobacteriales*. Bifidobacteria are irregular, anaerobic rods and one of the first colonizers of the intestinal tract in nursing babies.
- Members of the genus *Bifidobacterium* are often sold for their probiotic activity.

Compare, Hypothesize, Invent

1. Even though actinobacteria are high G + C organisms, there are regions of the genome that are AT-rich. Suggest a few such regions and explain why they must be more AT-rich.
2. Given that mycolic acids are essential for mycobacterial viability, how would you test their importance in mycobacterial infection?
3. *Streptomyces coelicolor* is studied as a model system for cellular differentiation. Some of the genes involved in sporulation contain an AT-rich leucine codon not used in vegetative genes. Suggest how *Streptomyces* might use this rare codon to regulate sporulation.
4. Suppose that you discovered a nodulated plant that could fix atmospheric nitrogen. How might you show that a bacterial symbiont was involved and that a *Frankia* sp. rather than a *Rhizobium* sp. was responsible?
5. It has long been held that soil microbes such as the streptomycetes produce antibiotics so that they can kill neighboring microbes and use the nutrients released. However, it has been found that each of 480 soil bacterial isolates were resistant to 6 to 20 different antibiotics. Separate research demonstrates that hundreds of soil bacteria can use assorted antibiotics as their sole carbon source. These data, together with the ability of sublethal concentrations of antibiotics to trigger diverse responses in nontarget microbes, have stimulated the hypothesis that in nature, antibiotics are used as signaling molecules rather than weapons. Do you think this argument has any merit and how would you test it?

Protists

Fruiting bodies of the social protist Dictyostelium discoideum. *This amazing microbe farms its food and has three "sexes," or mating types.*

Sustainable Farming Practiced by Amoebae

The advent of farming changed the course of human evolution; without the need to hunt and gather, our ancestors could form larger, more cohesive social groups. However, we are not the first farmers. For decades, scientists have known of beetles, termites, and ants that farm fungi (*see figure 32.12*). Now an even more primitive kind of farming has been discovered. It is performed by an amoeba called *Dictyostelium discoideum* (Dicty for short).

Dicty lives in soil where it grows as solitary, single-celled microbes preying on bacteria. If Dicty runs short of bacterial food, cells join forces and form a multicellular slug that migrates to a new, food-rich area (section 25.3). Once there, the slug forms a fruiting body consisting of two parts: a spherical sorus that houses cells that have become spores and a supporting stalk, also made of Dicty cells. While it was well established that fruiting body formation is a means of dispersal to a site with a better food supply, researchers at Rice University in Texas have now shown that about a third of Dicty fruiting bodies bring their food with them.

When grown in the presence of bacterial food, the farming Dicty stop eating before those that do not farm. Dicty farmers then pack up the leftovers (no brown bags involved) in each sorus. The sorus of nonfarming Dicty contains only amoebae. When slugs arrive at a spot deemed suitable for germination, the farmers have a ready food supply consisting of the bacteria they packed in the sorus. So regardless of where they move, they are sure to have their "favorite" species for consumption.

But there are a couple of drawbacks with this system. First, if farmer and nonfarmer slugs are placed in a head-to-head migration race, the nonfarmers go farther (but not necessarily faster). This means the nonfarmer is more likely to escape the poor conditions that triggered slug formation in the first place. Furthermore, if both types of Dicty settle in regions of equal food supply, the farmers have no advantage; farmers and nonfarmers grow equally well. Nonetheless, bacterial husbandry can be a lifesaver, so why is it found in only a third of all isolates? The answer may rest with the fact that Dicty eats a varied diet, consuming a wide range of soil bacteria. This presumably has prevented the kind of co-evolution between prey and predator seen in other systems ranging from viruses and their cellular hosts to superpredators and their quarry on the African plains.

So far, our discussion of microbial diversity has focused on *Bacteria* and *Archaea.* We now survey the vast diversity of the eukaryotic microbial world, starting with protists and moving on to fungi in chapter 26. The general structure of eukaryotic cells is reviewed in chapter 5; here we focus on adaptations that make these microorganisms successful competitors.

Eukaryotic microorganisms suffer from a confused taxonomic history. The kingdom Protista, as presented in many introductory biology texts, is an artificial grouping of over 64,000 different single-celled life forms that lack common evolutionary heritage; that is, they are not monophyletic (*see figure 1.2*). In this text, we refer to these organisms simply as **protists.** Protists are unified only by what they lack: absent is the level of tissue organization found in the more evolved fungi, plants, and animals. The term **protozoa** (s., protozoan; Greek *protos,* first, and *zoon,* animal) refers to chemoorganotrophic protists. The term **algae** can be used to describe photosynthetic protists that, like plant cells, possess a cell wall. The study of photosynthetic protists (algae) is often referred to as **phycology** and is the realm of both botanists and protistologists. The study of all protists, regardless of their metabolic type, is called **protistology,** although the term **protozoology** is more commonly used.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Draw a eukaryotic cell envelope and identify the structure and function of its component layers (section 5.2)
- ✔ List the three filaments that make up the cytoskeleton of eukaryotic cells and describe how they are used (section 5.3)
- ✔ Identify the structure and function of eukaryotic cellular organelles (sections 5.4–5.6)
- ✔ Describe the endocytic pathway in general terms (section 5.4)
- ✔ Explain the difference between a mitochondrion and a hydrogenosome (section 5.6)
- ✔ Describe the structure and function of eukaryotic flagella and cilia (section 5.7)

25.1 Protist Diversity Reflects Broad Phylogeny

After reading this section, you should be able to:

- Describe three nutritional strategies used by protists
- Draw a typical protist cell membrane and underlying features, labeling the plasmalemma, ecto- and endoplasm, and pellicle
- Explain how contractile vacuoles are used to maintain osmotic stability
- Trace the passage of a food particle as it is consumed by a protozoan
- Compare binary fission as it occurs in a protist with that in a bacterium or archaeon
- Outline the process of sexual reproduction and how it can vary in protists

Most eukaryotes are microbes. It is therefore not surprising that the vast diversity of protists is a function of their capacity to thrive in a wide variety of habitats. Their one common requirement is moisture because all are susceptible to desiccation. Most protists are free living and inhabit freshwater or marine environments. Many terrestrial chemoorganotrophic forms can be found in decaying organic matter and soil. Whether terrestrial or aquatic, protists play an important role in nutrient cycling. ▶▶| *Biogeochemical cycling sustains life on Earth (section 28.1)*

Some protozoa, or chemoorganoheterotrophic protists, are **saprophytes,** securing nutrients from dead organic material by releasing degradative enzymes into the environment. They then absorb the soluble products—a process sometimes called **osmotrophy.** Other protozoa employ **holozoic nutrition,** in which solid nutrients are acquired by phagocytosis. Photoautotrophic protists are strict aerobes and, like cyanobacteria, use photosystems I and II to perform oxygenic photosynthesis. It is difficult to classify the nutritional strategies of some protists because they simultaneously use reduced organic molecules and CO_2 as carbon sources. This strategy is called **mixotrophy.**

Protist Morphology

Despite their diversity, protists share many common features. In many respects, their morphology and physiology are the same as the cells of multicellular plants and animals. However, because many protists are unicellular, all of life's various functions must be performed within a single cell. Those that are multicellular lack highly differentiated tissues. Therefore the structural complexity observed in protists arises at the level of specialized organelles.

The protist cell membrane is called the **plasmalemma** and is identical to that of multicellular organisms (**figure 25.1**). In some protists, the cytoplasm immediately under the plasmalemma is divided into an outer gelatinous region called the **ectoplasm** and an inner fluid region, the **endoplasm.** The ectoplasm imparts rigidity to the cell body. Many protists also have a supportive mechanism called the **pellicle.** The pellicle consists of the plasmalemma and a relatively rigid layer just beneath it. The pellicle may be simple in structure. For example, *Euglena* spp.

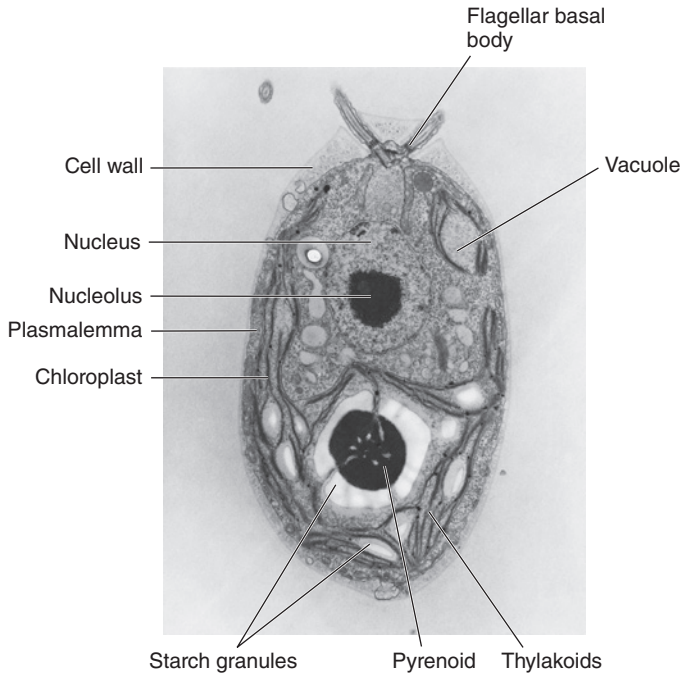

Figure 25.1 Protist Structure. A transmission electron micrograph of the photosynthetic protist *Chlamydomonas reinhardtii* is shown as an example.

are protists with a series of overlapping strips with a ridge at the edge of each strip fitting into a groove on the adjacent one, much like how the "tongue-and-groove" boards of a hardwood floor fit together. In contrast, the pellicles of ciliate protists are exceptionally complex with two membranes and a variety of associated structures. Although pellicles are not as strong and rigid as cell walls, for those that possess them, pellicles impart the characteristic shape associated with that particular species.

One or more vacuoles are usually present in the cytoplasm of protozoa. These are differentiated into contractile, secretory, and food or phagocytic vacuoles. **Contractile vacuoles** function as osmoregulatory organelles in protists that live in hypotonic environments, such as freshwater lakes. Contractile vacuoles maintain osmotic balance by continuous water expulsion. **Phagocytic vacuoles** are conspicuous in protists that ingest food by phagocytosis (holozoic protists). Phagocytic vacuoles are the sites of food digestion. In some organisms, they may occur anywhere on the cell surface, while others have a specialized structure for phagocytosis called the **cytostome** (cell mouth). Once the cytostome has engulfed a food particle, digestion commences when the phagocytic vacuole becomes acidic. As digestion proceeds, the vacuole membrane forms small blebs that pinch off and carry nutrients throughout the cytoplasm. The undigested contents of the original phagocytic vacuole are expelled from the cell either at a random site on the cell membrane or at a designated position called the **cytoproct** (Greek, *proktos,* anus).

The diversity of energy-conserving organelles observed in protists reflects their evolutionary history and life style. Most aerobic chemoorganotrophic protists have mitochondria, while photosynthetic forms have chloroplasts. A dense proteinaceous

area, the **pyrenoid,** which is associated with the synthesis and storage of starch, may be present in chloroplasts. The majority of anaerobic chemoorganotrophic protists lack mitochondria; some of these organisms have hydrogenosomes.

Many protists feature cilia or flagella at some point in their life cycle. Their formation is associated with a basal bodylike organelle called the kinetosome. In addition to aiding in motility, these organelles may be used to generate water currents for feeding and respiration.

Encystment and Excystment

Many protists are capable of **encystment.** During encystment, the organism becomes simpler in morphology and develops into a resting stage called a cyst. The cyst is a dormant form marked by the presence of a cell wall and very low metabolic activity. Cyst formation is particularly common among aquatic, free-living protists and parasitic forms. Cysts serve three major functions: (1) they protect against adverse changes in the environment, such as nutrient deficiency, desiccation, adverse pH, and low levels of O_2; (2) they are sites for nuclear reorganization and cell division (reproductive cysts); and (3) in parasitic species they are the infectious stage between hosts. Protists escape from cysts by a process called **excystment** (**figure 25.2**). Although the exact stimulus for excystment is unknown for most protists, it is generally triggered by a return to favorable environmental conditions. For example, cysts of parasitic species excyst after ingestion by the host.

Protist Reproductive Cells and Structures

Most protists have both asexual and sexual reproductive phases in their life cycles. The most common method of asexual reproduction is **binary fission.** During this process, the nucleus first undergoes mitosis and then the cytoplasm divides by cytokinesis to form two identical individuals (**figure 25.3**). Multiple fission is also common, as is budding. Some filamentous, photosynthetic protists undergo fragmentation so that each piece of the broken filament contains a nucleus and grows independently.

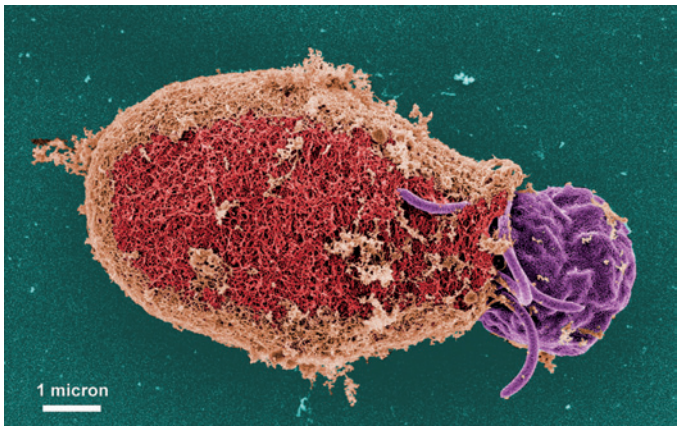

Figure 25.2 Excystment. This colorized scanning electron micrograph shows the protist *Giardia* sp. undergoing excystment. The flagellated vegetative cell, called a trophozoite, is emerging from the right of the cyst.

Sexual reproduction involves the formation of gametes. Protist cells that produce gametes are termed **gamonts.** The fusion of haploid gametes is called **syngamy.** Among protists, syngamy can involve the fusion of two morphologically similar gametes (isogamy) or two morphologically different types (anisogamy). Meiosis may occur before the formation and union of gametes, as in most animals, or just after fertilization, as is the case with lower plants. Furthermore, the exchange of nuclear material may occur in the familiar fashion—between two different individuals (**conjugation**)—or by the development of a genetically distinct nucleus within a single individual (autogamy).

With this level of reproductive complexity, perhaps it is not surprising that the nuclei among protists show considerable diversity. Most commonly, a vesicular nucleus is present. This is 1 to 10 μm in diameter, spherical, and has a distinct nucleolus and uncondensed chromosomes (figure 25.1). The uncondensed chromosomes give these nuclei a lacy or vesicular appearance when viewed microscopically. Ovular nuclei are up to 10 times this size and possess many peripheral nucleoli. Still others have chromosomal nuclei, in which the chromosomes remain condensed throughout the cell cycle. Finally, many ciliated forms have two types of nuclei: a large macronucleus with distinct nucleoli and condensed chromatin, and a smaller, diploid micronucleus with dispersed chromatin but lacking nucleoli. Genes in the macronucleus encode proteins involved in housekeeping functions and binary fission, whereas genes on the micronucleus function only in sexual reproduction (p. 574).

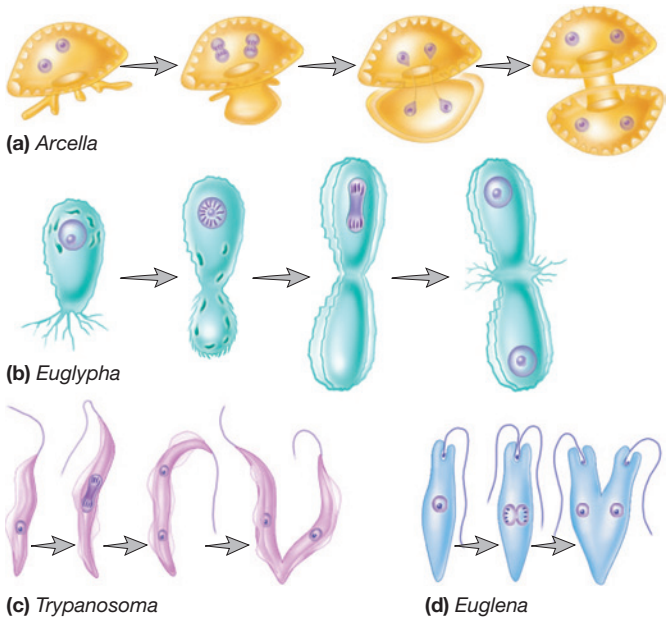

Figure 25.3 Binary Fission in Protists. (a) The two nuclei of a testate (shelled) amoeba in the genus *Arcella* divide as some of its cytoplasm is extruded and a new test for the daughter cell is secreted. (b) Members of another testate amoeba genus, *Euglypha,* begin to secrete new platelets before cytoplasm begins to move out of the aperture. The nucleus divides while the platelets are used to construct the test for the daughter cell. For many protists, all organelles must be replicated before the cell divides. This is also the case with species of (c) *Trypanosoma* and (d) *Euglena.*

Protist Taxonomy Is Controversial

Ever since Antony van Leeuwenhoek described the first protozoan "animalcule" in 1674, the taxonomic classification of protists has remained in flux. During the twentieth century, classification schemes were based on morphology and protists were typically classified into four major groups based on their means of locomotion: flagellates (*Mastigophora*), ciliates (*Infusoria* or *Ciliophora*), amoebae (*Sarcodina*), and stationary forms (*Sporozoa*). Although these terms may still be encountered, they are without evolutionary context and should be avoided. While it is now agreed that the old classification system is best abandoned, little agreement exists on what should take its place. Here we use a modified version of the higher-level classification system for the eukaryotes based on morphological, biochemical, and phylogenetic analyses proposed by the International Society of Protistologists in 2005. This scheme does not use formal hierarchical rank designations such as class and order, reflecting the fact that protist taxonomy remains an area of active research.

Retrieve, Infer, Apply

1. Describe the pellicle. What is its function?
2. Trace the path of a food item from the phagocytic vacuole to the cytoproct.
3. What functions do cysts serve for a typical protist? What causes excystment to occur?
4. What is a gamont? What is the difference between anisogamy, isogamy, and syngamy?
5. How does conjugation differ from autogamy?
6. Describe vesicular, ovular, and chromosomal nuclei. Which is most like the nuclei found in higher eukaryotes?
7. Why has taxonomic classification of protists been problematic?

25.2 Supergroup *Excavata:* Primitive Eukaryotes

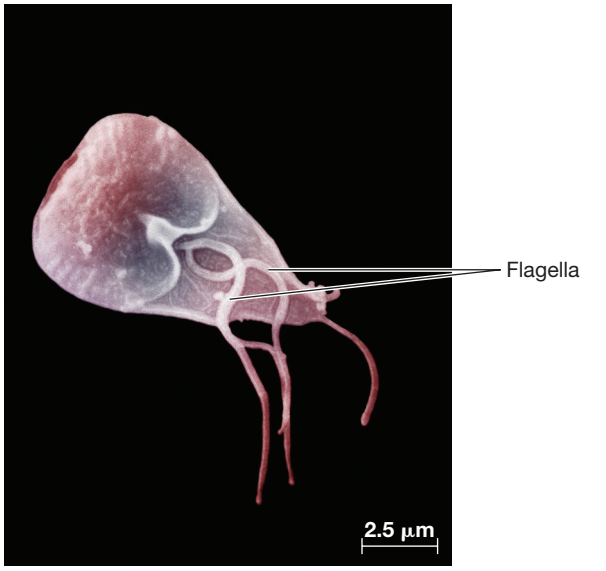
After reading this section, you should be able to:

- Differentiate a mitosome from a mitochondrion
- Identify which members of *Excavata* have hydrogenosomes
- Identify a location near your home or school where you might find protists in the taxa *Fornicata, Parabasalia,* and *Euglena*
- List one human and one veterinary disease caused by species of *Fornicata* and *Parabasalia*
- Draw a typical euglenoid cell and explain the function of the stigma and pyrenoid
- Discuss the etiology of Chagas' disease and African sleeping sickness

Excavata includes some of the most primitive, or deeply branching, eukaryotes. Most possess a cytostome characterized by a suspension-feeding groove with a posteriorly directed flagellum used to generate a feeding current. This enables the capture of small particles. Those that lack this morphological feature are presumed to have had it at one time during their evolution; that is, it is thought to have been secondarily lost.

Fornicata

Ever curious, van Leeuwenhoek described *Giardia lamblia* (**figure 25.4*a***) from his own diarrheic feces. Over 300 years later, this species, now known as *G. intestinalis,* continues to be a public health concern. Today this microaerophilic protist most often infects campers and other individuals who unwittingly



(a) *Giardia intestinalis*

Figure 25.4 Parasitic Members of the Supergroup *Excavata*. (a) *Giardia intestinalis.* (b) *Trichomonas vaginalis.* These specialized parasitic flagellates absorb nutrients from living hosts.

MICRO INQUIRY *How are these two protists morphologically similar but physiologically different?*

consume contaminated stream or river water. It is the most common cause of epidemic waterborne diarrheal disease in the United States (about 30,000 cases yearly). Members of *Fornicata* bear flagella and lack mitochondria. However, they possess mitochondria-like double-bounded membrane organelles called **mitosomes.** Although these primitive organelles share ancestry with mitochondria and hydrogenosomes, they do not appear to be involved in ATP synthesis. Instead the mitosomes of *G. intestinalis* are involved in producing FeS proteins. ▶▶| *The classic mitochondrion is only one member of the mitochondrial family of organelles (section 5.6)*

Cyst formation is key to *G. intestinalis* survival. Ingestion of only about 10 cysts is needed for infection, which involves its attachment to gut cells called enterocytes. When these enterocytes die and are sloughed from the gut, the microbe must "decide" whether to attach to another enterocyte or encyst and exit to find a new host. When a cyst enters a new host, the presence of bile and the slightly alkaline conditions of the small intestine trigger excystment (figure 25.2). ▶▶| *Giardiasis (section 40.5)*

Unlike *Giardia* spp. most members of *Fornicata* are harmless symbionts. The few free-living forms are most often found in waters that are heavily polluted with organic nutrients (a condition known as eutrophication). Only asexual reproduction by binary fission has been observed. Other pathogenic species include *Hexamida salmonis,* a fish parasite found in hatcheries and fish farms, and *H. meleagridis,* a turkey pathogen that is responsible for the annual loss of millions of dollars in poultry revenue.

Parabasalia

Members of *Parabasalia* are flagellated; most are endosymbionts of animals. They use phagocytosis to engulf food items, although they lack a distinct cytostome. Here we consider two subgroups: *Trichonymphida* and *Trichomonadida*. Trichonymphids are obligate mutualists in the digestive tracts of wood-eating insects such as termites and wood roaches. They secrete the enzyme cellulase needed for the digestion of wood particles, which they entrap with pseudopodia. One species, *Trichonympha campanula,* can account for up to one-third of the biomass of an individual termite (*see figure 32.2*). This species is particularly large for a protist (several hundred micrometers) and can bear several thousand flagella. Although asexual reproduction is the norm, a hormone called ecdysone produced by the host when molting triggers sexual reproduction. ▶▶| *Microorganism-insect mutualisms (section 32.1)*

Trichomonadida spp., or simply trichomonads, do not require oxygen and possess hydrogenosomes rather than mitochondria (*see figure 5.16*). They undergo asexual reproduction only. They are symbionts of the digestive, reproductive, and respiratory tracts of many vertebrates. *Tritrichomonas foetus* is a cattle parasite and an important cause of spontaneous abortion in these animals. Four species infect humans: *Dientamoeba fragilis, Pentatrichomonas hominis, Trichomonas tenax,* and *T. vaginalis* (figure 25.4*b*). *D. fragilis* has recently been recognized as a cause of diarrhea, while *T. vaginalis* has long been known to be pathogenic. It is found in the genitourinary tract of both men and women, and the sexual transmission of pathogenic strains accounts for an estimated 7 million cases of trichomoniasis annually in the United States and 180 million cases annually worldwide. ▶▶| *Protist pathogens (section 40.4)*

Euglenozoa

Members of *Euglenozoa* are commonly found in freshwater, although a few species are marine. About one-third of euglenids are photoautotrophic; the remaining are free-living chemoorganotrophs. Most chemoorganotrophic forms are saprophytic, although a few parasitic species have been described. The representative genus is *Euglena,* which contains photoautotrophic euglenids. A typical *Euglena* spp. cell (**figure 25.5**) is elongated and bounded by a plasmalemma. The pellicle consists of proteinaceous strips and microtubules; it is elastic enough to enable turning and flexing of the cell, yet rigid enough to prevent excessive alterations in shape. *Euglena* spp. contain chlorophylls *a* and *b* together with carotenoids. The large nucleus contains a prominent nucleolus. Euglenids store carbon as paramylon (a polysaccharide composed of β(1→3) linked glucose molecules), which is unique to euglenids. A red eyespot called a **stigma** helps the organism orient to light and is located near an anterior reservoir. A contractile vacuole near the reservoir continuously collects water from the cell and empties it into the reservoir, thus regulating the osmotic pressure within the organism. Two flagella arise from the base of the reservoir, although only one emerges from the canal and actively beats to move the cell. Reproduction in euglenids is by longitudinal mitotic cell division.

Trypanosomes are important members of *Euglenozoa*. These microbes exist only as parasites of plants and animals, and have global significance. For example, members of the genus *Leishmania,* which cause a group of conditions collectively termed leishmaniasis, are typanosomes that affect some 12 million people. Chagas' disease is caused by *Trypanosoma cruzi,* which is transmitted by "kissing bugs" (*Triatominae*), so called because they bite the face of sleeping victims (*see figures 40.10*

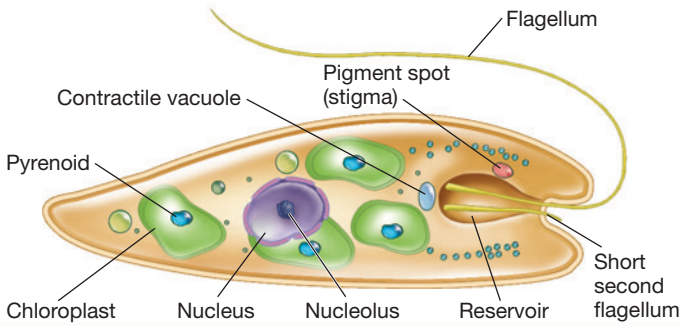

Figure 25.5 ***Euglena:*** **Principle Structures Found in This Euglenoid.** Notice that a short second flagellum does not emerge from the anterior invagination. In some euglenids, both flagella are emergent.

to *40.13*). ▶▶| *Leishmaniasis (section 40.3); Trypanosomiasis (section 40.3)*

The trypanosomes *T. gambiense* and *T. rhodesiense* (often considered a subspecies of *T. brucei*) cause African sleeping sickness (**figure 25.6**). Ingestion of these parasites by the blood-sucking tsetse fly triggers a complex cycle of development and reproduction, first in the fly's gut and then in its salivary glands (*see figure 40.12*). From there the parasite is easily transferred to a vertebrate host, where it often causes a fatal infection. It is estimated that about 65,000 people die annually of sleeping sickness. The presence of this dangerous parasite prevents the use of about 11 million square kilometers of African grazing land.

25.3 Supergroup *Amoebozoa* Includes Protists with Pseudopodia

After reading this section, you should be able to:

- Draw three different types of pseudopodia
- Differentiate between a naked and a testate amoeba
- Compare and contrast the structure, motility, and life cycles of acellular and cellular slime molds
- Explain the importance of molecular signaling in the morphological development of *Dictyostelium discoideum*
- Identify a nearby location where you might find members of the genera *Tubulinea, Entamoebida,* and *Eumycetozoa*

Because the amoeboid form arose independently numerous times from various flagellated ancestors, some amoebae are placed in the supergroup *Amoebozoa,* while others are in *Rhizaria*. One of the morphological hallmarks of amoeboid motility is the use of **pseudopodia** (meaning "false feet") for both locomotion and feeding (**figure 25.7**). Pseudopodia can be rounded (**lobopodia**), long and narrow (**filopodia**), or form a netlike mesh (**reticulopodia**). Amoebae that lack a cell wall and are surrounded only by a plasma membrane are called **naked amoebae.** In contrast, the plasma membrane of a **testate amoeba** is covered by material that is either made by the protist itself or collected by the organism from the environment. Binary fission is the usual means of asexual division, although some amoebae form cysts that undergo multiple fission.

Tubulinea

Members of *Tubulinea* inhabit almost any environment where they will remain moist; this includes glacial meltwater, marine environments, tide pools, lakes, and streams. Free-living forms are known to dwell in ventilation ducts and cooling towers, where they feed on microbial biofilms. Others are endosymbionts, commensals, or parasites of invertebrates, fishes, and mammals. Some harbor intracellular symbionts, including algae,

MICRO INQUIRY *How does a plasmodium differ from a single cell?*

bacteria, and viruses, but the nature of these relationships is not well understood. *Amoeba proteus,* a favorite among introductory biology laboratory instructors, is included in this group.

Entamoebida

Like *Excavata* protists, entamoebid protists lack mitochondria and hydrogenosomes but contain mitosomes. However, the identification of about 20 putative mitochondrial proteins in the free-living amoeba *Mastigamoeba balamuthi* suggests that these mitosomes are more advanced than those found in *Giardia* spp. *M. balamuthi* is a relative of *Entamoeba histolytica,* the cause of amoebic dysentery—the third-leading cause of parasitic death worldwide. Individuals acquire this pathogen by eating feces-contaminated food or by drinking water contaminated by *E. histolytica* cysts. These pass unharmed through the stomach and undergo multiple fission when introduced to the alkaline conditions in the intestines (*see figure 40.19*). There they graze on bacteria and produce a suite of digestive enzymes that degrade the gut epithelium. *E. histolytica* can cause intestinal ulceration and penetrate into the bloodstream, and migrate to the liver, lungs, or skin. Cysts in feces remain viable for weeks but are killed by heat greater than 40°C. ▶▶| *Amebiasis (section 40.5)*

Eumycetozoa

First described in the 1880s, members of *Eumycetozoa* or "slime molds" have been classified as plants, animals, and fungi. As we examine their morphology and behavior, the source of this confusion should become apparent. Recent analysis of certain proteins (e.g., elongation factor EF-1, α-tubulin, and actin) as well as physiological, behavioral, biochemical, and developmental data point to a monophyletic group. *Eumycetozoa* includes *Myxogastria* and *Dictyostelia.*

The **acellular slime mold (*Myxogastria*)** life cycle includes a distinctive stage when the organisms exist as streaming masses of colorful protoplasm. The protoplasm creeps along in amoeboid fashion over moist, rotting logs, leaves, and other organic matter, which it degrades (**figure 25.8**). Acellular slime molds derive their name from the stage in their life cycle when a large, multinucleate

mass called a plasmodium is formed; there can be as many as 10,000 synchronously dividing nuclei within a single plasmodium (figure 25.8*b*). When starved or dried, the plasmodium develops ornate fruiting bodies. As these mature, they form stalks with cellulose walls that are resistant to environmental stressors (figure 25.8*c,d*). When conditions improve, spores germinate and release haploid amoeboflagellates. These fuse, and as the resulting zygotes feed by endocytosis, nuclear divisions give rise to the multinucleate plasmodium.

Cellular slime molds (*Dictyostelia*) are strictly amoeboid and use endocytosis to feed on bacteria and yeasts. Their complex life cycle involves true multicellularity, despite their primitive evolutionary status (**figure 25.9**). The species *Dictyostelium discoideum* is an attractive model organism. During its life cycle, a pseudoplasmodium is formed. This consists of thousands of individual vegetative cells moving together as a mass. The pseudoplasmodium forms when starved cells release cyclic AMP (cAMP) and a specific glycoprotein, which serve as molecular signals. Other *D. discoideum* cells sense these compounds and respond by forming an aggregate around the signal-producing cells. In this way, large, motile, multicellular slugs develop and serve as precursors to fruiting body formation. Fruiting body morphogenesis commences when the slug stops and cells pile on top of each other. Cells at the bottom of this vertically oriented structure form a stalk by secreting cellulose, while cells at the tip differentiate into spores. Germinated spores become vegetative amoebae to start this asexual cycle anew.

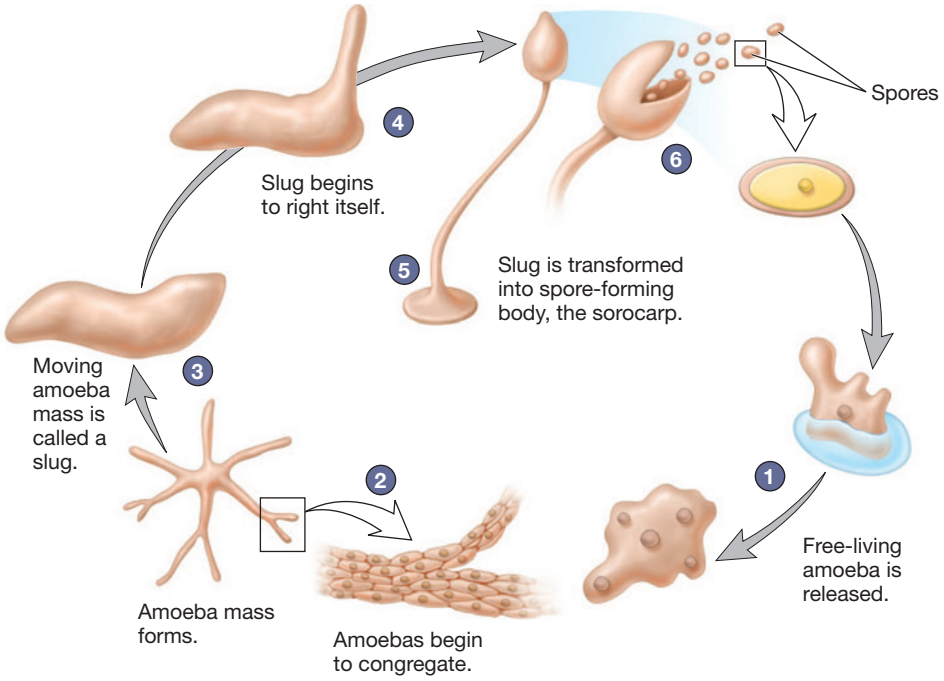

Figure 25.9 Life Cycle of *Dictyostelium discoideum,* a Cellular Slime Mold.

MICRO INQUIRY *How would a mutant strain unable to secrete cAMP behave if mixed with a wild-type strain? What if it were mixed with another cAMP mutant?*

Dictyostelium spp. display complex behaviors. In addition to farming, described in the chapter-opening story, they also differentiate to resemble primitive immune cells. During slug formation, some cells become "sentinel cells" and vanquish harmful bacteria. Sentinel cells accomplish this by producing proteins that are similar to those involved in immune responses in higher organisms. These cells roam within the slug as if patrolling for pathogenic bacteria such as *Legionella pneumophila,* which are known to infect *Dictyostelium* spp. Sentinel cells have been found in several species related to *Dictyostelium discoideum*; immunologists are not too surprised, noting that all multicellular organisms need protection against bacterial pathogens.

Sexual reproduction in *D. discoideum* involves the formation of special spores call macrocysts. These arise by a form of conjugation that has some unusual features. First, a group of amoebae become enclosed within a wall of cellulose. This brings cells into close contact so that conjugation can occur between members of different mating types. There are three mating types determined by the sequence of a single gene, as well as those capable of self-fertilization. Following conjugation, a large amoeba forms and cannibalizes the remaining amoebae. The now-giant amoeba matures into a macrocyst. Macrocysts can remain dormant within their cellulose walls for extended periods. Vegetative growth resumes after the diploid nucleus undergoes meiosis to generate haploid amoebae.

25.4 Supergroup SAR: Protists of Great Importance

After reading this section, you should be able to:

- Describe the morphology of the filopodia and axopodia found in members of *Rhizaria*
- Explain the morphology, feeding mechanisms, and reproduction of members of *Radiolaria* and *Foraminifera*
- Infer why the accretion of foraminiferan tests occurs and why it is important in oil exploration
- Describe the morphology, motility, and feeding behaviors of dinoflagellates

- Explain the importance of dinoflagellates to coral biology and the generation of "red tides"
- Diagram how a ciliate captures a food particle and consumes it
- Compare and contrast the morphology and function of the micro- and macronucleus and trace their fate during ciliate conjugation
- Identify the unique structures found in an apicomplexan cell and explain their function
- Outline the apicomplexan life cycle
- List at least two human diseases caused by apicomplexans
- Explain the importance of heterokont flagella in the taxonomy of the *Stramenopila*
- Review the structure, morphology, reproduction, and ecological importance of diatoms
- Deduce why the peronosporomycetes and *Labyrinthulids* were erroneously considered fungi

The supergroup SAR, which stands for stramenopiles, alveolates, and *Rhizaria,* has only recently been recognized. Phylogenomic evidence strongly supports the view that these organisms form a monophyletic clade. As such, it elevates stramenopiles and alveolates to the level of supergroup, and eliminates *Chromalveolata,* to which they were formerly assigned. The SAR supergroup encompasses some of the world's most important protists, including those that fix as much carbon as the rainforests (diatoms) and those that infect over 200 million people worldwide (*Plasmodium* spp., which cause malaria).

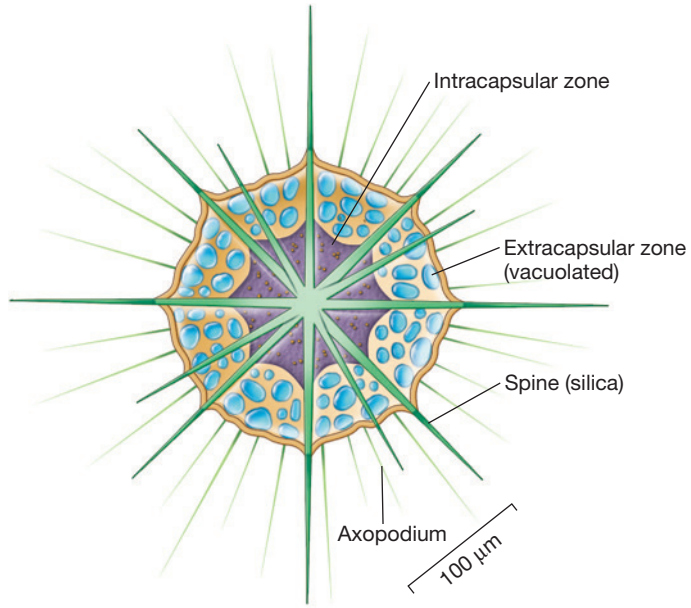
Rhizaria

Members of *Rhizaria* include those in *Radiolaria* and *Foraminifera*. These organisms are amoeboid in morphology and can be distinguished by their filopodia, which can be simple, branched, or connected. Filopodia supported by microtubules are known as **axopodia** (s., axopodium). Axopodia protrude from a central region of the cell called the axoplast and are primarily used in feeding (**figure 25.10*a***).

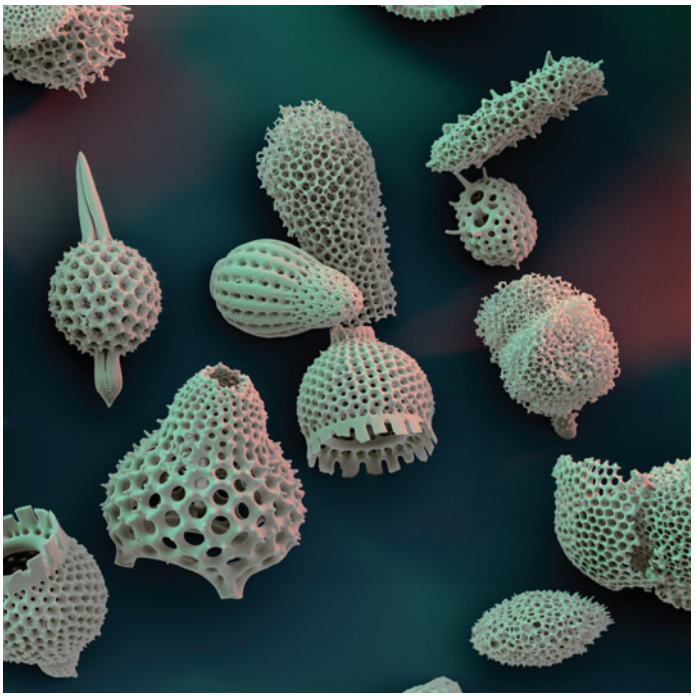
Radiolaria

Most radiolaria have an internal skeleton made of siliceous material; however, members of the subgroup *Acantharia* have endoskeletons consisting of strontium sulfate. A few genera contain species with an exoskeleton of siliceous spines or scales, while some lack a skeleton completely. Skeletal morphology is highly variable and often includes radiating spines that help the organisms float, as does the storage of oils and other low-density fluids (figure 25.10*b*).

Radiolaria feed by endocytosis, using mucus-coated filopodia to entrap prey including bacteria, other protists, and even small invertebrates. Large prey items are partially digested extracellularly by the secretion of degradative enzymes before becoming encased in a food vacuole. Many surface-dwelling radiolarians have algal symbionts thought to enhance their net carbon assimilation. Acantharians reproduce only sexually by consecutive mitotic and meiotic divisions that release hundreds of biciliated cells. Asexual reproduction (binary or multiple fission, or budding) is most common in other radiolaria, but sexual reproduction can be triggered by nutrient limitation or a heavy feeding. In this case, two haploid nuclei fuse to form a diploid zygote encased in a cyst from which it is released when survival conditions improve.



(a)



(b) Radiolarian shells

Figure 25.10 Radiolaria. (a) The radiolarian *Acanthometra elasticum* demonstrates the internal skeleton. (b) Radiolarian shells made of silica.

Foraminifera

Members of *Foraminifera* (also called forams) range in size from roughly 20 µm to several centimeters. Their filopodia are arranged in a branching network called reticulopodia. These bear vesicles at

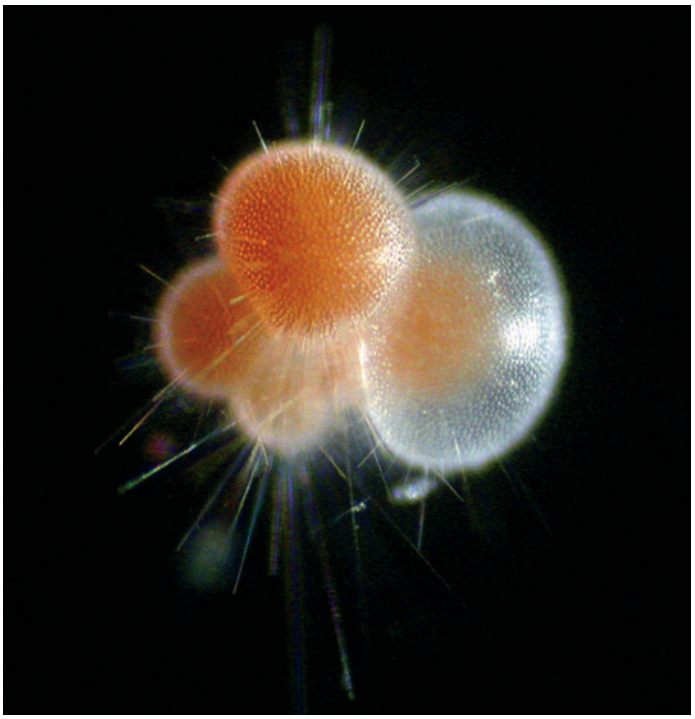


Figure 25.11 A Foraminiferan. The reticulopodia project through pores in the calcareous test, or shell, of this protist.

Figure 25.12 White Cliffs of Dover. The limestone that forms these cliffs is composed almost entirely of fossil shells of protists, including foraminifera.

their tips that secrete a sticky substance used to trap prey. Many species harbor endosymbiotic algae that migrate out of reticulopodia (without being eaten) to expose themselves to more sunlight. These algae contribute significantly to foram nutrition. Forams have characteristic tests (plates) arranged in multiple chambers that are sequentially added as the protist grows (**figure 25.11**).

Some forams are free-floating planktonic forms; others are benthic, living within the sediments. A few benthic forams inhabiting anoxic sediments perform denitrification, reducing nitrate completely to dinitrogen gas. Foraminifera were the first example of a denitrifying eukaryote; it is now known that a some fungi are also capable of this process. ⏮ *Anaerobic respiration uses the same three steps as aerobic respiration (section 11.7)* ⏭ *Nitrogen cycle (section 28.1)*

Foraminiferan life cycles can be complex. While some smaller species reproduce only asexually by budding or multiple fission, larger forms frequently alternate between sexual and asexual phases. During the sexual phase, flagellated gametes pair, fuse, and generate asexual individuals (agamonts). Meiotic division of the agamonts gives rise to haploid gamonts. There are several mechanisms by which gamonts return to the diploid condition. For instance, a variety of forams release flagellated gametes that become fertilized in the open water. In others, two or more gamonts attach to one another, enabling gametes to fuse within the chambers of the paired tests. When the shells separate, newly formed agamonts are released.

Forams are found in marine and estuarine habitats. Some are planktonic, but because most are benthic, their tests accumulate on the seafloor, where they create a fossil record dating back to the Early Cambrian (543 million years ago). This is helpful in oil exploration. Their remains, or ooze, can be up to hundreds of meters deep in some tropical regions. Foram tests make up most modern-day chalk, limestone, and marble, and are familiar to most as the white cliffs of Dover in England (**figure 25.12**). They also formed the stones used to build the great pyramids of Egypt.

Alveolata

Alveolata is a large group that includes *Dinoflagellata* (dinoflagellates), *Ciliophora* (ciliates), and *Apicomplexa* (apicomplexans). We begin our discussion with **dinoflagellates**—a large group most commonly found in marine plankton, where some species are responsible for the phosphorescence sometimes seen in seawater. Their nutrition is complex; photoautotrophy, heterotrophy, and mixotrophy are all observed. Most of the heterotrophic forms are saprophytic (using osmotrophy to assimilate nutrients), but some also use endocytosis (i.e., they are holozoic). Each cell bears two distinctively placed flagella: One is wrapped around a transverse groove (the girdle), and the other is draped in a longitudinal groove (the sulcus; **figure 25.13**). The orientation and beating patterns of these flagella cause the cell to spin as it is propelled forward; the name dinoflagellate is derived from the Greek *dinein,* "to whirl." Many dinoflagellates are covered with cellulose plates that are secreted within the alveolar sacs that lie just under the plasma membrane. These forms are said to be thecate or armored; those with empty alveoli are called athecate or naked and include members of the luminescent genus *Noctiluca.* Like some other protists, dinoflagellates have specialized compressed proteins called **trichocysts.** When attacked, trichocysts shoot out from the cell as a means of defense.

Most dinoflagellates are free living, although some form important associations with other organisms. Endosymbiotic

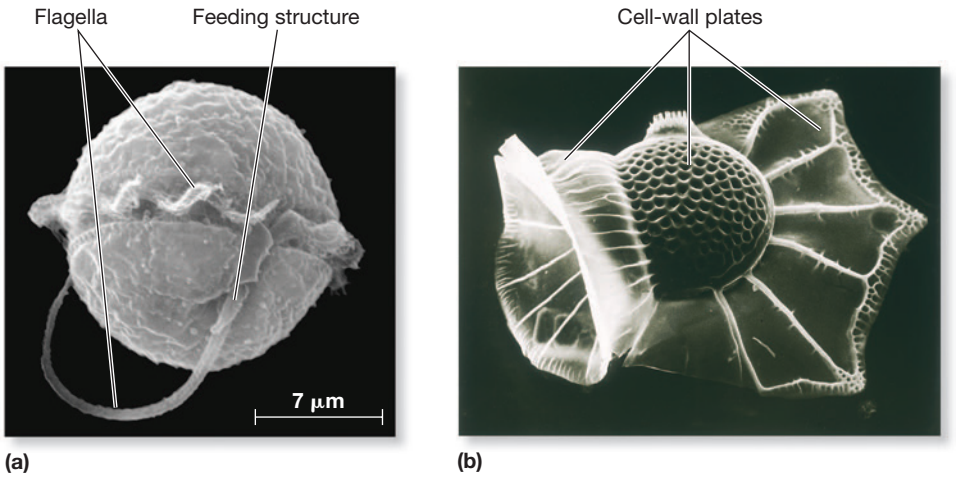

Figure 25.13 Dinoflagellates. (a) The surface of *Peridiniopsis berolinensis* is smooth because the alveoli appear empty. Two types of flagella can be seen in this freshwater dinoflagellate. One flagellum coils around the girdle; as it moves, this flagellum causes the cell to spin. The straight flagellum that extends from the cell acts as a rudder to determine the direction of movement. (b) The alveoli of a marine dinoflagellate in the genus *Ornithocercus* contains cellulose cell-wall plates. The cell wall extends to form sail-like structures.

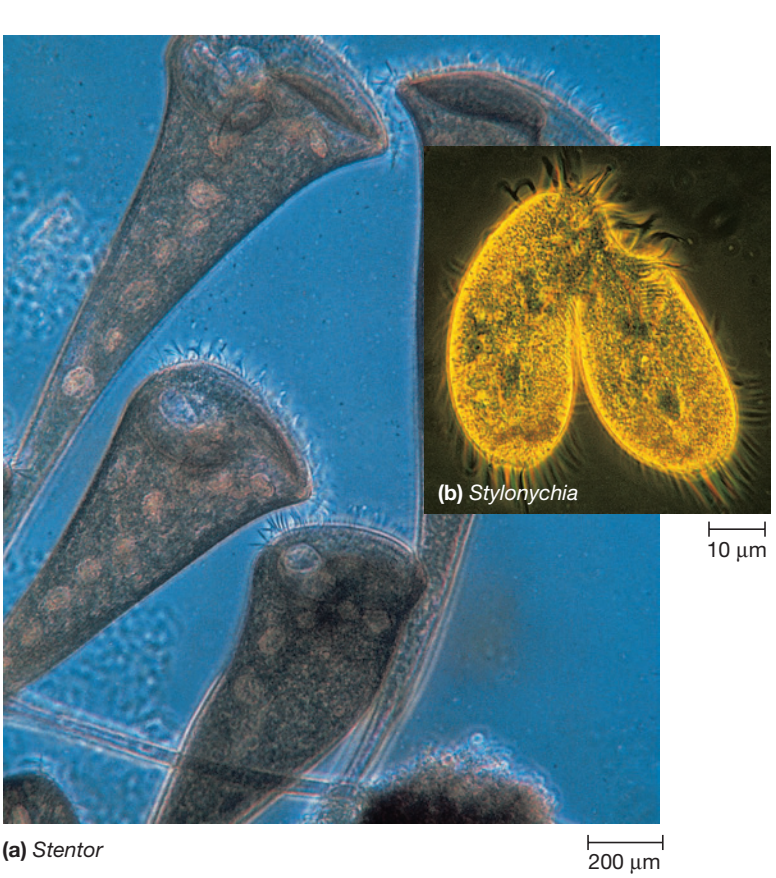
MICRO INQUIRY *What do you think is the function of the "sails" in* Ornithocercus *sp.?*

dinoflagellates that live as undifferentiated cells occasionally send out motile cells called **zooxanthellae.** The most well-known zooxanthellae belong to the genus *Symbiodinium*. These are photosynthetic endosymbionts of reef-building coral (*see figure 32.3*). They provide fixed carbon to the coral animal and help maintain the internal chemical environment needed for the coral to secrete its calcium carbonate exoskeleton. Dinoflagellates are also responsible for toxic "red tides" that harm other organisms, including humans. Common red tide dinoflagellates include members of the genera *Alexandrium* and *Lingulodinium* (formerly called *Gonyaulax; see figure 30.3*). ▶▶| *Microorganisms in coastal ecosystems are adapted to a changeable environment (section 30.2); Zooxanthellae (section 32.1)*

Ciliates (*Ciliophora*) include about 12,000 known species. All are chemoorganotrophic and range from about 10 μm to 4.5 mm long. They inhabit both benthic and planktonic communities in marine and freshwater systems, as well as moist soils. As their name implies, ciliates employ many cilia for locomotion and feeding. The cilia are generally arranged either in longitudinal rows (**figure 25.14**) or in spirals around the body of the organism.



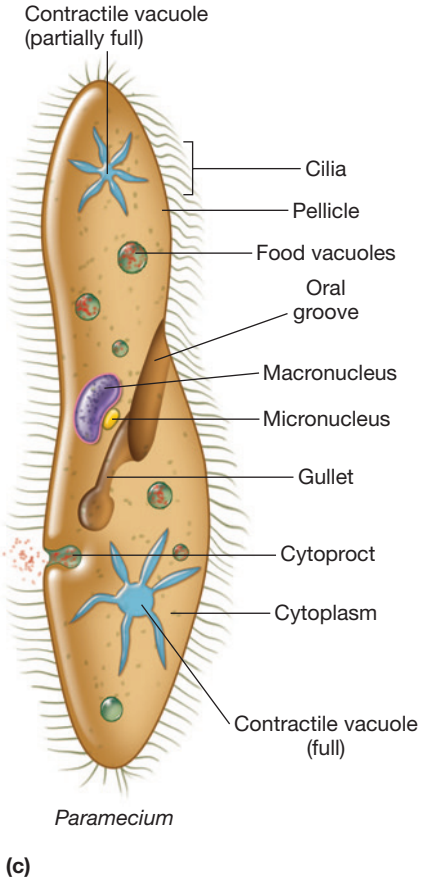


Figure 25.14 *Ciliophora*. (a) *Stentor*, a large, vase-shaped, freshwater protozoan. (b) Two *Stylonychia* cells conjugating. (c) Structure of *Paramecium* spp.

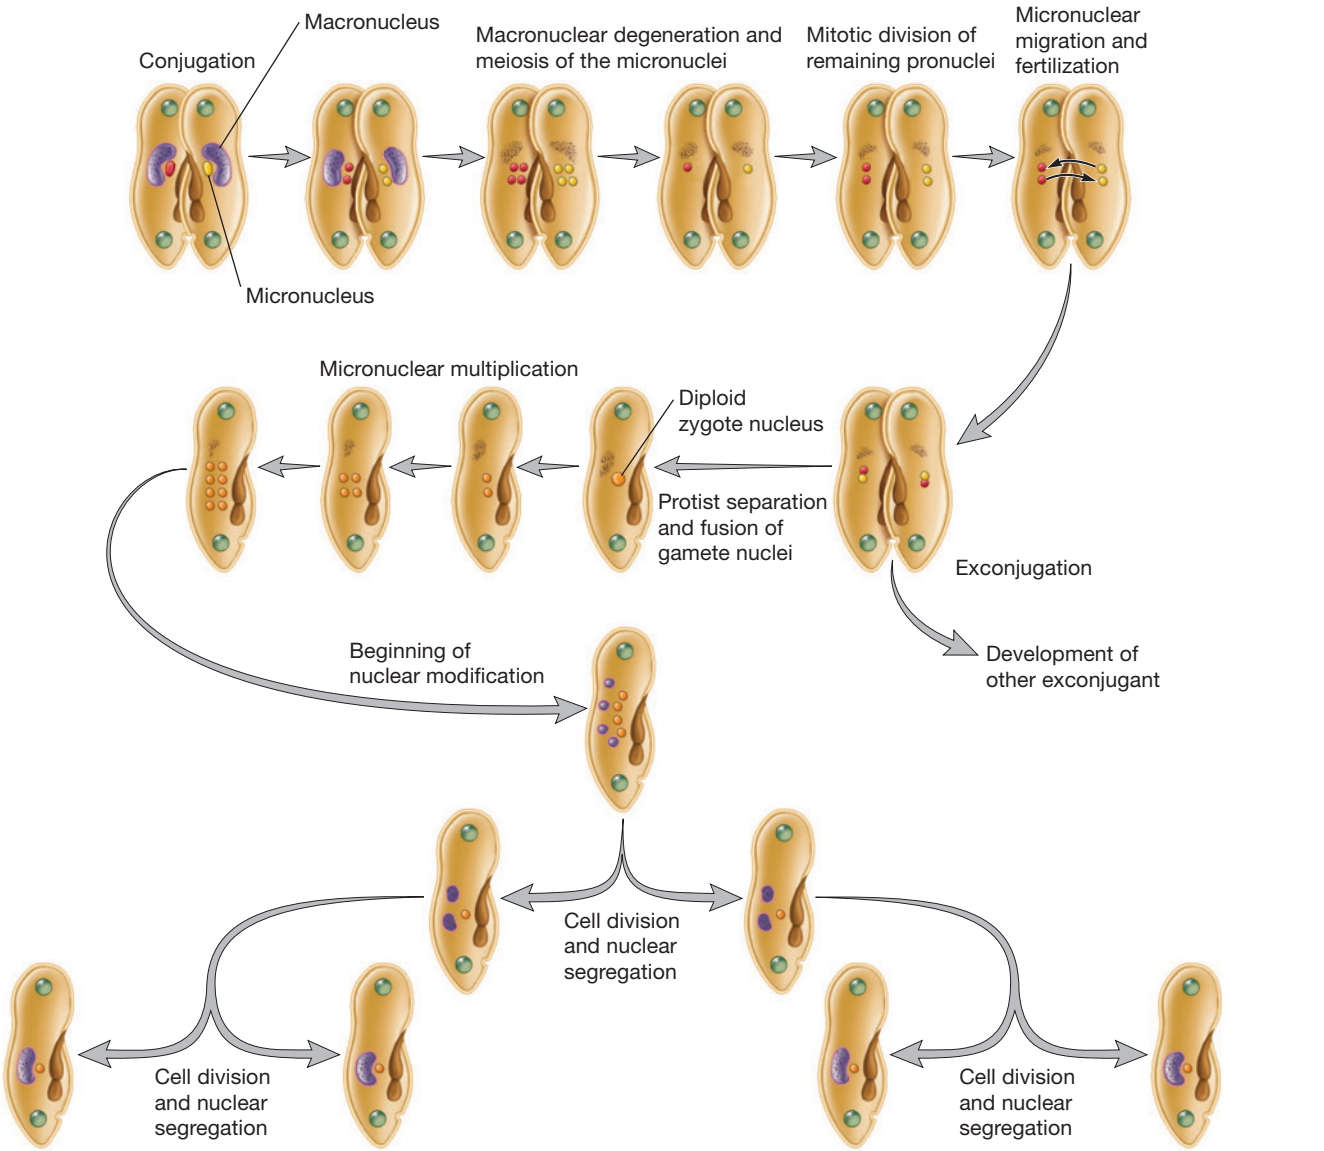

Figure 25.15 **Conjugation in *Paramecium caudatum*.** After the conjugants separate, only one of the exconjugants is shown; however, a total of eight new protists result from each conjugation.

MICRO INQUIRY *What are the functions of the micronucleus and macronucleus?*

They beat with an oblique stroke, causing the protist to revolve as it swims. Ciliary beating is so precisely coordinated that ciliates can go both forward and backward. There is great variation in shape, and most ciliates do not look like the slipper-shaped members of the genus *Paramecium.* Some species, including *Vorticella* spp., attach to substrates by a long stalk. *Stentor* spp. attach to substrates and stretch out in a trumpet shape to feed. A few species have tentacles for the capture of prey. Some can discharge toxic, threadlike darts called toxicysts, which are used in capturing prey. A striking feature of ciliates is their ability to quickly entrap many particles by the action of the cilia around the buccal cavity. Food first enters the cytostome and passes into phagocytic vacuoles that fuse with lysosomes after detachment from the cytostome and the vacuole's contents are digested. After the digested material has been absorbed into the cytoplasm, the vacuole fuses with the cytoproct and waste material is expelled.

Most ciliates have two types of nuclei: a large **macronucleus** and a smaller **micronucleus.** The micronucleus is diploid and contains the normal somatic chromosomes. It divides by mitosis and transmits genetic information through meiosis and sexual reproduction. Macronuclei gene expression is needed to maintain routine cellular functions and control normal cell metabolism. Macronuclei are derived from micronuclei by a complex series of steps. Within the macronucleus are many chromatin bodies, each containing many copies of only one or two genes. Macronuclei are thus polyploid and divide by elongating and then constricting.

The fate of the macro- and micronuclei can be followed during conjugation of *Paramecium caudatum* (**figure 25.15**). In this

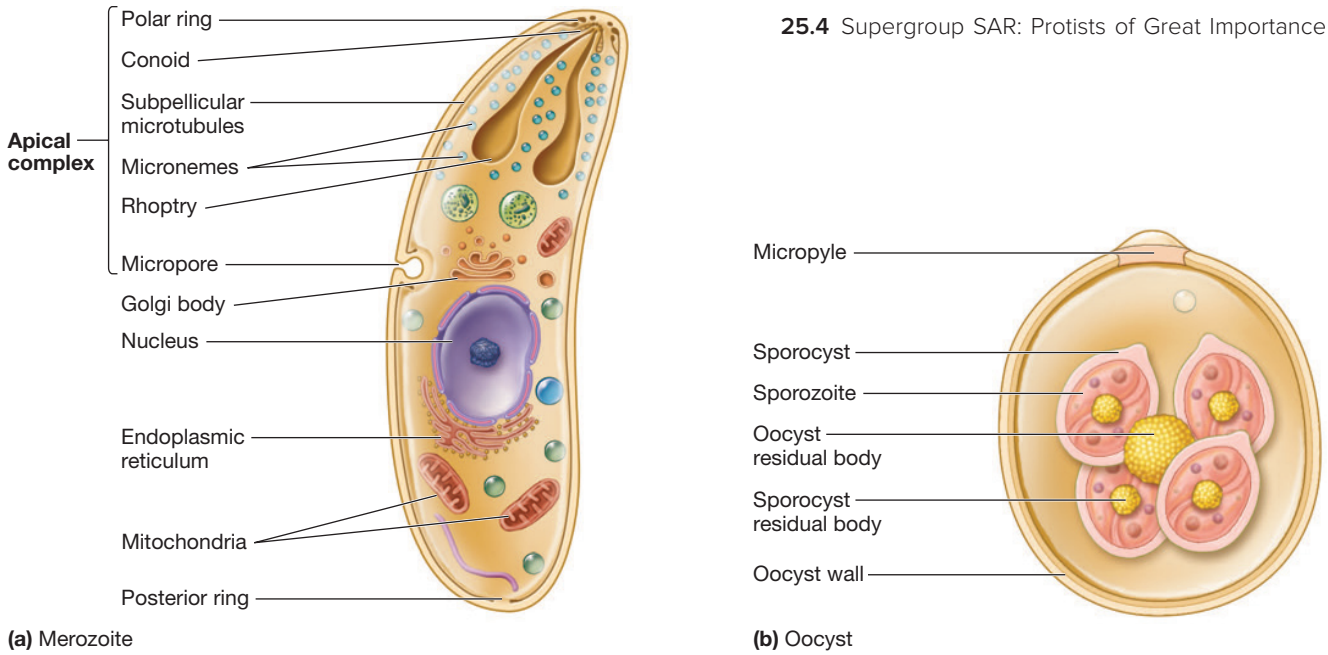

Figure 25.16 The Apicomplexan Cell. (a) The vegetative cell, or merozoite, illustrating the apical complex, which consists of the polar ring, conoid, rhoptries, subpellicular microtubules, and micropore. (b) The infective oocyst of *Eimeria* sp. The oocyst is the resistant stage and has undergone multiple fission after zygote formation (sporogony).

process, there is an exchange of gametes between paired cells of complementary mating types (conjugants). At the beginning of conjugation, two ciliates fuse their pellicles at the site of contact. The macronucleus is no longer needed, so it is degraded in each cell. The individual micronuclei undergo meiosis to form four haploid pronuclei, three of which disintegrate. The remaining pronucleus divides again mitotically to form two gametic nuclei—a stationary one and a migratory one. The migratory nuclei pass into the respective conjugants. Then the ciliates separate, the gametic nuclei fuse, and the resulting diploid zygote nucleus undergoes three rounds of mitosis. The eight resulting nuclei have different fates: one nucleus is retained as a micronucleus; three others are destroyed; and the four remaining nuclei develop into macronuclei. Each separated conjugant now undergoes cell division. Eventually progeny with one macronucleus and one micronucleus are formed.

Although most ciliates are free living, symbiotic forms also exist. Some live as harmless commensals; for example, *Entodinium* spp. are found in the rumen of cattle, and *Nyctotherus* protists occur in the colon of frogs. Other ciliates are strict parasites; for example, *Balantidium coli* lives in the intestines of mammals, including humans, where it can cause dysentery. *Ichthyophthirius* spp. live in freshwater, where they can attack many species of fish, producing a disease known as "ick."

All **apicomplexans** are either intra- or intercellular parasites of animals and are distinguished by a unique arrangement of fibrils, microtubules, vacuoles, and other organelles, collectively called the **apical complex,** which is located at one end of the cell (**figure 25.16*a***). There are three secretory organelles—the rhoptries, micronemes, and dense granules—that release enzymes and calcium needed to penetrate host cells. In addition, apicomplexans (with the exception of *Cryptosporidium* spp.) contain plastids, called **apicoplasts.** Although these arose by endosymbiosis of an ancient cyanobacterium, unlike chloroplasts, apicoplasts are not the site of photosynthesis. In the malaria-causing pathogen *Plasmodium* spp., apicoplasts are known to be the site of isoprenoid biosynthesis. In all apicomplexans studied to date, the apicoplast is essential for viability. This makes them attractive targets for the development of drugs to inhibit the growth of pathogenic apicomplexans. ◀◀ *Sterols and isoprenoid lipids (section 12.7)*

Apicomplexans have complex life cycles in which certain stages sometimes occur in one host and other stages occur in a different host. The life cycle has both asexual (clonal) and sexual phases, and is characterized by an alternation of haploid and diploid generations. The clonal and sexual stages are haploid, except for the zygote. The motile, infective stage is called the **sporozoite.** When this haploid form infects a host, it differentiates into a gamont; male and female gamonts pair and undergo multiple fission, which produces many haploid cells called merozoites. Merozoites may continue to infect new host cells or pair and fuse to form zygotes. Each zygote secretes a protective covering and is then considered a spore. Within the spore, the nucleus undergoes meiosis (restoring the haploid condition) followed by mitosis to generate eight sporozoites ready to infect a new host (figure 25.16*b*). Motility (flagellated or amoeboid) is confined to the gametes and zygotes of a few species.

Among the most important human pathogens are the five species in the apicomplexan genus *Plasmodium,* which cause malaria: *P. falciparum, P. malariae, P. vivax, P. knowlesi*, and *P. ovale.* The life cycle of *P. vivax* is shown in figure 40.7; it infects both the liver and red blood cells. Prevention measures have resulted in about a 42% decline in malaria since 2000; however, the disease still causes about 600,000 deaths per year. *P. falciparum* is the most deadly of the five species, accounting for at least one-third of malaria deaths. The energy metabolism of this microbe is unusual. While it has the genes for a mitochondrial ATP synthase, it is fermentative. Like all apicomplexans, *P. falciparum* cannot convert pyruvate to acetyl-CoA in the mitochondrion. Instead, phosphoenolpyruvate

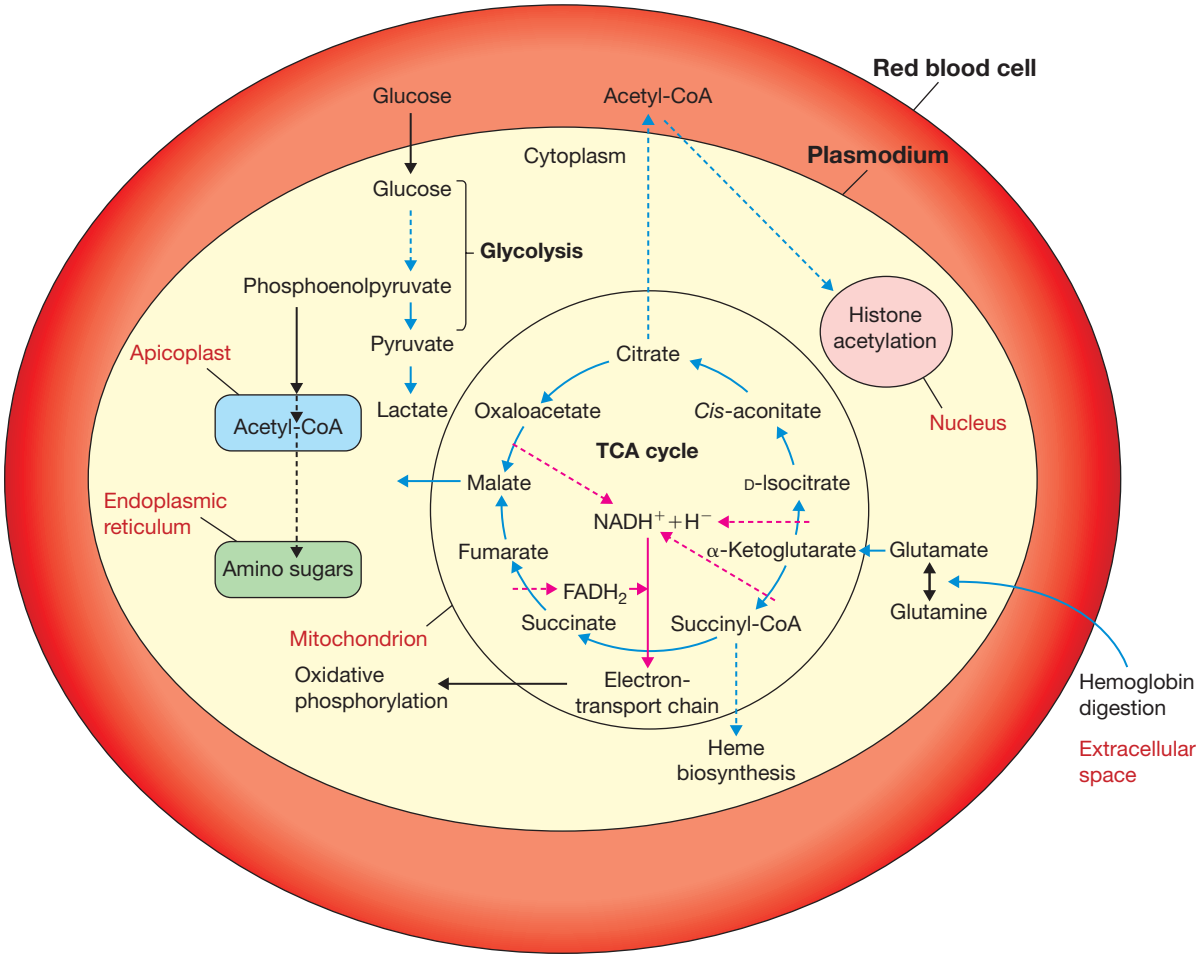

Figure 25.17 ***Plasmodium falciparum*** **Drives the TCA Cycle in Two Directions.** Glutamate is deaminated to yield α-ketoglutarate from which reactions proceed in both the oxidative and reductive direction. Pyruvate is fermented in the parasite's cytosol to lactate rather than oxidized to acetyl-CoA. Phosphoenolpyruvate is converted to acetyl-CoA in the apicoplast and used to synthesize amino sugars. The host may convert citrate produced by the protist to acetyl-CoA, which then re-enters the microbe, where it is thought to be used to acetylate histones. The uncertainty of these steps is denoted by a dashed line.

generated by the Embden-Meyerhof pathway in the cytosol is transported to the apicoplast where it is converted to acetyl-CoA. Without acetyl-CoA in the mitochondrion, the TCA cycle begins with the deamination of glutamate to α-ketoglutarate. Reactions then proceed in both the reductive and oxidative directions. Reductive TCA steps result in citrate and malate, which are exported from the mitochondrion, while in the oxidative direction, succinyl-CoA, a key precursor for heme biosynthesis, is generated (**figure 25.17**). ▶▶| *Malaria (section 40.3)*

A number of other apicomplexans are important infectious agents. Several species of *Eimera* are the causative agents of cecal coccidiosis in chickens, a condition that costs hundreds of millions of dollars in lost animals each year in the United States. *Theileria parva* and *T. annulata* are tick-borne parasites that cause a fatal disease in cattle called East Coast fever. This kills over a million animals annually in sub-Saharan Africa, costing over $200 million and affecting farmers who can least afford such losses. Toxoplasmosis, caused by members of the genus *Toxoplasma,* is transmitted either by consumption of undercooked meat or by fecal contamination from a cat's litter box. Cryptosporidia are responsible for cryptosporidiosis, an infection that begins in the intestines but can disseminate to other parts of the body. Cryptosporidiosis and members of another apicomplexan genus, *Cyclospora,* have become problematic for AIDS patients and other immunocompromised individuals. ▶▶| *Toxoplasmosis (section 40.5); Cryptosporidiosis (section 40.5)*

Retrieve, Infer, Apply

1. What adaptations do planktonic radiolaria have to help them float?
2. Compare how radiolaria use axopodia with the way forams use reticulopodia.
3. What are alveoli? Describe the difference between a naked and an armored dinoflagellate.
4. What is the morphology of a typical ciliate? Why do you think ciliates are the fastest-moving protists?
5. Describe conjugation as it occurs in ciliates. What is the fate of the micronucleus and the macronucleus during this process?
6. What is the apical complex seen in apicomplexans?
7. Consider the complex life cycle of apicomplexans. Which stage would be most vulnerable to drug treatment in an effort to treat a human disease caused by an apicomplexan?

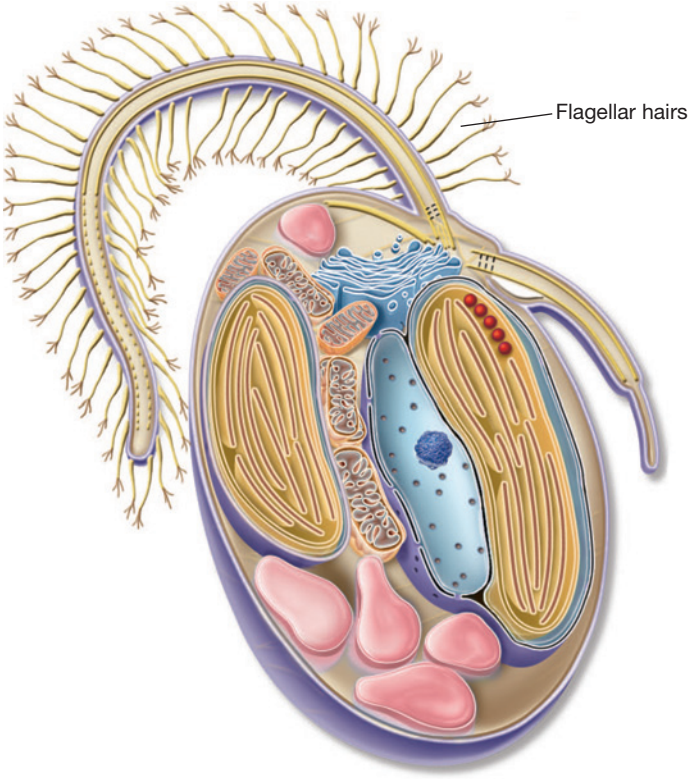

Figure 25.18 A Stramenopile Cell. Note the two flagella, one with "straw hairlike" projections.

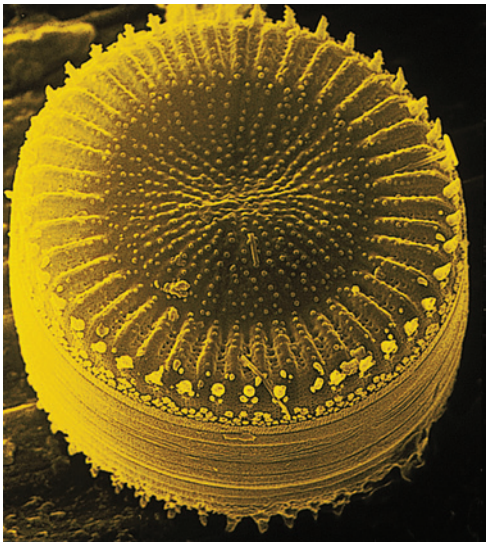
Stramenopila

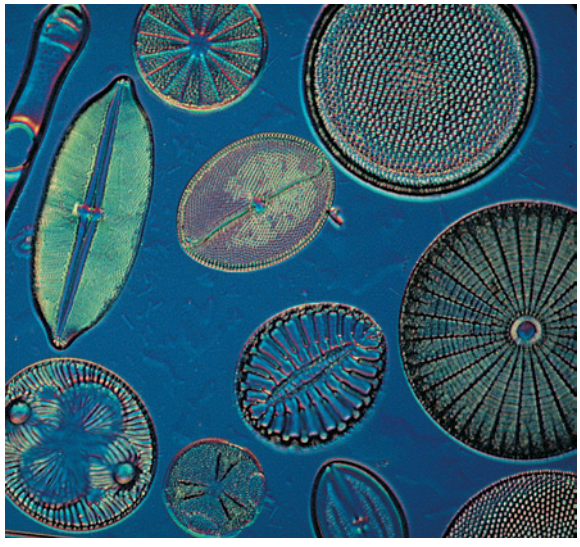
The large and diverse *Stramenopila* group (informally known as stramenopiles) includes photosynthetic protists such as diatoms, brown and golden algae (*Chrysophyceae*), as well as chemoorganotrophic (saprophytic) genera such as öomycetes (*Peronosporomycetes*), labyrinthulids (slime nets), and members of *Hyphochytriales*. Stramenopiles also include brown seaweeds and kelp that form large, rigid structures and macroscopic forms that were once considered fungi and plants. One unifying feature of these very diverse protists is the possession of **heterokont flagella** at some point in the life cycle. This is characterized by two flagella—one extending anteriorly and the other posteriorly. These flagella bear small hairs with a unique, three-part morphology; stramenopila means "straw hair" (**figure 25.18**).

Diatoms (*Bacillariophyta*) possess chlorophylls *a* and c_1/c_2, and the carotenoid fucoxanthin. When fucoxanthin is the dominant pigment, the cells have a golden-brown color. Their major carbohydrate reserve is chrysolaminarin, a polysaccharide storage product composed principally of β(1→3)–linked glucose residues. Diatoms have a distinctive, two-piece cell wall of silica called a **frustule** composed of crystallized silica [$Si(OH)_4$] with very fine markings. Diatom frustules are composed of two halves or thecae that overlap like those of a Petri dish (**figure 25.19**). The larger half is the epitheca, and the smaller half is the hypotheca. Frustule morphology is very useful in diatom identification, and diatom frustules have a number of practical applications. The fine detail and precise morphology of these frustules have made them attractive for nanotechnology. ▶▶| *Some microbes are products (section 42.6)*

Although the majority of diatoms are strictly photoautotrophic, some are facultative chemoorganotrophs, absorbing carbon-containing molecules through the holes in their walls. The vegetative cells of diatoms are diploid and can be unicellular, colonial, or filamentous. They lack flagella and have a single, large nucleus and smaller plastids. Reproduction consists of the organism dividing asexually, with each half then constructing a new hypotheca (**figure 25.20*a***). Because the epitheca and hypotheca are of different sizes, each time the parental hypotheca is used as an eptithecal template to construct a new hypotheca, the diatom gets smaller. This cannot go on forever without the diatom

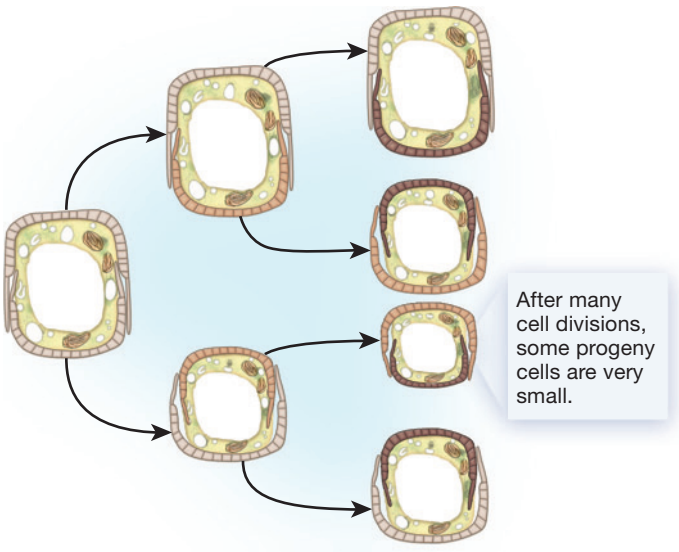


(a) *Cyclotella meneghiniana*

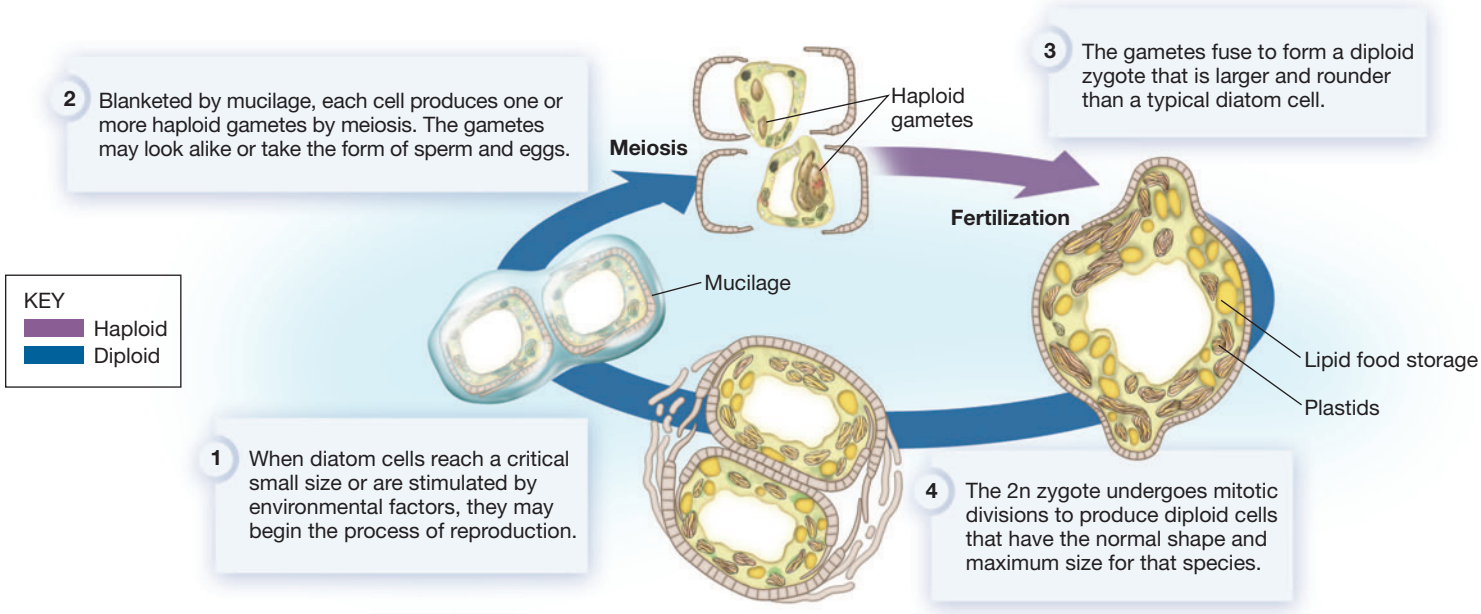


(b)

Figure 25.19 Diatoms. (a) The siliceous epitheca and hypotheca of the diatom *Cyclotella meneghiniana* fit together like halves of a Petri dish. (b) A variety of diatoms show the intricate structure of the silica cell wall.



(a) Asexual reproduction in diatoms



(b) Sexual reproduction in diatoms

Figure 25.20 Gametic Life Cycle as Illustrated by Diatoms. (a) Diatom asexual reproduction involves repeated mitotic divisions. Because a new lower cell-wall piece is always synthesized, asexual reproduction eventually causes the mean cell size to decline in a diatom population. (b) Small cell size triggers sexual reproduction, which regenerates maximal cell size.

MICRO INQUIRY *How does the trigger for sexual reproduction (i.e., reduced size) compare with more common stimuli that induce sexual reproduction? (Hint: Compare to radiolaria.)*

disappearing altogether, so when a cell has diminished to about 30% of its original size, sexual reproduction is usually triggered. The diploid vegetative cells undergo meiosis to form gametes, which then fuse to produce a zygote. The zygote develops into an auxospore, which increases in size again and forms a new wall. The mature auxospore eventually divides mitotically to produce vegetative cells with frustules of the original size (figure 25.20*b*).

Diatoms are found in freshwater lakes, ponds, streams, and throughout the world's oceans. Marine planktonic diatoms produce about 50% of the organic carbon in the ocean; they are therefore critical in global carbon cycling. In fact, marine diatoms are thought to contribute as much fixed carbon as all rain forests combined. ▶▶| *Carbon cycle (section 28.1); Microorganisms in the open ocean are adapted to nutrient limitation (section 30.2)*

A group of protists once considered fungi and traditionally called **öomycetes,** meaning "egg fungi," are now called **peronosporomycetes.** They differ from fungi in a number of ways, including their cell wall composition (cellulose and β-glucan instead of chitin) and the fact that they are diploid throughout their life cycle. When undergoing sexual reproduction, they form a relatively large egg cell (öogonium) that is fertilized by either a sperm cell or a smaller gametic cell (called an antheridium) to produce a zygote. When the zygote germinates, the asexual zoospores display heterokont flagellation.

Some peronosporomycetes help degrade plant and animal detritus, while others are pathogenic. For instance, species of *Saprolegnia* and *Achlya* are saprophytes that form cottony masses on dead algae and animals, mainly in freshwater

environments. By contrast, *Peronospora hyoscyami* is responsible for "blue mold" on tobacco plants, and grape downy mildew is caused by *Plasmopara viticola.* Certainly the most famous peronosporomycete is *Phytophthora infestans,* which attacked the European potato crop in the mid-1840s, spawning the Irish famine. The original classification of *P. infestans* as a fungus was misleading, and for decades farmers attempted to control its growth with fungicides, to which it is (of course) resistant. This protist continues to take its toll; potato blight costs some $6.7 billion annually worldwide. *P. sojae* is another agriculturally important species; it infects soybeans and costs this industry millions of dollars per year. Finally, *P. ramorum* is a plant pathogen that causes a disease called sudden oak death, which kills oak trees and a variety of woody shrubs.

Labyrinthulids also have a complex taxonomic history: like peronosporomycetes, they were formerly considered fungi. However, molecular phylogenetic evidence combined with the observation that they form heterokont flagellated zoospores places them in *Stramenopila*. The nonflagellated stage of the life cycle features spindle-shaped cells that form complex colonies that glide rapidly along an ectoplasmic net made by the organism. This net is actually an external network of calcium-dependent contractile fibers made up of actinlike proteins that facilitate the movement of cells. Their feeding mechanism is like that of fungi: osmotrophy aided by the production of extracellular degradative enzymes. In marine habitats, members of the genus *Labyrinthula* grow on plants and algae, and are thought to play a role in the wasting disease of eelgrass, an important intertidal plant.

Haptophyta

The phylogenetics of *Haptophyta* remains unsettled; it may be a sister group to the supergroup SAR. It includes the *Coccolithales,* photosynthetic protists that bear ornate calcite scales called coccoliths (**figure 25.21**). Together with forams, **coccolithophores** precipitate calcium carbonate ($CaCO_3$) in the ocean, thereby influencing Earth's carbon budget. Cells are usually biflagellated and possess a unique organelle called a haptonema, which is somewhat similar to a flagellum but differs in microtubule arrangement. One species, *Emiliania huxleyi,* has been studied extensively. Like all coccolithophores, it is planktonic and can cause massive blooms in the open ocean (*see figure 30.11*). These high concentrations or blooms of *E. huxleyi* can significantly alter nutrient flux as well as alter the weather by emitting sulfur (as dimethylsulfide or DMS) to the atmosphere. The release of DMS causes clouds to grow larger. Other coccolithophores are known to cause toxic blooms. ▶▶| *Water is the largest microbial habitat (section 30.1)*

Picozoa

The phylogenetic origin of another marine lineage, *Picozoa,* is very mysterious. Evidence for *Picozoa* (meaning "tiny animals") emerged in the early 2000s when 18S rRNA metagenomic data revealed the presence of eukaryotic organisms small enough to fit through filters of 2–3 μm. Originally thought to be photosynthetic, they were given the tentative name "phycobiliphytes." Further analysis showed that these protists are not photosynthetic. They are broadly distributed in high numbers throughout the world's oceans.

In 2013 the first cultured picozoan was reported. These protists, named *Picomonas judraskeda,* were isolated from marine coastal waters and consist of two roughly spherical halves divided by a deep cleft. Total cell size ranges from 2 × 2.5 μm to 2.5 × 3.8 μm. They have two flagella and demonstrate an unusual kind of motility that has been described as cycles of "jump-drag-skedaddle." They consume colloidal organic materials by endocytosis, and it is thought that their unusual motility assists in feeding.

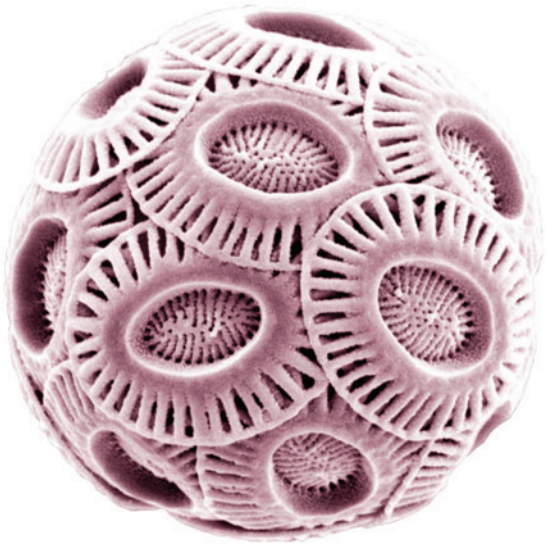


Figure 25.21 The Haptophyte *Emiliania huxleyi*. The ornamental scales are made of calcite.

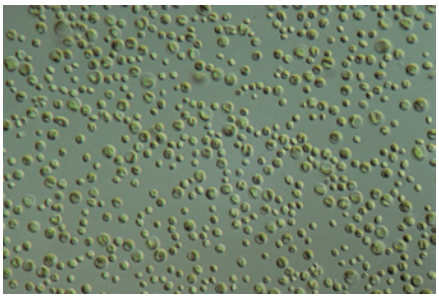
25.5 Supergroup *Archaeplastida* Includes "Green Algae"

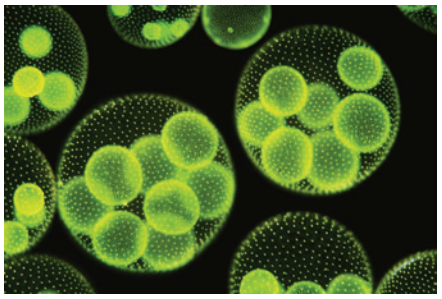
After reading this section, you should be able to:

- List at least three different morphologies found among the *Chloroplastida*
- Describe the structure and life cycle of the model organism, *Chlamydomonas*

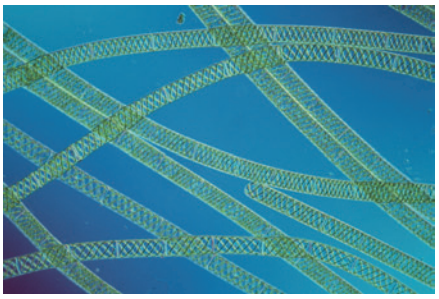
Archaeplastida includes all organisms with a photosynthetic plastid that arose through an ancient endosymbiosis with a cyanobacterium. It thus includes all higher plants as well as many protist species. |◀◀ *Mitochondria, mitochondria-like organelles, and chloroplasts evolved from endosymbionts (section 1.2)*



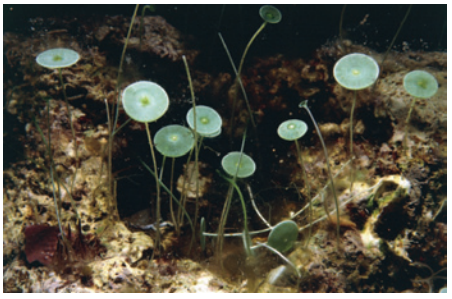
(a) *Chlorella*



(b) *Volvox*



(c) *Spirogyra*



(d) *Acetabularia*

Figure 25.22 ***Chlorophyta* (Green Algae); Light Micrographs.** (a) *Chlorella,* a unicellular nonmotile chlorophyte (×160). (b) *Volvox,* which demonstrates colonial growth. (c) *Spirogyra;* each filament contains ribbonlike, spiral chloroplasts. (d) *Acetabularia,* the mermaid's wine goblet.

Chloroplastida

Members of *Chloroplastida* are often referred to as green algae (Greek *chloros,* green). These phototrophs grow in fresh- and saltwater, in soil, and on and within other organisms. They have chlorophylls *a* and *b* along with specific carotenoids, and they store carbohydrates such as starch. Many have cell walls made of cellulose. They exhibit a wide diversity of body forms, ranging from unicellular to colonial, filamentous, membranous or sheetlike, and tubular types (**figure 25.22**). The smallest known free-living eukaryote, *Ostreococcus tauri,* is a member of *Chloroplastida* (subgroup *Prasinophyceae*). This marine, planktonic microbe is smaller than most bacteria and archaea, with an average size of 0.8 μm in diameter. Some species have a holdfast structure that anchors them to a substratum. Both asexual and sexual reproduction are observed.

Chlamydomonas spp. are members of the subgroup *Chlorophyta* (**figure 25.23**). Individuals have two flagella of equal

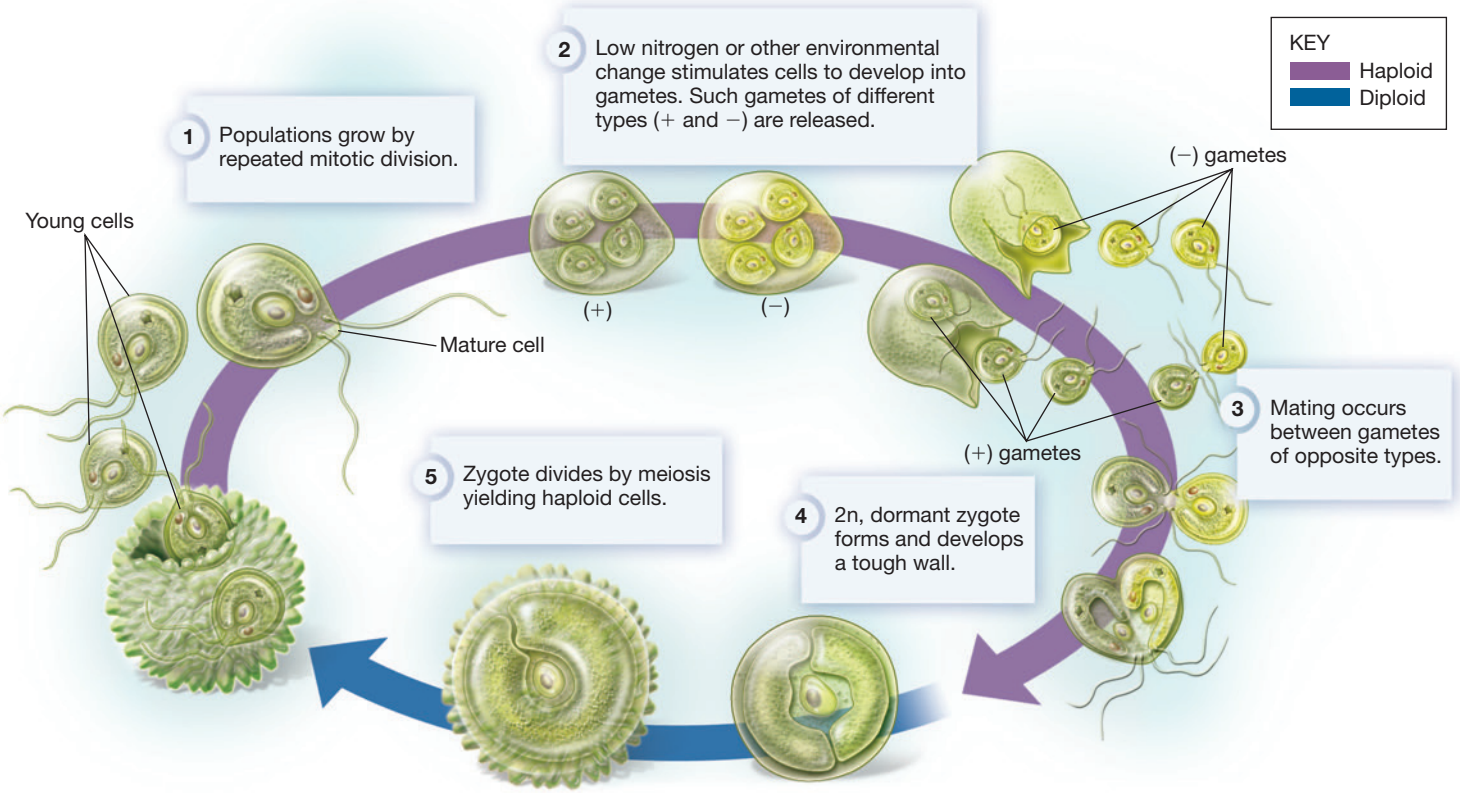


Figure 25.23 ***Chlamydomonas reinhardtii:* The Structure and Life Cycle of This Motile Green Alga.** During asexual reproduction, all structures are haploid; during reproduction, only the zygote is diploid.

MICRO INQUIRY *Which of the cells shown above are haploid and which are diploid?*

length at the anterior end by which they move rapidly in water. Each cell has a single haploid nucleus, a large chloroplast, a conspicuous pyrenoid, and a stigma that aids the cell in phototactic responses. Two small contractile vacuoles at the base of the flagella function as osmoregulatory organelles. *Chlamydomonas* spp. reproduce asexually by producing zoospores through mitotic division. Sexual reproduction occurs when some cells act as gametes and fuse to form a four-flagellated, diploid zygote that ultimately loses the flagella and enters a resting phase. Meiosis occurs at the end of this resting phase and produces four haploid cells that give rise to adults.

The chlorophyte *Prototheca moriformis* causes the disease protothecosis in humans and animals. *P. moriformis* cells are fairly common in the soil, and it is from this site that most infections occur. Severe systemic infections, such as massive invasion of the bloodstream, have been reported in animals. The subcutaneous type of infection is more common in humans. It starts as a small lesion and spreads slowly through the lymph glands, covering large areas of the body.

Retrieve, Infer, Apply

1. Explain the unique structural features of diatoms. How does their morphology play a role in the alternation between asexual and sexual reproduction?
2. Why do you think öomycetes and labyrinthulids were formerly considered fungi?
3. What is the ecological importance of coccolithophores?
4. What does the discovery of a large group of protists seemingly unrelated to any other organisms suggest about the state of our knowledge of the eukaryotic world?
5. Compare the morphology of members of the genus *Chlamydomonas* with those belonging to *Euglena* (figure 25.23).

Key Concepts

25.1 Protist Diversity Reflects Broad Phylogeny

- Protists are widespread in the environment, found wherever water, suitable nutrients, and an appropriate temperature occur.
- Protists are important components of many terrestrial, aquatic, and marine ecosystems, where they contribute to nutrient cycling. Many are parasitic in humans and animals, and some have become very useful in the study of molecular biology.
- The protistan cell membrane is called the plasmalemma, and the cytoplasm can be divided into the ectoplasm and the endoplasm. A pellicle lies beneath the plasma membrane of some protists. The cytoplasm contains contractile, secretory, and food (phagocytic) vacuoles.
- Energy metabolism occurs within mitochondria, hydrogenosomes, or chloroplasts.
- Some protists can secrete a resistant covering and go into a resting stage (encystment) called a cyst. Cysts protect the organism against adverse environments, function as a site for nuclear reorganization, and serve as a means of transmission in parasitic species (**figure 25.2**).
- Most protists reproduce asexually by binary or multiple fission or budding (**figure 25.3**).
- Protists also use a variety of sexual reproductive strategies, including syngamy and autogamy.
- Protist phylogeny is the subject of active research and debate. The classification scheme presented here is based on that of the International Society of Protistologists.

25.2 Supergroup *Excavata:* Primitive Eukaryotes

- The super group *Excavata* includes *Fornicata, Parabasalia,* and *Euglenozoa.* Most have a cytoproct and use a flagellum for suspension feeding.
- The human pathogen *Giardia lamblia* is a member of *Fornicata*. It is considered one of the most primitive eukaryotes (**figure 25.4**).
- Most parabasalids are flagellated endosymbionts of animals. They include the obligate mutualists of wood-eating insects such as *Trichonympha* spp. and the human pathogen *Trichomonas vaginalis.*
- Many members of *Euglenozoa* are photoautotrophic (**figure 25.5**). The remainder are chemoorganotrophs; most of these are saprophytic. Important human pathogens include members of this group cause leishmaniasis, Chagas' disease, and African sleeping sickness.

25.3 Supergroup *Amoebozoa* Includes Protists with Pseudopodia

- Amoeboid forms use pseudopodia, which can be lobopodia, filopodia, or reticulopodia (**figure 25.7**). Amoebae that bear external plates are called testate; those without plates are called naked or atestate amoebae.
- The *Amoebozoa* subgroup *Eumycetozoa* includes acellular and cellular slime molds. Acellular slime molds form a large, multinucleate mass of protoplasm (**figure 25.8**).
- Cellular slime molds produce a pseudoplasmodium, consisting of many individual cells moving together as a mass. *Dictyostelium discoideum* is a cellular slime mold that is used as a model organism in the study of chemotaxis, cellular development, and cellular behavior (**figure 25.9**).

25.4 Supergroup SAR: Protists of Great Importance

- *Rhizaria* encompasses amoeboid forms, including members of *Radiolaria,* which have a siliceous internal skeleton and filopodia that are used to entrap prey (**figure 25.10**).
- Members of *Foraminifera* bear netlike reticulopodia and tests. Most foraminifera are benthic, and their tests accumulate on the ocean floor, where they are useful in oil exploration (**figure 25.11**).

- *Alveolata* consists of dinoflagellates, ciliates, and apicomplexans.
- Dinoflagellates are a large group of nutritionally complex protists. Most are marine and planktonic. They are known for their phosphorescence and for causing toxic blooms (**figure 25.13**).
- Ciliates are chemoorganotrophic protists that use cilia for locomotion and feeding. In addition to asexual reproduction, conjugation is used in sexual reproduction (**figures 25.14** and **25.15**).
- Apicomplexans are parasitic with complex life cycles. The motile, infective stage is called the sporozoite. This group includes a number of pathogens, including five species of *Plasmodium,* which cause malaria (**figure 25.16**).
- Stramenopiles are extremely diverse and include diatoms, golden and brown algae, peronosporomycetes, and labyrinthulids. Diatoms are found in fresh- and saltwater, and are important components of marine plankton (**figures 25.18 to 25.20**).
- Haptophytes include coccolithophores, planktonic photosynthetic protists that contribute to the global carbon budget by precipitating calcium carbonate for their ornate scales (**figure 25.21**).
- The *Picozoa* are new group that includes very small, heterotrophic, marine protists with a global distribution.

25.5 Supergroup *Archaeplastida* Includes "Green Algae"

- *Archaeplastida* includes *Chlorophyta,* also known as green algae. All are photosynthetic with chlorophylls *a* and *b* along with specific carotenoids. They exhibit a wide range of morphologies (**figure 25.22**).
- *Chlamydomonas* spp. are model protists, which undergo sexual and asexual reproduction (**figure 25.23**).

Compare, Hypothesize, Invent

1. Protist encystment is usually triggered by changes in the environment. Compare and contrast this with endospore formation in Gram-positive bacteria.
2. Which of the protists discussed in this chapter do you think are the most evolutionarily advanced or derived? Explain your reasoning.
3. Vaccine development for diseases caused by protists (e.g., malaria, Chagas' disease) has been much less successful than for bacterial or viral diseases. Discuss one biological reason and one geopolitical reason for this fact.
4. Some protists reproduce asexually when nutrients are plentiful and conditions are favorable for growth but reproduce sexually when environmental or nutrient conditions are not favorable. Why is this an evolutionarily important and successful strategy?
5. Most apicomplexans bear the unpigmented chloroplast remnant called the apicoplast (p. 575). Only the recently described apicomplexan *Chromera velia* has been shown to use the apicoplastid as the site of photosynthesis. What genetic and physiological features do you think were characterized to show that this organism is truly photosynthetic? How would you determine if this protist is photoautotrophic, photoheterotrophic, or mixotrophic?
6. Benthic foraminifera inhabit marine sediments. It was discovered that the benthic foram *Globobulimina pseudospinescens* stores intracellular nitrate, which it reduces to nitrogen gas. This is the first and only case of eukaryotic denitrification. How would you go about designing a comparative analysis of eukaryotic and bacterial denitrification? What physical factors and physiological and enzymatic features would you characterize?

   Read the original paper: Risgaard-Peterson, N., et al. 2006. Evidence for complete denitrification in a benthic foraminifera. *Nature.* 443:93.

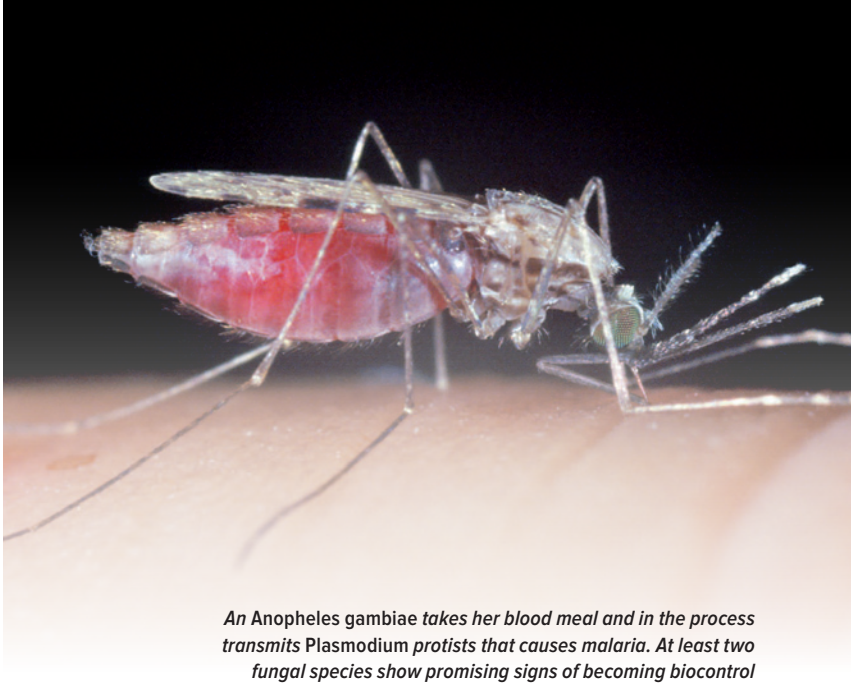
Fungi (Eumycota)



An* Anopheles gambiae *takes her blood meal and in the process transmits* Plasmodium *protists that causes malaria. At least two fungal species show promising signs of becoming biocontrol agents to fight the transmission of this devastating disease.

Fungi May Be Key to Quelling Malaria

Every minute someone dies of malaria. That someone is usually a child under the age of five living in sub-Saharan Africa. Sadly, these children could be protected by bed nets impregnated with insecticide. But even for those kids lucky enough to have bed nets, the insecticide may be losing its effectiveness because mosquitoes are acquiring resistance to these chemicals. Likewise, the protozoa that cause malaria—members of the genus *Plasmodium*—are losing susceptibility to the antimalarial drugs used to treat the disease. All things considered, it's a grim situation.

What's needed is a new approach. Some see entomopathogenic fungi as just that. Simply put, entomopathogenic fungi kill insects, in this case mosquitoes. There are two entomopathogenic fungal species of particular interest: *Metarhizium anisopliae* and *Beauveria bassiana*. Both have performed well in laboratory tests, where they are toxic to *Anopheles* mosquitoes carrying *Plasmodium* cells. But there is serious debate about how to harness these potential biocontrol agents.

Is it best to kill the adult mosquito or the larvae, or to focus on preventing transmission? Researchers targeting adult mosquitoes field-tested bed nets treated with *B. bassiana*. Although this killed more than twice as many insecticide-resistant mosquitoes than untreated nets, the viability of the fungus declined within days. In separate tests designed to prevent maturation of mosquito larvae, fungal spores were mixed with nontoxic oil and spread over the surface of *Anopheles*-infested water. Again there was a two-fold increase in mosquito death, and of those that survived, only about a fifth were able to pupate. However, some scientists argue that by killing mosquitoes susceptible to fungi, resistant mosquitoes will ultimately predominate. To address this, a genetically modified (GM) *M. anisopliae* strain that prevents the entrance of *Plasmodium* sporozoites into the mosquito's salivary gland when taking a blood meal was developed. Within two days of infection with GM fungi, 80% of the mosquitoes failed to transmit *Plasmodium* cells compared with 32% of those infected with non-GM fungi and 14% of fungal-free mosquitoes.

There are clear advantages and disadvantages in all three approaches. Some question the wisdom of releasing GM fungi. Others point to the cost of introducing any new technology. Perhaps there is no single correct approach. The only certainty is that too many lives continue to be lost to malaria.

In this chapter, we introduce ***Fungi,*** sometimes referred to as true fungi or *Eumycota* (Greek *eu*, true, and *mykes*, fungus). The term fungus (pl., fungi; Latin *fungus*, mushroom) describes eukaryotic organisms that are spore-bearing, have absorptive nutrition, lack chlorophyll, and reproduce both sexually and asexually. Scientists who study fungi are **mycologists,** and the scientific discipline devoted to fungi is called **mycology.** The study of fungal toxins is called **mycotoxicology,** and the diseases caused by fungi in animals are known as **mycoses** (s., mycosis).

Fungi consists of an enormous group of organisms; about 90,000 fungal species have been described, although some estimate the true number of species to be about 1.5 million. It is thus not surprising that the taxonomy of these organisms has been revised numerous times. The application of molecular techniques combined with morphological and ecological considerations has led to a better understanding of the phylogenetic relationships between various fungal groups (**figure 26.1**). For instance, neither *Zygomycota* nor *Chytridiomycota* are monophyletic. Most recently, metagenomic analysis from a wide range of soils revealed a large clade of environmental RNA sequences. This has led to the approval of a new phylum called *Cryptomycota*, meaning "hidden fungi" because they may constitute almost half the fungal biomass in some locations but until now have been unnoticed. Here we present the six major fungal groups that have representatives grown in culture: *Chytridiomycota, Zygomycota, Glomeromycota, Ascomycota, Basidiomycota,* and *Microsporidia,* shown in **figure 26.2** and summarized in **table 26.1**.

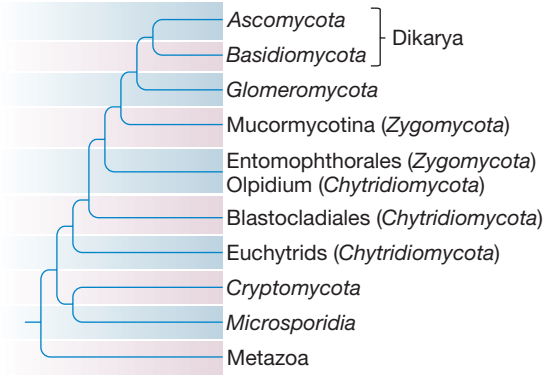


Figure 26.1 The Major Branches of *Fungi*. Phylogenetic analysis of the seven fungal groups. Some suggest that the *Microsporidia* and *Cryptomycota* be combined into a single phylum.

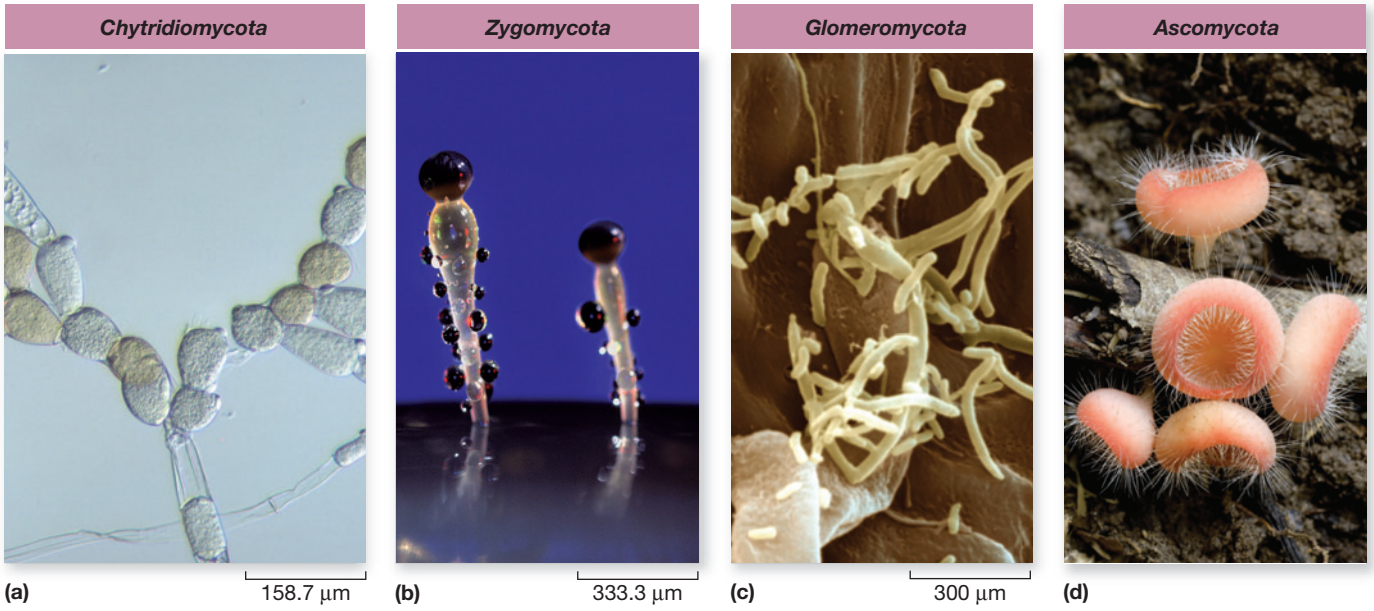
MICRO INQUIRY *Compare the nodes and branches that lead to the monophyletic taxa* Basidiomycota *and* Ascomycota. *How do they differ from those leading to* Zygomycota *and* Chytridiomycota? *What can be concluded from this?*



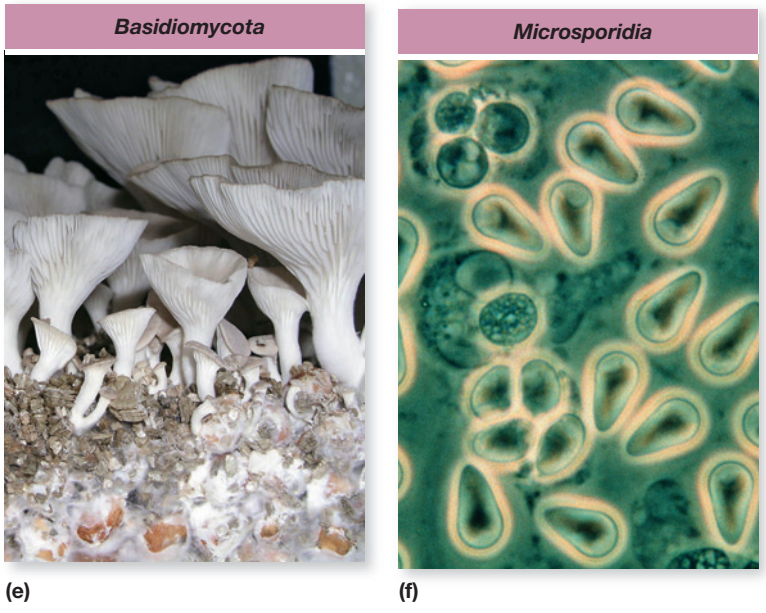


Figure 26.2 Representatives of the Fungal Groups. (a) The free living chytrid *Allomyces macrogynus,* which lives in mud. (b) *Pilobolus* sp., a zygomycete, grows on animal dung and on culture medium. Stalks about 10 mm long contain dark, spore-bearing sacs. (c) Mycorrhizae are glomeromycetes associated with roots. (d) The cup fungus *Cookeina tricholoma* is an ascomycete from the rain forest of Costa Rica. In cup fungi, the spore-producing structures line the cup; in basidiomycetes that form mushrooms such as *Amanita* sp. they line the gills beneath the cap of the mushroom. (e) *Pleurotus ostreatus,* the oyster mushroom, is a basidiomycete. All visible structures of fungi arise from an extensive network of hyphae that penetrate and are interwoven with the substrate as they grow. (f) By contrast, the unusual fungi that belong to *Microsporidia* form spores that germinate in host cells. Shown here is the mosquito pathogen *Edhazardia aedis.*

Table 26.1 Abbreviated Classification of *Fungi*

Subclass	Characteristics	Examples
Chytridiomycota	Flagellated cells in at least one stage of life cycle; may have one or more flagella. Cell walls with chitin and β-1,3 / 1,6-glucan; glycogen is used as a storage carbohydrate. Sexual reproduction often results in a zygote that becomes a resting spore or sporangium; saprophytic or parasitic. Chytrid subdivisions include *Blastocladiales, Monoblepharidales, Neocallimastigaceae, Spizellomycetales,* and *Chytridiales.*	*Allomyces* *Blastocladiella* *Coelomomyces* *Physoderma* *Synchytrium*
Zygomycota	Thalli usually filamentous and nonseptate, without cilia; sexual reproduction gives rise to thick-walled zygospores that are often ornamented. Includes seven subdivisions: *Basidiobolus, Dimargaritales, Endogonales, Entomophthorales, Harpellales, Kickxellales, Mucorales,* and *Zoopagales.* Human pathogens found in *Mucorales* and *Entomophthorales.*	*Amoebophilus* *Mucor* *Phycomyces* *Rhizopus* *Thamnidium*
Ascomycota	Sexual reproduction involves meiosis of a diploid nucleus in an ascus, giving rise to haploid ascospores; most also undergo asexual reproduction with the formation of conidiospores with specialized aerial hyphae called conidiophores. Many produce asci within complex fruiting bodies called ascocarps. Includes saprophytic, parasitic forms; many form mutualisms with phototrophic microbes to form lichens. Four monophyletic subdivisions: *Saccharomycetes, Pezizomycotina, Taphrinomycotina,* and *Neolecta.*	*Ascobolus* *Aspergillis* *Candida* *Crinula* *Neurospora* *Penicillium* *Pneumocystis* *Saccharomyces*
Basidiomycota	Includes many common mushrooms and shelf fungi. Sexual reproduction involves formation of a basidium (small, club-shaped structure that typically forms spores at the ends of tiny projections) within which haploid basidiospores are formed. Usually four spores per basidium but can range from one to eight. Sexual reproduction involves fusion with opposite mating type resulting in a dikaryotic mycelium with parental nuclei paired but not initially fused. No subdivisions recognized. Also includes plant pathogens (rusts and smuts) belonging to *Urediniomycota* and *Ustilaginomycota.*	*Agaricus* *Boletes* *Dacrymyces* *Lycoperdon* *Polyporus* *Uromyces* *Ustilago*
Glomeromycota	Filamentous, most are endomycorrhizal, arbuscular; lack cilium; form asexual spores outside of host plant; lack centrioles, conidia, and aerial spores. No subdivisions recognized.	*Acaulospora* *Entrophospora* *Glomus*
Microsporidia	Obligate intracellular parasites usually of animals. Lack mitochondria, peroxisomes, kinetosomes, cilia, and centrioles; spores have an inner chitin wall and outer wall of protein; produce a tube for host penetration. Subdivisions currently uncertain.	*Amblyospora* *Encephalitozoon* *Enterocytozoon* *Nosema*
Cryptomycota	3–5 µm roughly spherical cells, flagellated, osmotrohpic. Cell wall does not possess chitin. Broadly distributed in soil, freshwater, and aquatic sediments.	*Rozella*

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Draw a eukaryotic cell envelope and identify the structure and function of its component layers (section 5.2)
- ✔ List the three filaments that make up the cytoskeleton of eukaryotic cells and describe how they are used (section 5.3)
- ✔ Identify the structure and function of eukaryotic cellular organelles (sections 5.4–5.6)
- ✔ Describe the endocytic pathway in general terms (section 5.4)
- ✔ Describe the structure and function of eukaryotic flagella and cilia (section 5.7)

26.1 Fungal Biology Reflects Vast Diversity

After reading this section, you should be able to:

- Discuss the importance of fungi in the environment as well as their practical importance
- Differentiate between a yeast and a mold, and between hypha and mycelium
- Compare and contrast different spore morphologies
- Explain how mating types govern sexual reproduction
- Infer what is meant by a “dikaryotic fungus”
- Assess the role of fungal decomposition on global carbon flux

Fungal Distribution and Importance

Unlike protists, fungi are primarily terrestrial organisms. They have a global distribution from polar to tropical regions. Fungi are **saprophytes,** securing nutrients from dead organic material by releasing degradative enzymes into the environment. This enables their absorption of the soluble products—a process sometimes called **osmotrophy** (Greek, *osmos,* pushing; perhaps a misnomer, as nutrients are transported rather than pushed into the cell). Fungi are important decomposers. They degrade complex organic materials in the environment to simple organic compounds and inorganic molecules. In this way, carbon, nitrogen, phosphorus, and other critical constituents of dead organisms are released and made available for living organisms. Many fungi are pathogenic, with over 5,000 species known to attack economically valuable crops and many other plants. About 20 new human fungal pathogens are documented each year. Conversely, fungi also form beneficial relationships with other organisms. For example, the vast majority of vascular plant roots form important associations with fungi called mycorrhizae. ▶▶| *Mycorrhizae facilitate the growth of most plants (section 31.3)*

Fungi, especially yeasts (single-celled fungi), are essential to many industrial processes involving fermentation. Examples include the making of bread, wine, beer, cheeses, and soy sauce. They are also important in the commercial production of many organic acids (citric, gallic) and certain drugs (ergometrine, cortisone), and in the manufacture of many antibiotics (penicillin, griseofulvin) and the immunosuppressive drug cyclosporine. In addition, fungi are important research tools in the study of fundamental biological processes. Cytologists, geneticists, biochemists, biophysicists, and microbiologists regularly use fungi in their research. The yeast *Saccharomyces cerevisiae* is the best understood eukaryotic cell. It has been a valuable model organism in the study of cell biology, genetics, and cancer. ▶▶| *Microbiology of fermented foods (section 41.5); Microbes are the source of many products of industrial importance (section 42.1)*

Fungal Structure

The body or vegetative structure of a fungus is called a **thallus** (pl., thalli). It varies in complexity and size. Single-cell microscopic fungi are referred to as yeasts, while multicellular masses are called molds. Fungi also include macroscopic puffballs and mushrooms. Like most bacteria, fungi possess cell walls; however, fungal cell walls are made of glucans, mannans, glycoproteins, and chitin. Chitin is a strong but flexible nitrogen containing polysaccharide consisting of *N*-acetylglucosamine residues.

A **yeast** is a unicellular fungus with a single nucleus that reproduces either asexually by budding and transverse division or sexually through spore formation. Each bud that separates can grow into a new cell, and some group together to form colonies. Generally yeast cells are larger than bacteria and are commonly spherical to egg-shaped. They lack flagella and cilia but have most other eukaryotic organelles (*see figures 5.2 and 5.3a*).

The thallus of a **mold** consists of long, branched, threadlike filaments called **hyphae** (s., hypha; Greek *hyphe,* web) that form a tangled mass called a **mycelium** (pl., mycelia). In some fungi, protoplasm streams lengthwise through the hyphae, uninterrupted by cross walls. These hyphae are called **coenocytic** or **aseptate hyphae** (**figure 26.3*a***). The hyphae of other fungi (figure 26.3*b*) have cross walls called **septa** (s., **septum**) with either a single pore (figure 26.3*c*) or multiple pores (figure 26.3*d*) that enable cytoplasmic streaming. These hyphae are termed **septate hyphae.**

Hyphae are composed of an outer cell wall and an inner lumen, which contains the cytosol and organelles. A plasma membrane surrounds the cytoplasm and lies next to the cell wall. The filamentous nature of hyphae results in a large surface area relative to the volume of cytoplasm. This makes nutrient absorption by osmotrophy possible.

Fungal Reproduction

Reproduction in fungi can be either asexual or sexual. Asexual reproduction is accomplished in several ways: (1) a parent cell undergoes mitosis and divides into two daughter cells by a central constriction and formation of a new cell wall (**figure 26.4*a***), or (2) mitosis in vegetative cells may be concurrent with budding to produce a smaller daughter cell. This is very common in yeasts. The formation of asexual spores often accompanies asexual reproduction and is usually used as a means of dispersal. There are many types of asexual spores, each with its own name. **Arthroconidia** (**arthrospores**) are formed when hyphae fragment (figure 26.4*b*). **Sporangiospores** develop within a sac called a **sporangium** (pl., sporangia) at a hyphal tip (figure 26.4*c*).

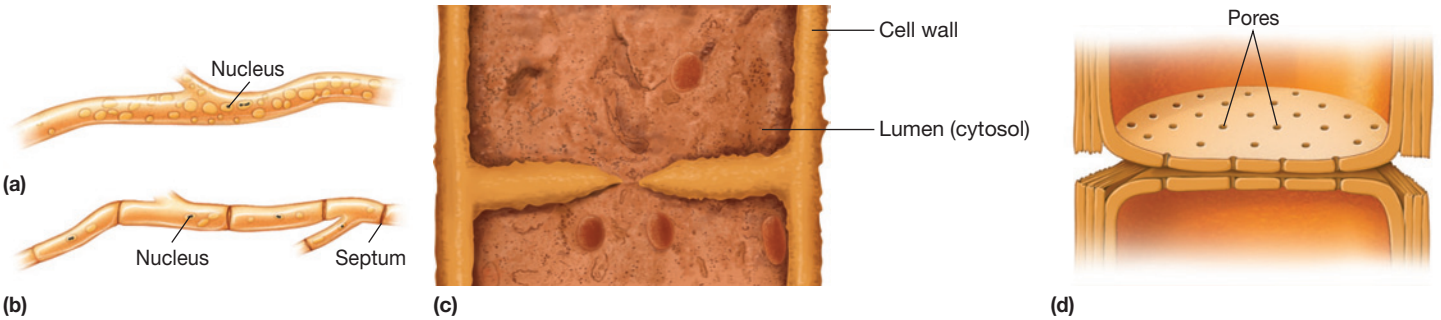

Figure 26.3 Hyphae. Drawings of (a) coenocytic hyphae (aseptate) and (b) hyphae divided into cells by septa. (c) A section of a representative fungal filament demonstrates that in some species, cellular compartments communicate by a single pore. (d) Drawing of a multiperforate septal structure.

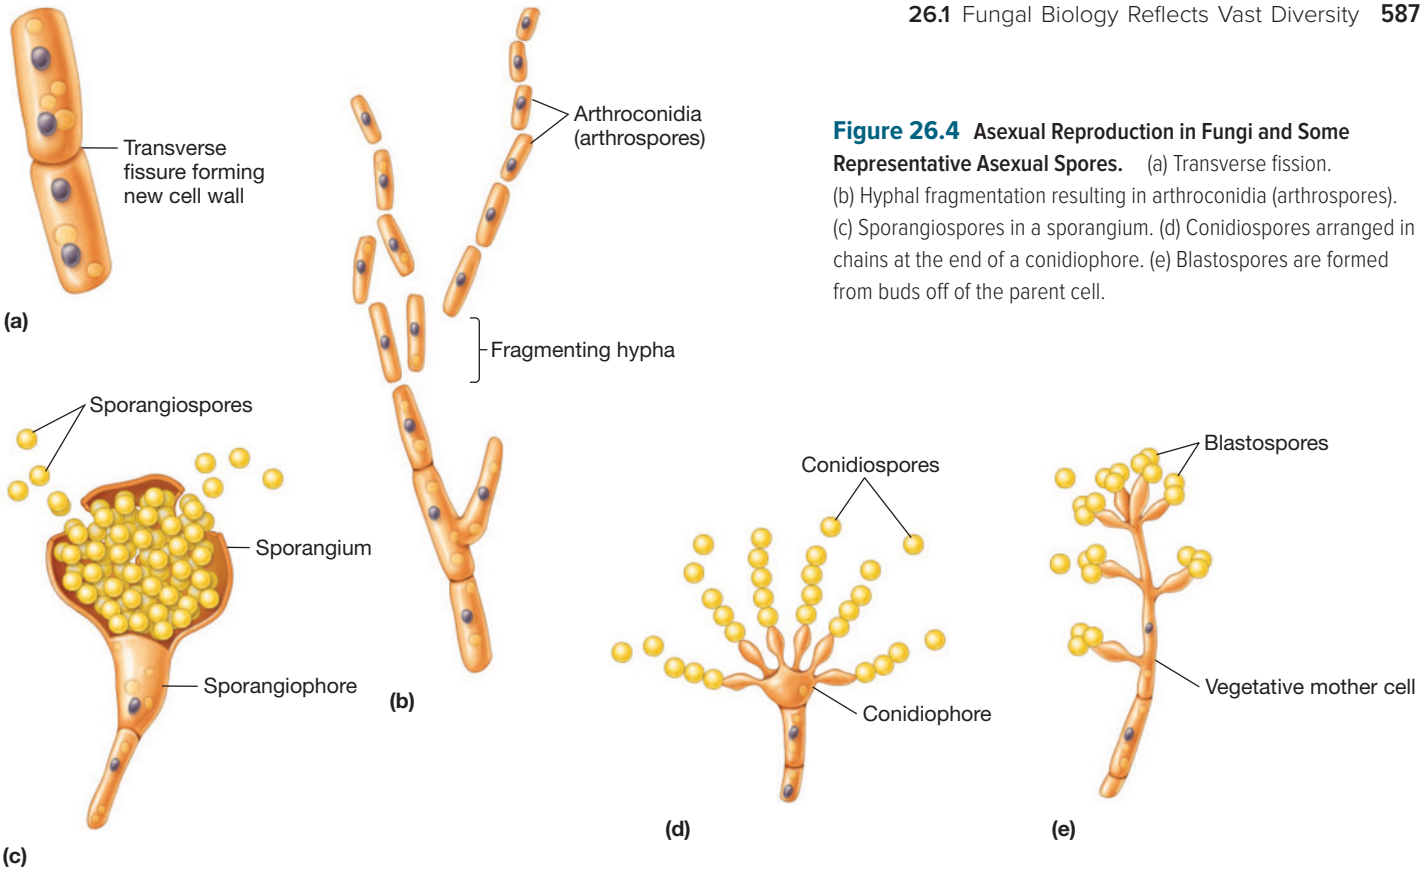

Figure 26.4 Asexual Reproduction in Fungi and Some Representative Asexual Spores. (a) Transverse fission. (b) Hyphal fragmentation resulting in arthroconidia (arthrospores). (c) Sporangiospores in a sporangium. (d) Conidiospores arranged in chains at the end of a conidiophore. (e) Blastospores are formed from buds off of the parent cell.

Conidiospores are spores that are not enclosed in a sac but produced at the tips or sides of the hypha (figure 26.4*d*). **Blastospores** are produced from a vegetative mother cell budding (figure 26.4*e*).

Sexual reproduction in fungi involves the fusion of compatible nuclei. Homothallic fungal species are self-fertilizing and produce sexually compatible gametes on the same mycelium. Heterothallic species require outcrossing between different but sexually compatible mycelia called mating types. Depending on the species, sexual fusion may occur between haploid gametes, gamete-producing bodies called **gametangia,** or hyphae. Sometimes both the cytoplasm and haploid nuclei fuse immediately to produce the diploid zygote, as seen in higher eukaryotes. More often, cytoplasmic fusion occurs before nuclear fusion. This produces a **dikaryotic stage** in which a single cell contains two separate haploid nuclei (N + N), one from each parent (**figure 26.5**). After a period of dikaryotic existence, the two nuclei fuse and undergo meiosis to yield haploid spores. This is seen in both ascomycetes and basidiomycetes, so these are sometimes referred to as dikaryotic fungi.

Fungal spores are important for several reasons. They enable fungi to survive environmental stresses such as desiccation, nutrient limitation, and extreme temperatures, although they are not as stress resistant as bacterial endospores. They aid in fungal dissemination, which helps explain their wide distribution. Because spores are often small and light, they can remain suspended in air for long periods and are often spread by adhering to the bodies of insects and other animals. The bright colors and fluffy textures of many molds often are due to their aerial hyphae and spores. Finally, the size, shape, color, and number of spores are useful in the identification of fungal species.

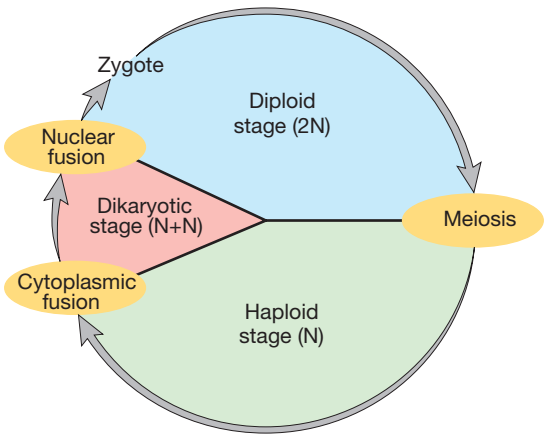

Figure 26.5 Reproduction in Fungi. A drawing of the generalized life cycle for fungi showing the alternation of haploid and diploid stages. Some fungal species do not pass through the dikaryotic stage indicated in this drawing. The asexual (haploid) stage is used to produce spores that aid in the dissemination of the species. The sexual (diploid) stage involves the formation of spores that survive adverse environmental conditions (e.g., cold, dryness, heat).

26.2 *Chytridiomycota* Produce Motile Spores

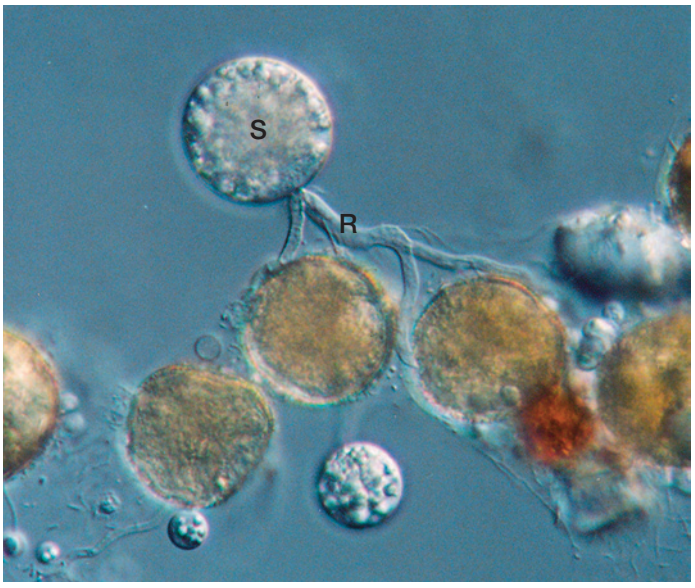
After reading this section, you should be able to:

- Explain why chytrids are unique among fungi
- Identify several habitats where chytrids grow
- Describe general chytrid morphology

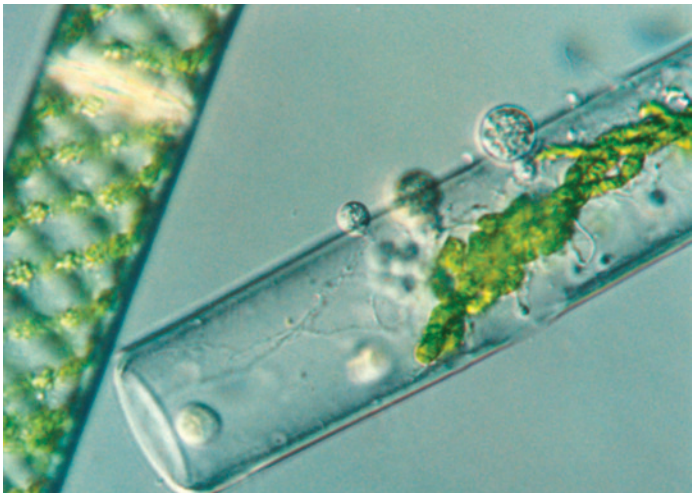
Chytridiomycota, commonly called **chytrids,** includes free-living and parasitic genera. Free-living chytrids are saprophytic, living on plant or animal matter in freshwater, mud, or soil. Parasitic forms infect aquatic plants and animals, including insects (**figure 26.6**). A few are found in the anoxic rumen of herbivores. The chytrid *Batrachochytrium dendrobatidis* is responsible for large-scale mortality of amphibians worldwide. This includes over 100 species of harlequin frogs (*Atelopus*) native to tropical America, in which infection has caused rapid population declines and, in some cases, extinction.

Chytrids are unique among fungi in the production of a spore with a single, posterior, whiplash flagellum. It has been hypothesized that all fungi were once flagellated with at least four independent losses of flagella during the evolution of more advanced fungal groups. The loss of flagella is thought to have coincided with the development of other means of spore distribution, such as aerial dispersal from mycelial mats. Chytrids are not considered monophyletic (note three clades of *Chytridiomycota* in figure 26.1). Instead, they derive from early diverging lineages that bear spores. The largest clade, *Euchytrids,* unites several orders of chytrids.

Chytrids display a variety of life cycles involving both asexual and sexual reproduction. Members of this group are microscopic in size and may consist of a single cell, a small multinucleate mass, or a true mycelium. Many are capable of degrading cellulose and even keratin, which enables the degradation of crustacean exoskeletons. The model chytrid *Allomyces macrogynus* has a complex life cycle that includes four types of sporangia and five developmentally distinct spore types.



(a)



(b)

Figure 26.6 ***Chytridiomycota.*** (a) A chytrid with a single round sporangium (S) that is about 50 μm in diameter. (b) Parasitic chytrids attached to the surface of a photosynthetic protist (a green alga).

MICRO INQUIRY *What is the function of the chytrid rhizoids?*

26.3 *Zygomycota:* Fungi with Coenocytic Hyphae

After reading this section, you should be able to:

- Recognize zygomycetes in nature
- Outline the life cycle of a *Rhizopus* species
- List at least two reasons zygomycetes benefit humans

Zygomycota contains fungi informally called **zygomycetes.** Most live on decaying plant and animal matter in the soil; a few are parasites of plants, insects, and other animals, including humans. The hyphae of zygomycetes are coenocytic (aseptate), with many haploid nuclei. Asexual spores develop in sporangia at the tips of aerial hyphae and are usually wind dispersed. Sexual reproduction produces tough, thick-walled zygotes called **zygospores** that can remain dormant when the environment is too harsh for growth of the fungus.

The mold *Rhizopus stolonifer* is a common member of this division. This fungus grows on the surface of moist, carbohydrate-rich foods, such as breads, fruits, and vegetables. Hyphae called rhizoids extend into the substrate and absorb nutrients. Other hyphae (stolons) become erect, then arch back into the substratum, forming new rhizoids. Still others remain erect and produce at their tips asexual sporangia filled with hundreds of black spores, giving the mold its characteristic color. Each spore, when liberated, can germinate to start a new mycelium.

Rhizopus spp. usually reproduce asexually, but if food becomes scarce or environmental conditions unfavorable, sexual reproduction occurs (**figure 26.7**). Sexual reproduction requires compatible strains of opposite mating types (called + and −). When + and − hyphae are close, each produces a different hormone, called a pheromone, that causes their hyphae to form projections called progametangia; these mature into gametangia. First the gametangia fuse, a process called plasmogamy. Then, the nuclei of the two gametes fuse (karyogamy), forming a zygote. The zygote develops a thick, rough, black coat and becomes a dormant zygospore. Meiosis often occurs at the time of germination; the zygospore then splits open and produces a hypha that bears an asexual sporangium filled with haploid spores that begin the cycle again.

One important member of the genus *Rhizopus* is involved in the rice disease known as seedling blight. If one considers that rice feeds more people on Earth than any other crop, the implications of this disease are obvious. It was thought that the fungus secreted a toxin that kills rice seedlings, so scientists set about isolating the toxin and the genes that produce it. Much to everyone's surprise, the toxin is produced by an α-proteobacterium, *Burkholderia* sp., growing within the fungus.

Zygomycetes also contribute to human welfare. For example, one species of *Rhizopus* is used in Indonesia to produce a food called tempeh from boiled, skinless soybeans. Other zygomycetes (*Mucor* spp.) are used with soybeans in Asia to make a curd called sufu. Others are employed in the commercial preparation of some anesthetics, birth control agents, industrial alcohols, meat tenderizers, and the yellow coloring used in margarine and butter substitutes. ▶▶| *Microbiology of fermented foods (section 41.5)*

26.4 *Glomeromycota* Are Mycorrhizal Symbionts

After reading this section, you should be able to:

- Describe the functional importance of glomeromycetes
- Differentiate between ectomycorrhizae and arbuscular mycorrhizae

Glomeromycetes are of critical ecological importance because they are mycorrhizal symbionts of vascular plants. **Mycorrhizal fungi** form important associations with the roots of almost all herbaceous plants and tropical trees. This is considered a mutualistic relationship because both the host plant and the fungus benefit: the fungus delivers soil nutrients to the plant, and the plant in turn provides carbohydrate to the fungus. As discussed in chapter 31, most mycorrhizal fungi belong to one of two groups. Ectomycorrhizae do not penetrate host root cells; instead, the fungal hyphae grow between and around cells. By contrast, arbuscular mycorrhizal hyphae penetrate the host root cell wall but not the plasma membrane (*see figures 31.4–31.8*). ▶▶| *Mycorrhizae facilitate the growth of most plants (section 31.3)*

Glomeromycetes have aseptate hyphae and produce large, multinucleate spores. Only asexual reproduction is known to occur. This can occur by fragmentation of filaments in the soil or on a plant. Spores germinate when in contact with the roots of a suitable host plant. Unlike other filamentous fungi, glomeromycetes have evolved specialized flat hyphae called **appressoria** (s., appressorium) to penetrate their host plants.

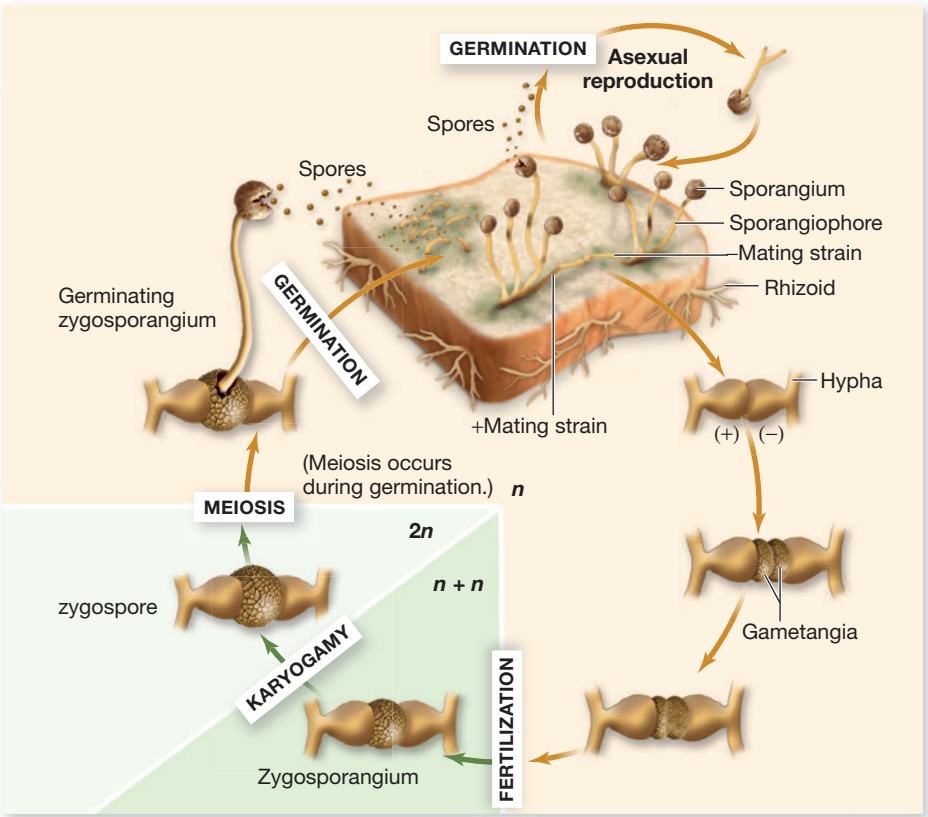


Figure 26.7 ***Rhizopus stolonifer*, a Zygomycete That Grows on Simple Sugars.** This fungus is often found on moist bread or fruit. The life cycle of *Rhizopus* spp. involves sexual and asexual phases as shown. *Zygomycota* is named for the zygosporangia characteristic of members of the genus *Rhizopus*.

3. How do different mating types of *Rhizopus stolonifer* recognize each other?
4. Given that mycorrhizal fungi obtain carbohydrates from their plant partners, what specific nutrients are the fungi likely to provide to plants?
5. Which fungal class would you most likely find in each of the following environments: two-week-old cake, mud, tree roots?

26.5 *Ascomycota* Includes Yeasts and Molds

After reading this section, you should be able to:

- Describe ecological, economic, and medical importance of ascomycetes
- Diagram the *Saccharomyces cerevisiae* life cycle
- Outline the mechanisms used by typical filamentous ascomycetes to reproduce, survive unfavorable conditions, and disperse
- Explain the function of sclerotia
- Identify the origin of St. Anthony's fire, LSD, and "sick building syndrome"

Members of *Ascomycota,* or **ascomycetes,** commonly known as **sac fungi,** are named for their characteristic reproductive structure, the saclike **ascus** (pl., asci; Greek *askos,* sac), which holds **ascospores.** Ascomycetes are ecologically important in freshwater, marine, and terrestrial habitats because they degrade many chemically stable organic compounds, including lignin, cellulose, and collagen. Many species are quite familiar and economically important (**figure 26.8**). For example, most of the red, brown, and blue-green molds that cause food spoilage are ascomycetes. The powdery mildews that attack plant leaves and the fungi that cause chestnut blight and Dutch elm disease are ascomycetes. Many, if not most, fungi that infect humans are ascomycetes. On the other hand, many yeasts as well as edible morels and truffles are also ascomycetes. The pink bread mold *Neurospora crassa* is an important research tool in genetics and biochemistry.

Some ascomycetes are yeasts, while others have a life cycle that alternates between yeast and filamentous forms. The life cycle of the yeast *Saccharomyces cerevisiae,* commonly known as brewer's or baker's yeast, is well understood (**figure 26.9**). *S. cerevisiae* alternates between haploid and diploid states. As long as nutrients remain plentiful, haploid and diploid cells undergo mitosis to produce haploid and diploid daughter cells, respectively. Each daughter cell leaves a scar on the mother cell as it separates, and daughter cells bud only from unscarred regions of the cell wall. When a mother cell has no more unscarred cell wall remaining, it can no longer reproduce and will senesce (die). When nutrients are limited, diploid *S. cerevisiae* cells undergo meiosis to produce four haploid cells that remain bound within a common cell wall, the ascus. Upon the addition of nutrients, two haploid cells of opposite mating types (a and α) come into contact and fuse to create a

(b) *S. cerevisiae* life cycle

Figure 26.9 **The Life Cycle of the Yeast *Saccharomyces cerevisiae.*** (a) Budding division results in asymmetric septation and the formation of a smaller daughter cell. (b) When nutrients are abundant, haploid and diploid cells undergo mitosis and grow vegetatively. When nutrients are limited, diploid *S. cerevisiae* cells undergo meiosis to produce four haploid cells that remain bound within a common cell wall, the ascus. Upon the addition of nutrients, two haploid cells of opposite mating types (a and α) fuse to create a diploid cell.

MICRO INQUIRY *What determines when a yeast cell can no longer bud?*

Figure 26.10 Asexual Reproduction in Filamentous Ascomycetes. Characteristic conidiospores of *Aspergillus* spp. as viewed with the scanning electron microscope.

diploid. Typically only cells of opposite mating types can fuse; this process is tightly regulated by the action of pheromones.

S. cerevisiae is a valuable model organism. Research on this organism has revealed the importance of many cellular processes. For instance, it is a favorite model system for studying cell cycling and the events during mitosis. This research is critical not only for our understanding of normal cell division, but also for exploring the loss of cell cycle control that occurs in cancerous cells.

One of the hallmarks of filamentous ascomycetes is the formation of septate hyphae. Asexual reproduction is common and is associated with the production of externally produced asexual spores called **conidia** (**figure 26.10**). Sexual reproduction involves two strains of opposite mating types. Hyphae from one mating type form a specialized structure called an ascogonium, and hyphae of the other mating type form an antheridium (**figure 26.11**). The nuclei from the antheridium migrate to the ascogonium during the exchange of cytoplasm (plasmogamy). The nuclei do not yet fuse, rather nuclei from each mating type pair and replicate in unison during the ensuing dikaryotic phase. The ascogonium is said to be fertilized and the hyphae are called **ascogenous hyphae.** Ascogenous hyphae, supported by sterile hyphae, next develop into a cup-like structure called an **ascocarp.** This is where ascogenous

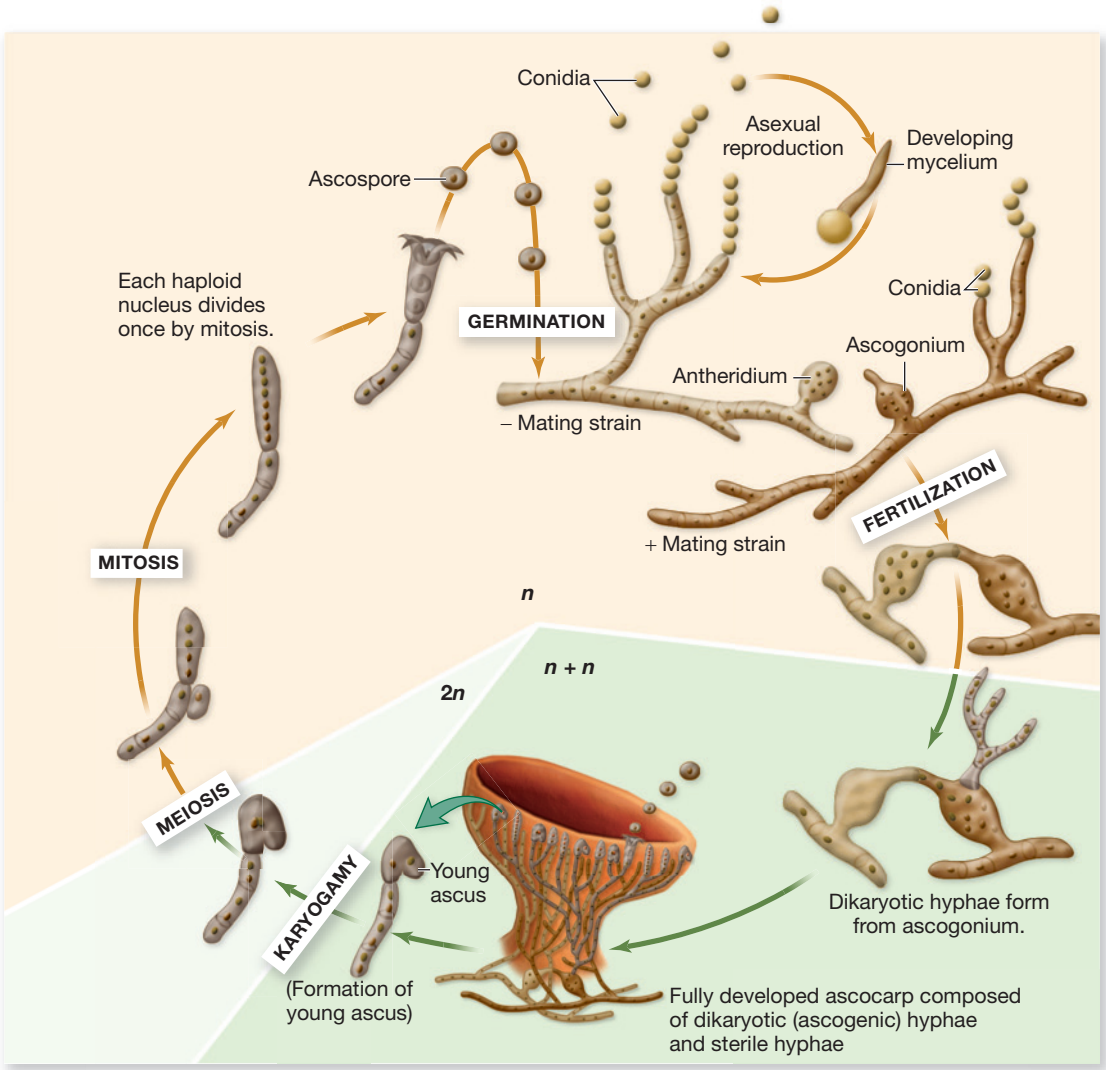

Figure 26.11 The Typical Life Cycle of a Filamentous Ascomycete. Sexual reproduction involves the formation of asci and ascospores. The events pictured on the left side of the figure (karyogamy, meiosis, mitosis, and release of ascospores) occur within the ascocarp.

MICRO INQUIRY *In what ways is the life cycle of filamentous ascomycetes similar to that of the zygomycete shown in figure 26.7? How do the two life cycles differ?*

hyphae mature, and nuclear fusion (karyogamy) takes place. The diploid zygote nucleus then undergoes meiosis, and the resulting four haploid nuclei divide mitotically again to produce a row of eight nuclei in each developing ascus. These nuclei are walled off from one another and each will develop into an **ascospore.** Thousands of asci may be packed together in an ascocarp. When the ascospores mature, they often are released from the asci with great force. If the mature ascocarp is jarred, it may appear to belch puffs of "smoke" consisting of thousands of ascospores. Upon reaching a suitable environment, the ascospores germinate and start the cycle anew.

Although conidia are the major form of dissemination, structures called **sclerotia** are compact masses of dormant hyphae that permit survival in stressful conditions. Sclerotia confer a competitive advantage to the fungi that produce them. For instance, some species of *Aspergillus* that infect plants form sclerotia to remain viable in the soil, where they can take advantage of nutrient resources when the temperature rises.

Several *Aspergillus* species are noteworthy. *A. fumigatus* is ubiquitous in the environment, commonly found in homes and the workplace. It is known to trigger allergic responses and is implicated in the increased incidence of severe asthma and sinusitis. It is also pathogenic, infecting immunocompromised individuals with a mortality rate of nearly 50%. *A. nidulans* is a model organism used to study questions of eukaryotic cell and developmental biology. *A. oryzae* is used in the production of traditional fermented foods and beverages in Japan, including saki and soy sauce. Because *A. oryzae* secretes many industrially useful proteins and can be genetically manipulated, it has become an important organism in biotechnology. ▶▶| *Microbiology of fermented foods (section 41.5)*

Many ascomycetes are parasites of higher plants. *Claviceps purpurea* parasitizes rye and other grasses, causing the plant disease **ergot** (**figure 26.12**). Ergotism, the toxic, delusional condition in humans and animals that eat grain infected with the fungus, is often accompanied by gangrene, nervous spasms, abortion, and convulsions. During the Middle Ages, ergotism, then known as St. Anthony's fire, killed thousands of people. For example, over 40,000 deaths from ergot poisoning were recorded in France in the year 943. It has been suggested that the widespread accusations of witchcraft in Salem Village and other New England communities in the 1690s may have resulted from outbreaks of ergotism. The pharmacological activities are due to an active ingredient, lysergic acid diethylamide (LSD). In controlled dosages, other active compounds can be used to induce labor, lower blood pressure, and ease migraine headaches.

Figure 26.12 Ergot of Rye. The ascomycete *Claviceps purpurea* infects rye and other grasses, producing hard masses of hyphae known as ergots in place of some of the grains (fruits). Ergots produce alkaloids that cause psychotic delusions in humans and animals when products made with infected grain are consumed. Ergots have been used to treat migraine headaches and hasten childbirth.

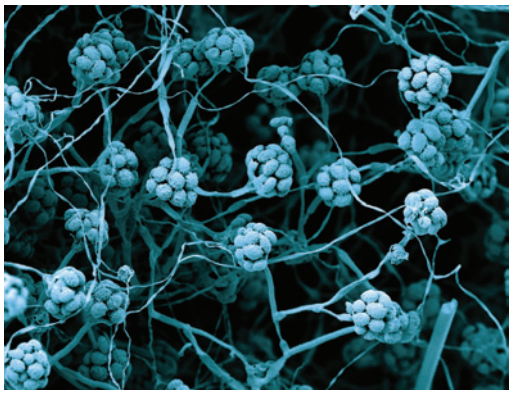

Figure 26.13 Fungal "Sick Building Syndrome" Can Be Caused by an Ascomycete. Scanning electron micrograph of dense mycelia and conidiophores characteristic of *Stachybotrys chartarum*.

Most fungal pathogens that infect animals, including humans, are ascomycetes (**Disease 26.1**). Notable examples include members of the genera *Candida, Blastomyces,* and *Histoplasma*. In addition, one cause of "sick building syndrome," *Stachybotrys chartarum* is also an ascomycete (**figure 26.13**). Finally, the *Aspergillus* and *Fusarium* toxins known as aflatoxins and fumonisins, respectively, are important causes of food contamination (*see figures 41.5 and 41.6*). Exposure to aflatoxins can result in liver cancer. These and other fungal pathogens are discussed in chapter 40, while aflatoxins are covered in chapters 40 and 41.

26.6 *Basidiomycota* Includes Mushrooms and Plant Pathogens

After reading this section, you should be able to:

- Describe the life cycle of a typical basidiomycete
- Identify the fungi that cause plant rusts
- Describe one human and one plant disease caused by a basidiomycete

Fungi in *Basidiomycota* are commonly known as **basidiomycetes,** or **club fungi.** Examples include jelly fungi, rusts, shelf fungi, stinkhorns, puffballs, toadstools, mushrooms, and bird's nest fungi. Most are saprophytes that decompose plant debris,

DISEASE

26.1 White-Nose Syndrome Is Decimating North American Bat Populations

Bats evoke all kinds of images. Some people immediately think of vampire bats and are repulsed. Others think of large fruit bats often called flying foxes. If you have spent a summer evening outdoors on the east coast of North America, mosquitoes and the small bats that eat them may come to mind. A new scene can now be added to these: bats with white fungal hyphae growing around their muzzles (**box figure**). This is the hallmark of white-nose syndrome (WNS), and if its rate of infection continues unchecked, it is projected to eliminate the most common bat species in eastern North America (*Myotis lucifugus*) by 2026.

WNS was first spotted in 2006 among bats hibernating in a cave near Albany, NY. Scientists quickly became alarmed for two reasons. First, it spreads rapidly—it's known to occur in at least 11 bat species and is now found in 25 states in the United States and three Canadian provinces. Second, it is deadly. The population of bats declines from 30 to 99% in any given infected hibernacula (the place where bats hibernate, which unfortunately rhymes with Dracula).

WNS is caused by the ascomycete *Pseudogymnoascus destructans* (formerly *Geomyces destructans*). It colonizes a bat's wings, muzzle, and ears where it erodes the epidermis before invading the underlying skin and connective tissue. Despite the name WNS, the primary site of infection (and the anatomical site harmed most) is the wing. Wings provide a large surface area for colonization, and once infected, the thin layer of skin is easily damaged, leading to adverse physiological changes during hibernation. These in turn result in premature awakening, loss of essential fat reserves, and strange behavior.

Where did this pathogen come from and why does it infect bats? The best hypothesis regarding its origin is that humans inadvertently brought it from Europe, where it causes mild infection in at least one hibernating bat species. This makes *P. destructans* an apparent case of pathogen pollution—the human introduction of invasive pathogens of wildlife and domestic animal populations that threaten biodiversity and ecosystem function.

The capacity of *P. destructans* to sweep through bat populations results from a "perfect storm" of host- and pathogen-associated factors. *P. destructans* is psychrophilic, with a growth optimum around 12°C; it does not grow above 20°C. All infected bat species hibernate in cold and humid environments such as caves and mines. Because their metabolic rate is drastically reduced during hibernation, their body temperature reaches that of their surroundings, between 2 and 7°C. Thus WNS is only seen in hibernating bats or those that have just emerged from hibernation. When metabolically active, the bat's body temperature is too warm to support pathogen growth.

While it is too late to save the estimated 6 million bats that have already succumbed to WNS, microbiologists, conservationists, and government agencies are trying to limit the continued decline in bat populations. Caves have been closed to human traffic, and protocols for decontamination after visiting hibernacula have been developed to limit the spread from cave to cave. Although we cannot cure sick bats, it is our responsibility to stop the continued spread of this pathogen.

Geomyces destructans causes WNS. A little brown bat (*Myotis lucifugus*) with the white fungal hyphae (arrow) for which WNS is named.

Read more: Langwig, K.E., et al. 2014. Invasion dynamics of white-nose syndrome fungus, midwestern United States, 2012–2014. Emerging Infectious Diseases. *21: 1023–1026.*

especially cellulose and lignin. For example, the common fungus *Polyporus squamosus* forms large, shelflike structures that project from the lower portion of dead trees, which they help decompose. Many mushrooms are used as food, and the cultivation of the mushroom *Agaricus campestris* is a multimillion-dollar business. Of course, not all mushrooms are edible. Many mushrooms produce alkaloids that act as either poisons or hallucinogens. One such example is the "death angel" mushroom, *Amanita phalloides* (**figure 26.14**). Two toxins isolated from this species are phalloidin and α-amanitin. Phalloidin primarily attacks liver cells, where it binds to and ruptures plasma membranes. Alpha-amanitin attacks the cells lining the stomach and small intestine, causing severe gastrointestinal symptoms associated with mushroom poisoning. *A. muscaria* is both poisonous and hallucinogenic.

Basidiomycetes are named for their characteristic structure or cell, the **basidium,** which is involved in sexual reproduction (figure 24.15*b*). A basidium (Greek *basidion,* small base) is

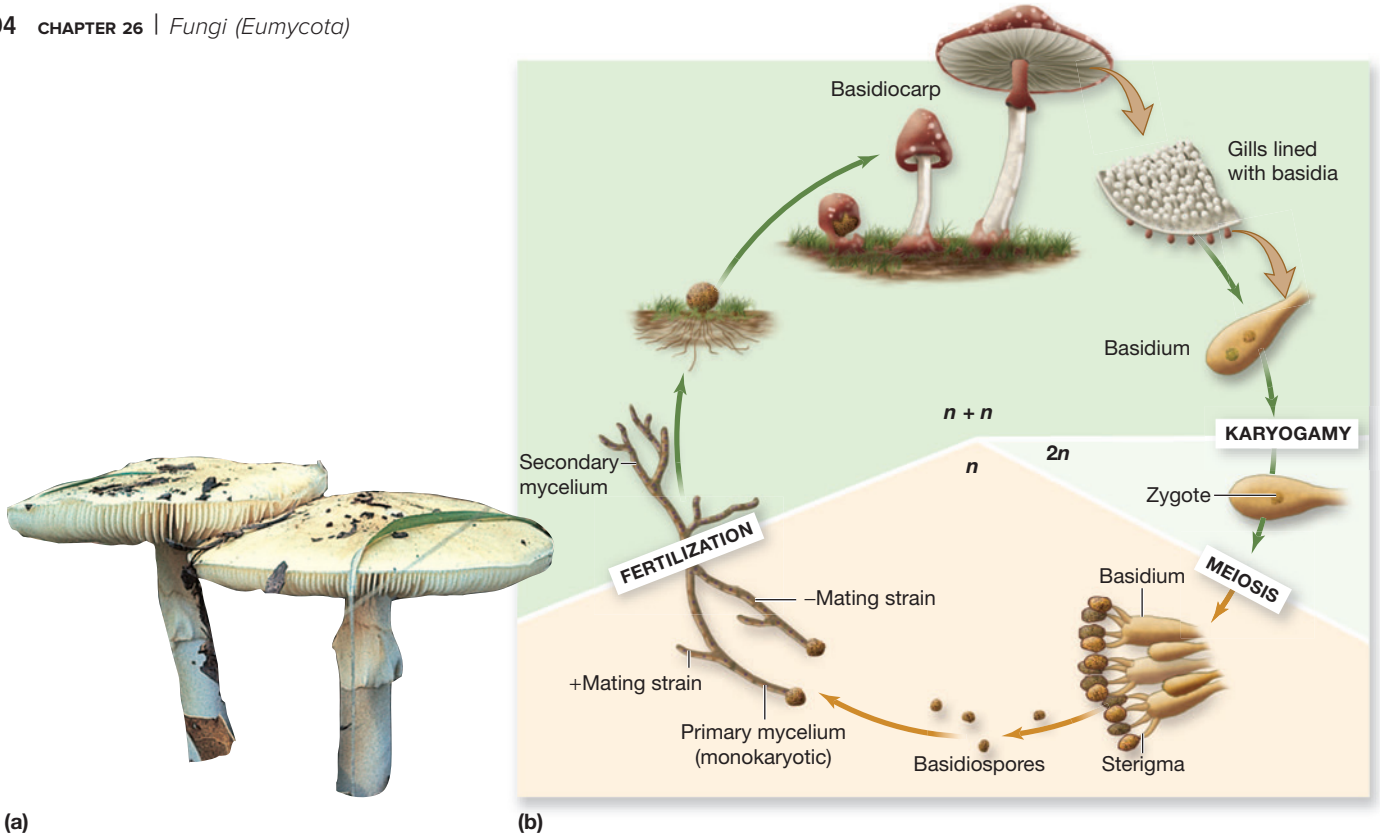

Figure 26.14 ***Basidiomycota.*** (a) The death cap mushroom *Amanita phalloides* is usually fatal when eaten. (b) The life cycle of a typical soil basidiomycete starts with a basidiospore germinating to produce a monokaryotic mycelium (a single nucleus in each septate cell). The mycelium grows and spreads throughout the soil. When this primary mycelium meets another monokaryotic mycelium of a different mating type, the two fuse to initiate a dikaryotic secondary mycelium. The secondary mycelium is divided by septa into cells, each of which contains two nuclei, one of each mating type. This dikaryotic mycelium is eventually stimulated to produce basidiocarps. A solid mass of hyphae forms a button that pushes through the soil, elongates, and develops a cap. The cap contains many platelike gills, each of which is coated with basidia. The two nuclei in the tip of each basidium fuse to form a diploid zygote nucleus, which immediately undergoes meiosis to form four haploid nuclei. These nuclei push their way into the developing basidiospores, which are then released at maturity.

produced at the tip of hyphae and normally is club-shaped. Two or more **basidiospores** are produced by the basidium, and basidia may be held within fruiting bodies called **basidiocarps.** Basidiocarps can reach 60 cm in diameter and have many pores, each lined with basidia that produce basidiospores. Thus a single fruiting body can produce millions of spores. Like ascomycete hyphae, the hyphae of basidiomycetes are septate.

The basidiomycete *Cryptococcus neoformans* is an important human and animal pathogen. It causes a disease called cryptococcosis, an infection primarily involving the lungs and central nervous system. In the human host, this fungus always grows as a large, budding yeast, and the production of an elaborate capsule is an important virulence factor for the microbe. In the environment, *C. neoformans* is a saprophyte with a worldwide distribution. ⏭ *Cryptococcosis (section 40.2)*

Basidiomycetes known as urediniomycetes and ustilaginomycetes include important plant pathogens causing "rusts" and "smuts," respectively, that destroy millions of dollars worth of crops annually. These fungi do not form large basidiocarps. Instead, small basidia arise from hyphae at the surface of the host plant. The hyphae grow extracellularly in plant tissue. In addition, some urediniomycetes are human pathogens.

The ustilaginomycete *Ustilago maydis* is a common corn pathogen that has become a model organism for plant smuts (**figure 26.15**). It is dimorphic; plant-associated fungi grow in the mycelial form but are yeastlike in the external environment. Yeastlike saprophytic *U. maydis* cells can be easily grown in the laboratory. In nature, the yeast (haploid sporidia) must mate to produce infectious, filamentous dikaryons that depend on the

Figure 26.15 ***Ustilago maydis.*** This pathogen causes tumor formation in corn. Note the enlarged tumors releasing dark teliospores in place of normal corn kernels.

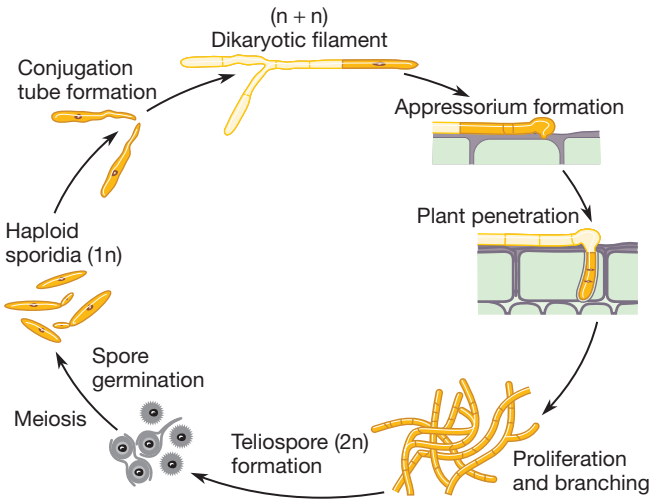

Figure 26.16 **Life Cycle of the Plant Pathogen *Ustilago maydis*.** Haploid sporidia must mate to form infectious dikaryons, which in turn depend on the host plant for continued development. The formation of fungal appressoria within the host induces tumor formation.

MICRO INQUIRY *What adaptations do you think* U. maydis *has evolved that has led to its pathogenicity? Contrast this with mycorrhizae.*

host plant for continued development (**figure 26.16**). Once a plant is infected, *U. maydis* forms appressoria within the host. This triggers the plant to form tumors in which the fungus proliferates and eventually produces diploid spores called **teliospores.** Upon germination, cells undergo meiosis and haploid sporidia are released. These sporidia can spread from plant to plant, where they start the growth and infection cycle again.

26.7 *Microsporidia* Are Intracellular Parasites

After reading this section, you should be able to:

- Explain why microsporidia are no longer considered protists
- Describe the microsporidian life cycle and relate its unique morphology to host invasion
- List at least two human diseases caused by microsporidia

Of all the fungi, members of ***Microsporidia*** have the most confused taxonomic history. These obligately endoparasitic microbes are sometimes still considered protists. However, analysis of ribosomal RNA and specific proteins such as α- and β-tubulin shows that they are fungi. However, unlike other fungi, they lack mitochondria, peroxisomes, and centrioles but possess

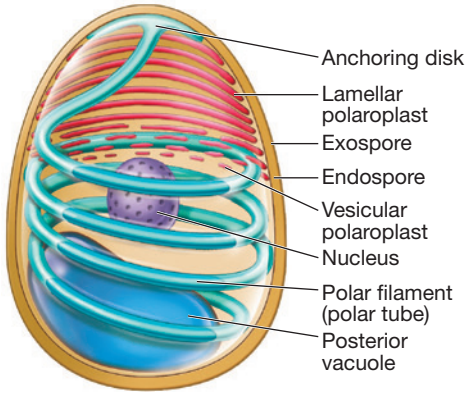

Figure 26.17 **The Unique Structure of a Microsporidian Spore.** Upon germination in a host cell, the polar tube is ejected with enough force to pierce the host cell membrane, allowing the fungus to gain entry.

mitosomes, like some protists. Their genomes are highly reduced in size and complexity. But like most fungi, microsporidian cell walls contain chitin and trehalose.

Microsporidial morphology is also unique among eukaryotes. It is distinct in the possession of an organelle called the polar tube that is essential for host invasion. Small spores of 1 to 40 μm are viable outside the host. Depending on the species, spores may be spherical, rodlike, or egg- or crescent-shaped. Spore germination occurs only in the host, where it expels the tightly packed polar tube or filament (**figure 26.17**). The polar tube is ejected with enough force to pierce the host cell membrane, permitting parasite entry. Once inside the host cell, the microsporidian undergoes a developmental cycle that differs among the various microsporidian species. However, in all cases, more spores are produced and eventually take over the host cell.

Microsporidia are important obligate intracellular parasites that infect insects, fish, and humans. They are particularly problematic for immunocompromised individuals, especially those with HIV/AIDS. Human pathogens include *Enterocytozoon bieneusi,* which causes diarrhea and pneumonia (depending on whether it was acquired through ingestion or inhalation, respectively), and *Encephalitozoon cuniculi,* which causes encephalitis and nephritis (kidney disease). Aquatic birds are an important source of pathogenic microsporidia in nature; indeed, a single flock of waterfowl can deposit over 10^8 microsporidian spores in surface waters after one visit. ▶▶| *Microsporidiosis (section 40.6)*

1. What is the difference between a basidiocarp and a basidium?
2. How do cryptococci differ from most basidiomycetes?
3. How does *Ustilago maydis* trigger tumor formation? How is tumor formation advantageous to the fungi?
4. Why do you think members of *Microsporidia* are still sometimes considered protists? What structure is essential for the germination of a microsporidian spore? Describe its function.

Key Concepts

26.1 Fungal Biology Reflects Vast Diversity

- Fungi are important decomposers that break down organic matter; live as parasites on animals, humans, and plants; play a role in many industrial processes; and are used as research tools in the study of fundamental biological processes. Fungi secrete enzymes outside their body structure and absorb the digested food.

- A fungus is a eukaryotic, spore-bearing organism that has absorptive nutrition and lacks chlorophyll; reproduces asexually, sexually, or by both methods; and normally has a cell wall usually containing chitin.
- Hyphae are long, branched, threadlike filaments that form a tangled mass called a mycelium. Hyphae may be either septate or coenocytic (nonseptate). The mycelium can produce reproductive structures (**figure 26.3**).
- Asexual reproduction in the fungi often leads to the production of specific types of spores that are easily dispersed (**figure 26.4**).
- Sexual reproduction is initiated in fungi by the fusion of hyphae (or cells) of different mating strains. In some fungi, the nuclei in the fused hyphae immediately combine to form a zygote. In others, the two genetically distinct nuclei remain separate, forming pairs that divide synchronously. Eventually some nuclei fuse (**figure 26.5**).

26.2 *Chytridiomycota* Produce Motile Spores

- Fungi belonging to *Chytridiomycota* produce motile spores. Most are saprophytic; some reside in the rumen of herbivores (**figure 26.6**).
- These fungi are microscopic and display both sexual and asexual reproduction.

26.3 *Zygomycota:* Fungi with Coenocytic Hyphae

- Most zygomycetes are saprophytic. One example is the common bread mold, *Rhizopus stolonifer.* Sexual reproduction occurs through conjugation between strains of opposite mating type (**figure 26.7**).
- Zygomycetes are used in food and pharmaceutical manufacturing.

26.4 *Glomeromycota* Are Mycorrhizal Symbionts

- *Glomeromycota* includes mycorrhizal fungi that grow in association with plant roots. They serve to increase plant nutrient uptake.
- Most mycorrhizal fungi are either ectomycorrhizae, which do not penetrate the host plant cells, or arbuscular mycorrhizae, which grow between the plant cell wall and plasma membrane.

26.5 *Ascomycota* Includes Yeasts and Molds

- Members of *Ascomycota* are known as sac fungi because they form a sac-shaped reproductive structure called an ascus. Ascomycetes can have either a yeast morphology (**figure 26.9**) or a mold morphology (**figure 26.11**).
- Important ascomycetes include the yeast *Saccharomyces cerevisiae, Aspergillus* spp., *Claviceps purpurea* (the cause of ergotism), and the indoor mold *Stachybotrys chartarum*.

26.6 *Basidiomycota* Includes Mushrooms and Plant Pathogens

- Members of *Basidiomycota* are called club fungi. They are named after their basidium that produces basidiospores (**figure 26.14**).
- Genera from urediniomycetes and ustilaginomycetes include important plant pathogens (**figure 26.15**).

26.7 *Microsporidia* Are Intracellular Parasites

- Members of *Microsporidia* have a unique morphology and are still sometimes considered protists.
- They include virulent human pathogens; some infect other vertebrates and insects (**figure 26.17**).

Compare, Hypothesize, Invent

1. What are some physiological or morphological targets to exploit in treating animals or plants suffering from fungal infections? Compare these with the targets you would use when treating infections caused by bacteria.
2. Some fungi can be viewed as coenocytic organisms that exhibit little differentiation. When differentiation does occur, such as in the formation of reproductive structures, it is preceded by septum formation. Why does this occur?
3. Both bacteria and fungi are major environmental decomposers. Obviously competition exists in any given environment, but fungi usually have an advantage. What characteristics specific to fungi provide this advantage?
4. *Neurospora crassa* and several other filamentous fungi demonstrate a circadian rhythm such that conidiation occurs in roughly 21.5-hour cycles, depending on temperature and the light/dark regime. This can be observed in nature as bands of conidia alternating with bands of undifferentiated fungi. Suggest why these fungi evolved a circadian rhythm? If you were to study this phenomenon, what questions would you want to explore?
5. Analysis of sclerotia and conidia formation in the filamentous ascomycete *Aspergillus flavus* suggests that formation of these structures is cell density dependent. Specifically, high cell density cultures yield conidia, whereas low cell density triggers sclerotia formation. Review the structure and function of conidia and sclerotia, and formulate a hypothesis to explain why their development would be regulated in a density-dependent manner. List several specific testable predictions based on your hypothesis.

Viruses

Sheep are just one of the targets of Schmallenberg virus.

Deadly New Virus Strikes European Farm Animals

Imagine the shock and dismay of a farmer who sees that his prized ewe just gave birth to a horribly deformed, stillborn lamb. This is exactly what some farmers in several European countries experienced in 2012 as a newly discovered virus spread from farm to farm.

Disease caused by Schmallenberg virus (SBV) was first detected in adult animals in November 2011, when dairy cows in Schmallenberg, Germany, became ill. The cows had a fever, but the most striking symptom was drastically reduced milk production, an obvious loss of income for farmers. Unfortunately, this was just the tip of the iceberg. Within about a month, the first deformed lambs were born, indicating that the virus not only had spread from cows to sheep, but also transmitted vertically from cows and ewes to their offspring. Goats were the next animals to be attacked. During 2012, increasing numbers of adult animals were infected, and more and more of their offspring affected. For farmers, this virus is a two-pronged threat: decreased milk production from the adult animals and loss of progeny from infected females.

The emergence of Schmallenberg virus should not come as a surprise. Over the last several decades, several new viruses or virus strains have been discovered—consider HIV, SARS and MERS coronaviruses, Ebola virus, and new influenza viruses. The ongoing discovery of new viruses is a reminder of the diversity of viruses.

As we outline in chapter 6, viral diversity is in part due to virion structure, especially the nature of the viral genome. A virus's genome dictates important aspects of its life cycle and is in part the basis of a scheme (the Baltimore system) that greatly simplifies the discussion of viral life cycles. The Baltimore system is not the classification system used by virologists to identify and name viruses. That system is developed by the International Committee on Taxonomy of Viruses; however, our discussion is organized by the Baltimore system due to its relative simplicity. For each Baltimore group, we present a brief overview of how viruses in the group multiply, as well as the life cycle of at least one virus.

Another aspect of viral diversity is the variety of strategies viruses use to regulate events in their life cycles and activities of their host cells. Like many viruses, SBV inhibits transcription of host cell genes. This in turn prevents the host from mounting an immune response against the virus. We examine some of these strategies in this chapter as well. In many ways, this discussion is a continuation of topics introduced in chapters 14 and 15, where we consider the regulation of cellular processes, and is continued in chapter 38, where we discuss diseases caused by human viruses. For a virus to multiply (and therefore cause disease), it must "know" its host intimately so that it can take advantage of cellular processes as needed. Indeed, viruses are masters of regulation, both of their own life cycles and of the behaviors of their hosts.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Describe common virion structures and morphology (section 6.2)
- ✔ Summarize the five steps common to the life cycle of most viruses (section 6.3)
- ✔ Describe the events that occur during the three phases of DNA replication, transcription, and translation (sections 13.3, 13.5, 13.7 15.2, 15.3, and 15.4)
- ✔ Draw typical bacterial, archaeal, and eukaryotic protein-coding genes (sections 13.4, 13.5, and 15.3)

27.1 Virus Phylogeny Is Difficult to Establish

After reading this section, you should be able to:

- Distinguish between the Baltimore system of grouping viruses and the official taxonomy of viruses proposed by the International Committee on Taxonomy of Viruses
- Determine if a virus has a positive- or negative-strand genome
- Differentiate the Baltimore groups of viruses

In 1971 the International Committee on Taxonomy of Viruses (ICTV) developed a uniform classification system for viruses.

Since then the number of viruses and taxa has continued to expand. In its ninth report, the ICTV describes over 2,000 virus species and places them in 6 orders, 87 families, 19 subfamilies, and 349 genera. (See the table **Characteristics of Some Virus Families** posted to Connect.) The committee considers many viral characteristics but places greatest weight on the following properties to define families: nucleic acid type, presence or absence of an envelope, symmetry of the capsid, and dimensions of the virion and capsid. Virus order names end in *-virales;* virus family names in *-viridae;* subfamily names in *-virinae;* and genus names in *-virus*. An example of this nomenclature scheme is shown in **figure 27.1**. ◀◀ *Virion structure is defined by capsid symmetry and presence or absence of an envelope (section 6.2)*

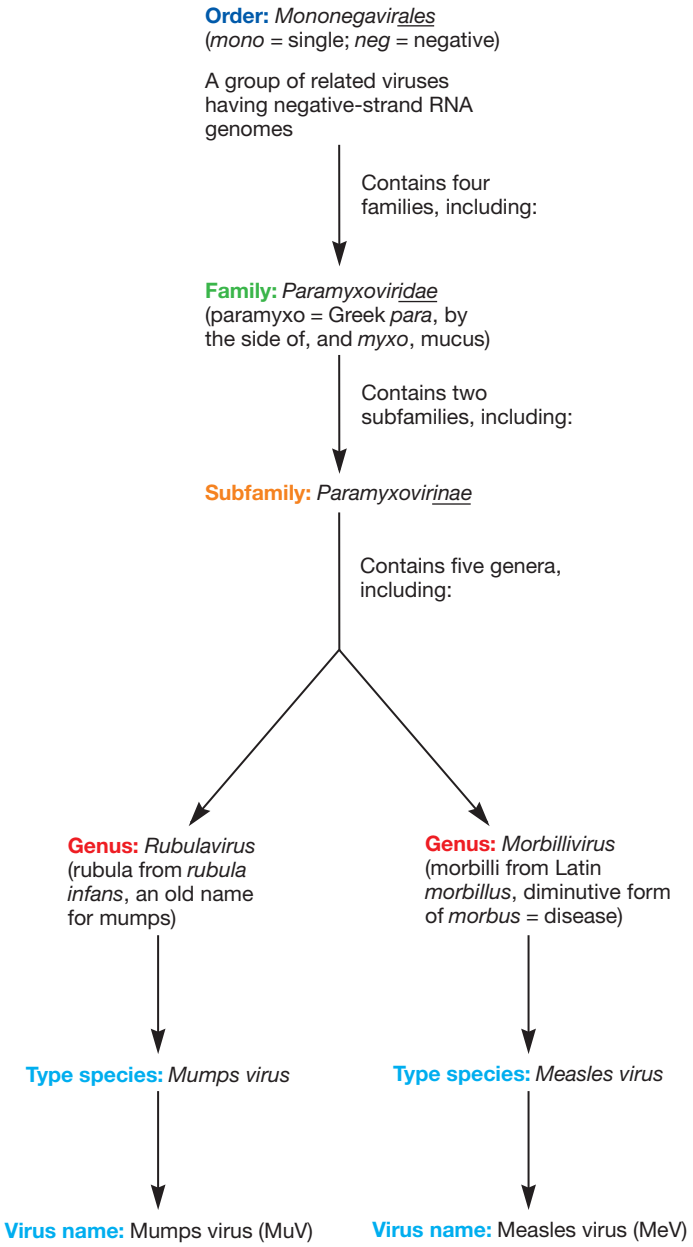

Figure 27.1 Virus Taxonomy. Because of the difficulty in establishing evolutionary relationships, most virus families have not been placed into an order. The taxa names are derived from various aspects of the biology and history of the members of the taxa, including features of their structure, diseases they cause, and locations where they were first identified or recognized. The suffixes used for each type of taxon (e.g., order, family) are underlined.

As we discuss in chapter 19, a goal of taxonomy is to classify organisms based on their evolutionary history. To piece together the phylogenetic relationships of viruses, virologists are increasingly using two major approaches: comparisons of genome sequences and comparisons of protein folds observed in their major capsid proteins. Both approaches are challenging, in part because horizontal gene transfer among unrelated viruses and between viruses and their host cells is clearly evident. Despite this, evidence suggests that retroviruses (section 27.7) and reverse transcribing DNA viruses (section 27.8) share a common evolutionary history. All of these viruses use an enzyme called reverse transcriptase in their life cycles. Evidence also suggests that double-stranded (ds) DNA viruses can be divided into two lineages based on folding of their capsid proteins. These viruses include nucleocytoplasmic large DNA (NCLD) viruses (section 27.2), which have garnered considerable interest in part because they seem to blur the distinctions between cells and viruses.

Although ICTV reports are the official authority on viral taxonomy, many virologists find it useful to group viruses using a scheme devised by Nobel laureate David Baltimore. The Baltimore system complements the ICTV system but focuses on the viral genome and the process used to synthesize viral mRNA. Recall from chapter 6 that all four nucleic acid types can be found in viruses: dsDNA, single-stranded (ss) DNA, dsRNA, and ssRNA. The characterization of the genome of a ssRNA virus is further differentiated by the sense of the ssRNA—that is, whether the genome is identical to or complementary to the mRNA produced by the virus. ssRNA viruses with an RNA genome that is identical in base sequence to that of the mRNA it produces are said to have **plus-strand** or **positive-strand RNA** genomes (**figure 27.2**). Other ssRNA viruses have genomes that are complementary to the mRNA they produce. These viruses are said to have **minus-strand** or **negative-strand RNA.** Baltimore's system organizes viruses into seven groups (**table 27.1**). This system helps virologists (and microbiology students) simplify the vast array of viral life cycles into a relatively small number of basic types; thus we use it here.

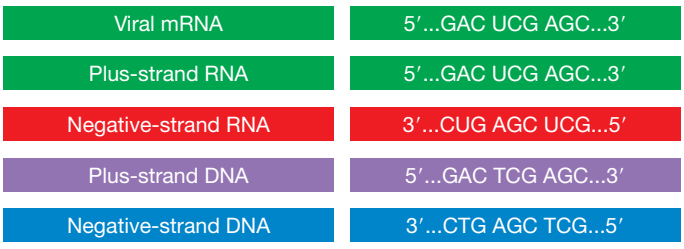

Figure 27.2 Plus-Strand and Negative-Strand Viral Genomes. The genomes and replication intermediates of viral genomes can be either plus strand or negative strand. This designation is relative to the sequence of nucleotides in the mRNA of the virus. Plus-strand genomes have the same sequence as the mRNA, either using DNA nucleotides if a DNA genome or RNA nucleotides if an RNA genome. Negative-strand genomes are complementary to the viral mRNA.

Table 27.1 The Baltimore System

Group	Description
Double-stranded (ds) DNA viruses	Genome replication: dsDNA → dsDNA mRNA synthesis: dsDNA → mRNA
Single-stranded (ss) DNA viruses	Genome replication: ssDNA → dsDNA → ssDNA mRNA synthesis: ssDNA → dsDNA → mRNA
Double-stranded RNA viruses	Genome replication: dsRNA → ssRNA → dsRNA mRNA synthesis: dsRNA → mRNA
Plus-strand RNA (+RNA) viruses	Genome replication: +RNA → −RNA → +RNA mRNA synthesis: +RNA = mRNA → −RNA → mRNA
Negative-strand RNA (−RNA) viruses	Genome replication: −RNA → +RNA → −RNA mRNA synthesis: −RNA → mRNA
Retroviruses	Genome replication: ssRNA → dsDNA → ssRNA mRNA synthesis: ssRNA → dsDNA → mRNA
Reverse transcribing DNA viruses	Genome replication: dsDNA → ssRNA → dsDNA mRNA synthesis: dsDNA → mRNA

Retrieve, Infer, Apply

1. List some characteristics used in classifying viruses. Which seem to be the most important?
2. Consider these terms: *Equine torovirus, Nidovirales, Torovirinae,* Equine torovirus (EToV), *Toroviridae*, and *Torovirus*. Construct a figure similar to figure 27.1 using these terms.

27.2 Double-Stranded DNA Viruses Infect All Cell Types

After reading this section, you should be able to:

- Describe in general terms the strategy used by double-stranded (ds) DNA viruses to synthesize their nucleic acids and proteins
- Describe in general terms how bacteriophage lambda regulates the switch between lytic and lysogenic cycles
- Choose one specific bacterial, archaeal, and eukaryal dsDNA virus and outline the major events in their life cycles, noting, when possible, the specific mechanisms used to accomplish each step

Perhaps the largest group of known viruses is the double-stranded (ds) DNA viruses; most bacteriophages have dsDNA genomes, as do several insect viruses and a number of important vertebrate viruses, including herpesviruses and poxviruses. The pattern of multiplication for dsDNA viruses is shown in **figure 27.3**. The synthesis of DNA and RNA is similar to what occurs in cellular organisms; therefore some dsDNA viruses can rely entirely on their host's DNA and RNA polymerases.

Bacteriophage T4: A Virulent Bacteriophage

The life cycle of T4 bacteriophage (family *Myoviridae,* species *Enterobacteria phage T4*) serves as our example of a virulent dsDNA

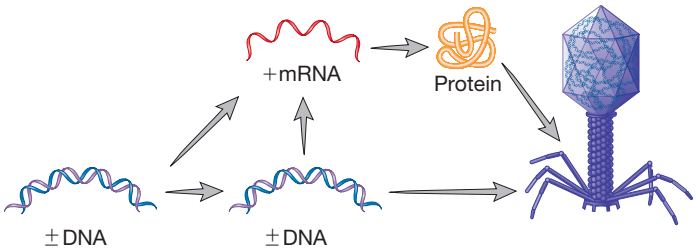

Figure 27.3 Multiplication Strategy of Double-Stranded DNA Viruses. Because the genome of dsDNA viruses is similar to that of the host, genome replication and mRNA synthesis closely resemble that of the host cell and can involve host polymerases, viral polymerases, or both. The DNA genome serves as the template for DNA replication and mRNA synthesis. Translation of the mRNA by the host cell's translation machinery yields viral proteins, which are assembled with the viral DNA to make mature virions. These are eventually released from the host.

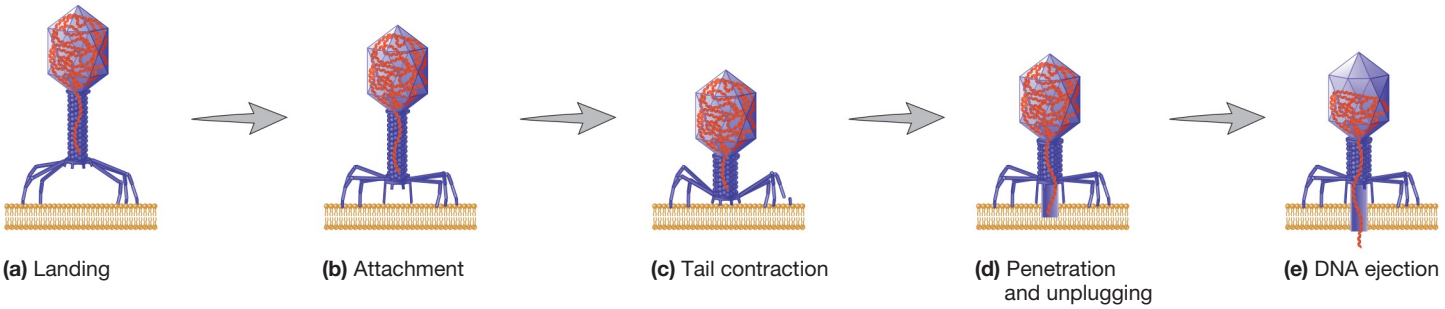
phage. Virulent (lytic) bacteriophages are capable only of the lytic cycle. That is, their infection of a host always ends with cell lysis. As with most viruses (except plant viruses), the first step of viral infection is attachment (adsorption) to the host cell surface. T4 attachment begins when a tail fiber contacts either the lipopolysaccharide or certain proteins in the outer membrane of its *Escherichia coli* host (**figure 27.4*a***). As more tail fibers make contact, the baseplate settles down on the surface (figure 27.4*b*). After the baseplate is seated firmly on the cell surface, the baseplate and sheath change shape, and the tail sheath reorganizes so that it shortens from a cylinder 24 rings long to only 12 rings (figure 27.4*c,d*). As the sheath becomes shorter and wider, the central tube located within the sheath is pushed through the bacterial cell wall. The baseplate contains the protein gp5, which has lysozyme activity. Lysozyme is an enzyme that breaks the bonds linking the sugars of peptidoglycan together (*see figure 33.4*). Thus this protein aids in the penetration of the tube through the peptidoglycan layer. Finally, the linear DNA is extruded from the head, probably through the central tube, and into the host cell (figure 27.4*e,f*). The tube may interact with the plasma membrane to form a pore through which DNA passes.

Within 2 minutes after entry of T4 DNA into an *E. coli* cell, the *E. coli* RNA polymerase starts synthesizing T4 mRNA (**figure 27.5**). This mRNA is called early mRNA because it is made before viral DNA is made. Within 5 minutes, viral DNA synthesis commences, catalyzed by a virus-encoded **DNA-dependent DNA polymerase.** DNA replication is initiated from several origins of replication and proceeds bidirectionally from each. Viral DNA replication is followed by the synthesis of late mRNAs, which are important in later stages of the infection.

As with most viruses, expression of T4 genes is carefully timed, and the transcripts and protein products of the genes are named to reflect the time of appearance. Thus depending on the virus, terms such as immediate-early, middle, and late may be used. T4 controls the expression of its genes by regulating the activity of the *E. coli* RNA polymerase. Initially T4 genes are transcribed by the host RNA polymerase and the housekeeping sigma factor σ^{70} (*see table 14.3*). After a short interval, a viral enzyme



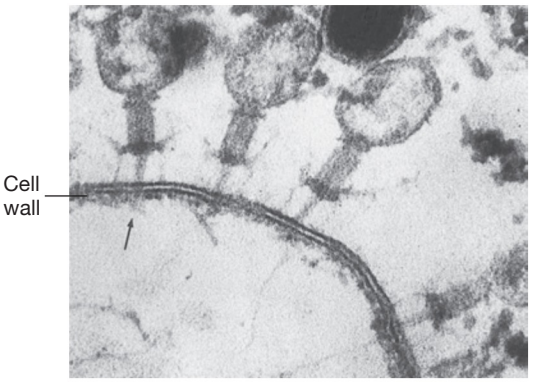


Figure 27.4 **T4 Phage Adsorption and DNA Entry.** (a–e) Adsorption and viral DNA entry into the *E. coli* host are mediated by the phage's tail fibers and base plate. (f) An electron micrograph of an *E. coli* cell being infected by T-even phages. These phages have released their dsDNA into the cell and now have empty capsids.

MICRO INQUIRY *What enzyme found in the T4 baseplate facilitates penetration through the cell wall?*

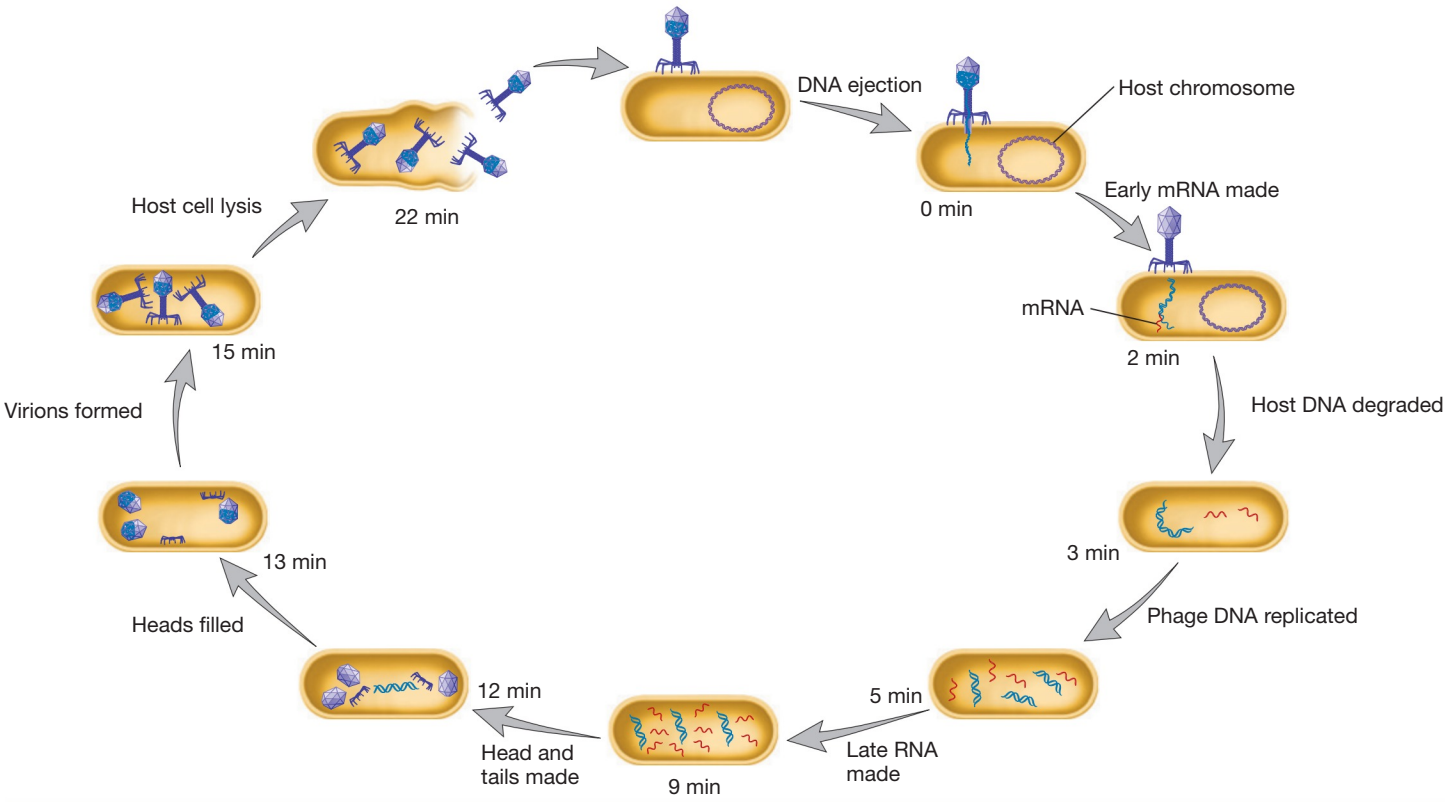

Figure 27.5 **The Life Cycle of Bacteriophage T4.** A diagram depicting the life cycle with the minutes after DNA ejection given for each stage.

MICRO INQUIRY *Why do you think T4 evolved to initiate DNA replication from multiple origins, rather than from a single origin of replication as seen in its host cell?*

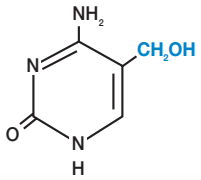

Figure 27.6 5-Hydroxymethylcytosine (HMC). In T4 DNA, the HMC often has glucose attached to its hydroxyl.

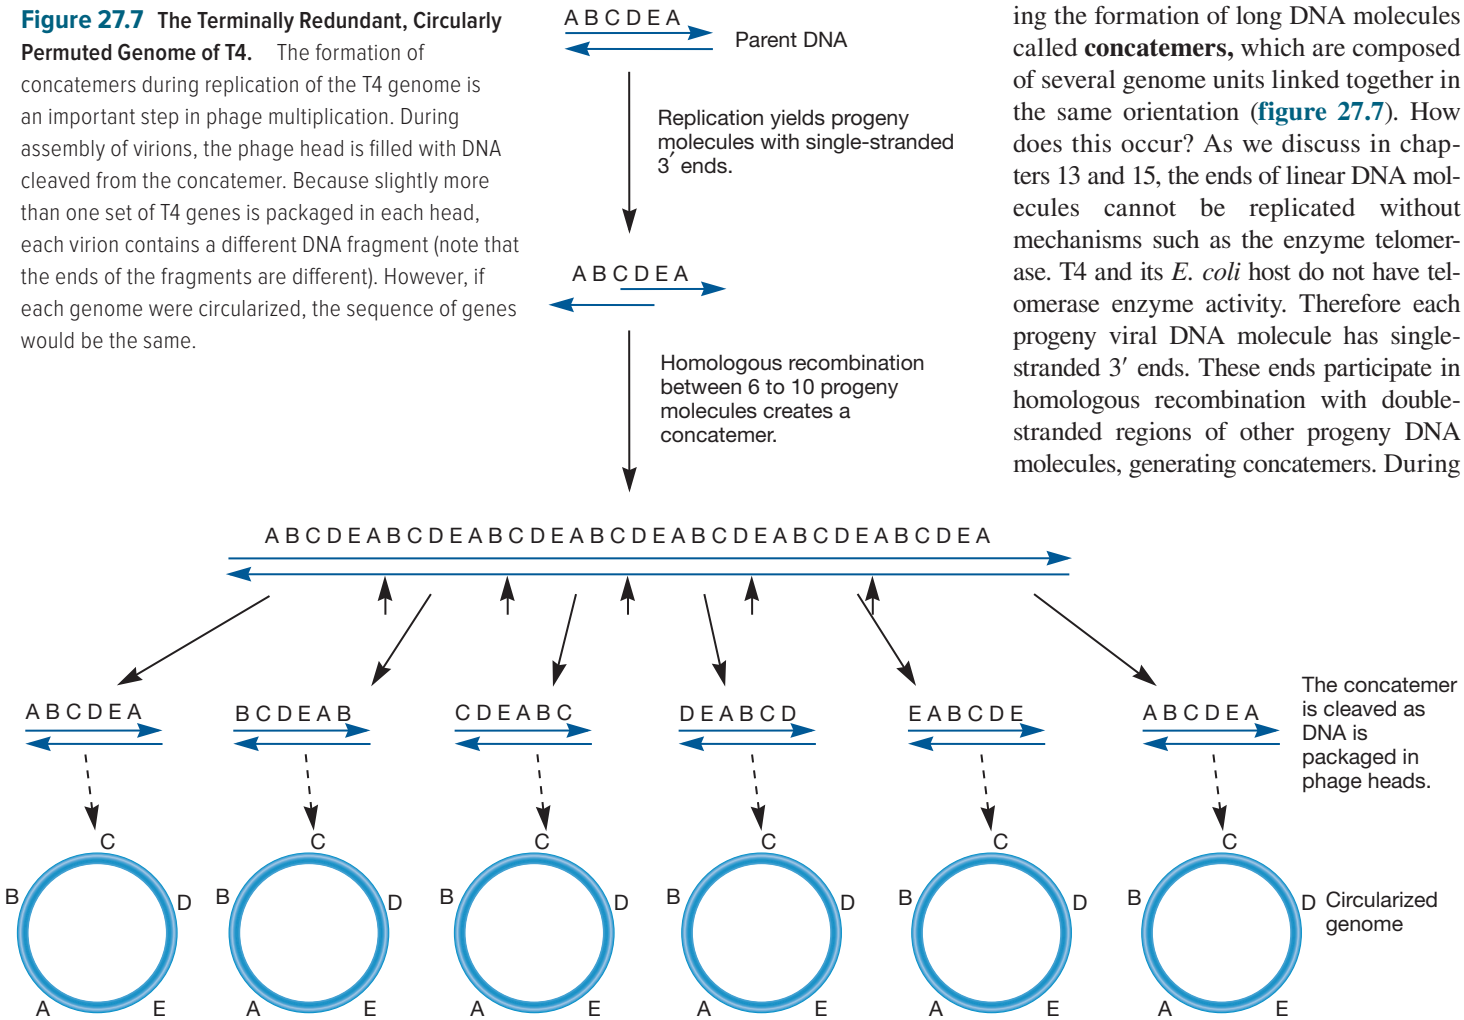
MICRO INQUIRY *What function does HMC glycosylation serve?*

catalyzes addition of the chemical group ADP-ribose to one of the α-subunits of RNA polymerase (*see figure 13.23*). This modification helps inhibit the transcription of host genes and promotes viral gene expression. Later the second α-subunit receives an ADP-ribosyl group. This halts transcription of some early T4 genes but not before the product of one early gene (*motA*) stimulates transcription of somewhat later genes. One of these later genes encodes the sigma factor gp55. This viral sigma factor helps the host cell's RNA polymerase core enzyme bind to viral late promoters and transcribe the late genes, around 10 to 12 minutes after infection. ⏮ *Bacteria combine several regulatory mechanisms to control complex cellular processes (section 14.5)*

The tight regulation of T4 gene expression is aided by the organization of the T4 genome, in which genes with related functions—such as the genes for phage head or tail fiber construction—are usually clustered together. Early and late genes also are clustered separately on the genome; they are even transcribed in different directions. A considerable portion of the T4 genome encodes products needed for its replication, including all the protein subunits of its replisome and enzymes needed to prepare for DNA synthesis. Some of these enzymes synthesize an important component of T4 DNA, hydroxymethylcytosine (HMC) (**figure 27.6**). HMC is a modified nucleotide that replaces cytosine in T4 DNA. Once HMC is synthesized, replication ensues by a mechanism similar to that seen in bacteria. After T4 DNA has been synthesized, it is modified by the addition of glucose (a process called glycosylation) to the HMC residues. Glycosylated HMC residues protect T4 DNA from attack by *E. coli* endonucleases called **restriction enzymes,** which would otherwise cleave the viral DNA and destroy it. This bacterial defense mechanism is called **restriction.** Other phages also chemically modify their DNA to protect against host restriction. ⏮ *Restriction enzymes (section 17.1)*

The linear dsDNA genome of T4 is generated in an interesting manner involving the formation of long DNA molecules called **concatemers,** which are composed of several genome units linked together in the same orientation (**figure 27.7**). How does this occur? As we discuss in chapters 13 and 15, the ends of linear DNA molecules cannot be replicated without mechanisms such as the enzyme telomerase. T4 and its *E. coli* host do not have telomerase enzyme activity. Therefore each progeny viral DNA molecule has single-stranded 3′ ends. These ends participate in homologous recombination with double-stranded regions of other progeny DNA molecules, generating concatemers. During

Figure 27.7 The Terminally Redundant, Circularly Permuted Genome of T4. The formation of concatemers during replication of the T4 genome is an important step in phage multiplication. During assembly of virions, the phage head is filled with DNA cleaved from the concatemer. Because slightly more than one set of T4 genes is packaged in each head, each virion contains a different DNA fragment (note that the ends of the fragments are different). However, if each genome were circularized, the sequence of genes would be the same.



assembly, concatemers are cleaved such that the genome packaged in the capsid is slightly longer than the T4 gene set. Thus each progeny virus has a genome unit that begins with a different gene and ends with the same set of genes. If each genome of the progeny viruses were circularized, the sequence of genes in each virion would be the same. Therefore the T4 genome is said to be terminally redundant and circularly permuted, and the genetic map of T4 is drawn as a circular molecule.

The formation of new T4 phage particles is an exceptionally complex self-assembly process that involves viral proteins and some host cell factors (*see figure 6.13*). Late mRNA transcription begins about 9 minutes after entry of T4 DNA into *E. coli* (figure 27.5). Late mRNA products include phage structural proteins, proteins that help with phage assembly but do not become part of the virion, and proteins involved in cell lysis and phage release. These proteins are used in four fairly independent subassembly lines that ultimately converge to generate a mature T4 virion.

A critical step in T4 virion construction is filling the head portion of the virion with the T4 genome. This is no simple matter—the dsDNA genome is somewhat rigid and has many negatively charged moieties. Therefore the dsDNA must essentially be crammed into the developing head. This is accomplished by a complex of proteins sometimes called the "packasome." The T4 packosome has more power than an automobile engine.

The packasome includes a protein called terminase, which has two functions: to cut the concatemers formed during T4 genome replication and to push the DNA into the T4 head. For each head filled, it uses these functions in the order "cut, push, cut." The first cut generates a double-stranded end on a concatemer. This end is then threaded into the portal, as terminase pushes the DNA into the head, using energy supplied by ATP hydrolysis, until the phage head is filled with DNA—a DNA molecule roughly 3% longer than the length of one set of T4 genes. Terminase then makes its second cut, and the packaging process for that head is complete. Terminase then leaves the head, and several other viral proteins bind the head at the portal through which the DNA entered. This seals the head and prepares it for addition of the tail and tail fibers.

Finally, virions are released so that they can infect new cells and begin the cycle anew. T4 lyses *E. coli* when about 150 virus particles have accumulated in the host cell. T4 encodes two proteins to accomplish this. The first, called holin, creates holes in the *E. coli* plasma membrane. The second, an endolysin called T4 lysozyme, degrades peptidoglycan in the host's cell wall. Thus the activity of holin enables T4 lysozyme to move from the cytoplasm to the peptidoglycan so that both the plasma membrane and the cell wall are destroyed.

Bacteriophage Lambda: A Temperate Bacteriophage

Unlike bacteriophage T4, temperate bacteriophages, such as phage lambda (family *Siphoviridae,* species *Enterobacteria phage lambda*), can enter either the lytic or lysogenic cycle upon infecting a host cell. If a temperate virus enters the lysogenic cycle, its dsDNA genome often is integrated into the host's

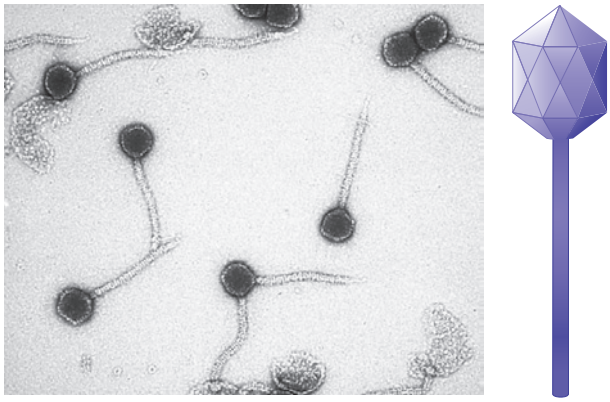


Figure 27.8 Bacteriophage Lambda (λ). The icosahedral head illustrated in the drawing is not obvious in the photomicrograph at this resolution.

chromosome, where it resides as a prophage until conditions for induction occur (*see figure 6.16*). Upon induction, the viral genome is excised from the host genome and the lytic cycle is initiated. ⏮ *Lytic and lysogenic infections are common for bacterial and archaeal cells (section 6.4)*

How does a temperate phage "decide" which cycle to follow? The process by which phages make this decision is best illustrated by bacteriophage lambda (λ), which infects *E. coli*. As shown in **figure 27.8**, λ has an icosahedral head 55 nm in diameter and a noncontractile tail with a thin tail fiber at its end. Its DNA genome is a linear molecule with cohesive ends—single-stranded stretches, 12 nucleotides long, that are complementary to each other and can base-pair.

Like most bacteriophages, λ attaches to its host and then releases its genome into the cytoplasm, leaving the capsid outside. Once inside the cell, the linear genome is circularized when the two cohesive ends base-pair with each other; the breaks in the strands are sealed by the host cell's DNA ligase (**figure 27.9**). The λ genome has been carefully mapped, and over 40 genes have been identified (**figure 27.10**). Most genes are clustered according to their function, with separate groups involved in head synthesis, tail synthesis, lysogeny, DNA replication, and cell lysis. This organization is important because once the genome is circularized, a cascade of regulatory events occurs that determine if the phage pursues a lytic cycle or establishes

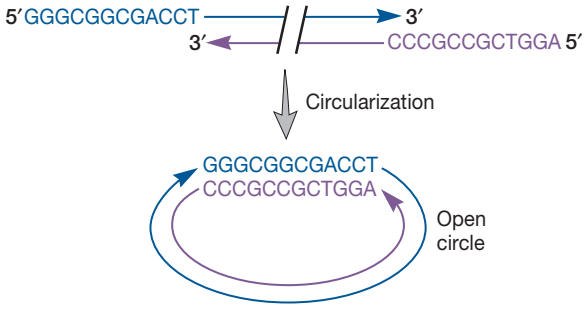

Figure 27.9 Lambda Phage DNA. A diagram of λ phage DNA showing its 12-base, single-stranded cohesive ends.

lysogeny. Regulation of appropriate genes is facilitated by clustering and coordinated transcription from the same promoters.

The cascade of events leading to either lysogeny or the lytic cycle serves as a model for complex regulatory processes. It involves the action of several regulatory proteins that function as transcriptional repressors or activators or both, proteins that regulate transcription termination, and antisense RNA molecules (**figure 27.11**). The protein cII is an activator protein that plays a pivotal role in determining if λ will establish lysogeny or follow a lytic pathway. If the cII protein reaches high enough levels early in the infection, lysogeny will occur; if it does not reach a critical level, the lytic cycle will occur.

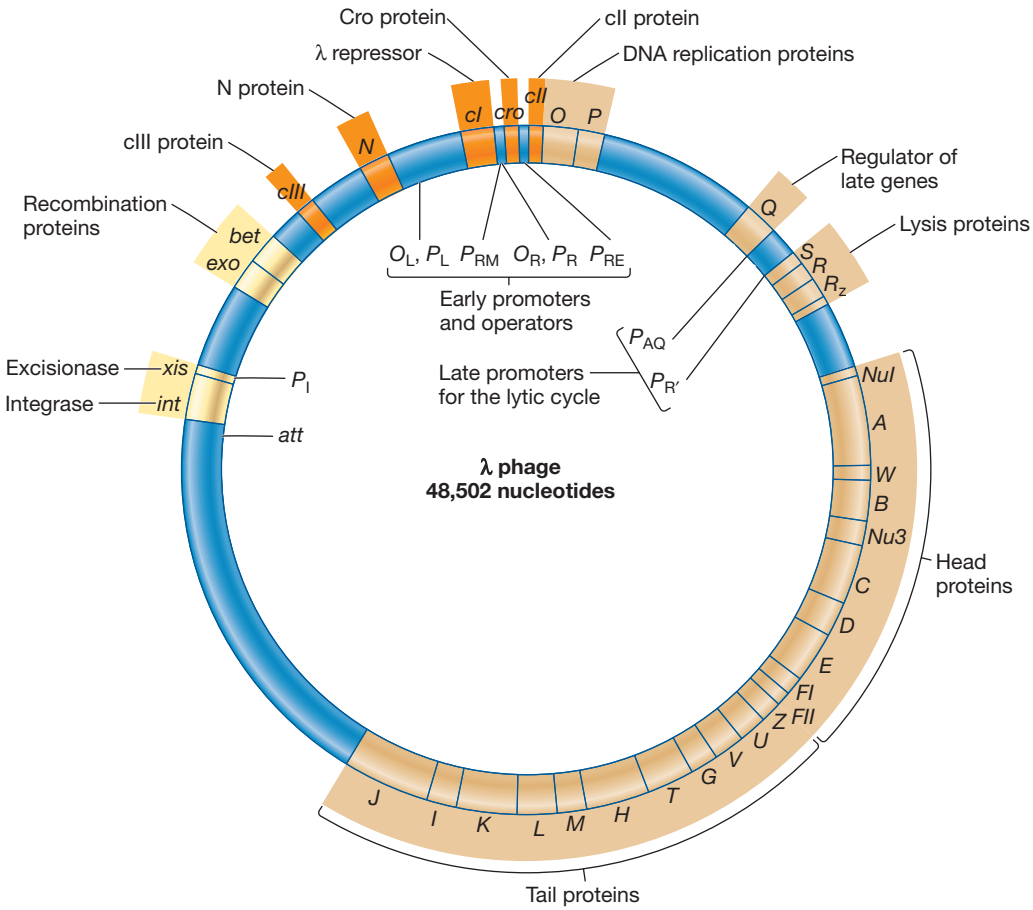

Figure 27.10 The Genome of Phage λ. The genes are color-coded according to function. Those genes shaded in orange encode regulatory proteins that determine if the lytic or lysogenic cycle will be followed. Genes involved in establishing lysogeny are shaded in yellow. Those required for the lytic cycle are shaded in tan. Important promoters and operators are also noted.

Transcription of the λ genome is catalyzed by the host cell's **DNA-dependent RNA polymerase** (an RNA polymerase that uses DNA as the template for RNA synthesis), and the cII protein is synthesized relatively early in the infection. If the cII protein levels are high enough, it will increase transcription of the *int* gene, which encodes the enzyme integrase. **Integrase** catalyzes integration of the λ genome into the host cell's chromosome, thus establishing lysogeny. The cII protein also increases transcription of the *cI* gene. This gene encodes a regulatory protein that is often called the λ repressor because it represses the transcription of all genes (except its own). This repression maintains the lysogenic state. As just noted, the cI protein (λ repressor) allows transcription of its own gene. This is because cI functions as an activator protein when it binds to the P_{RM} promoter from which the *cI* gene can be transcribed (**table 27.2**).

Integration of the λ genome into the host chromosome takes place at a site in the host chromosome called the attachment site (*att*). A corresponding site is present on the phage genome, and the λ integrase catalyzes site-specific recombination between the two sites. The bacterial site is located between the galactose (*gal*) and biotin (*bio*) operons, and as a result of integration, the circular λ genome becomes a linear stretch of DNA located between these two host operons (*see figure 16.31*). The prophage can remain integrated indefinitely, being replicated as the bacterial genome is replicated. ◀◀ *Molecular recombination (section 16.4)*

Because the cII protein is made early in the infection, it might seem that it would accumulate quickly and ensure that lysogeny occurs. However, cII is degraded by a host enzyme (HflB) unless it is protected by a viral protein called cIII. The cIII protein is synthesized at the same time as cII, and as long as its levels remain high enough, cII will be protected. However, if cII is not protected sufficiently from the host degradative enzyme, the level of a protein called Cro (product of the *cro* gene) will increase. Cro protein is both a repressor protein and an activator protein. It inhibits transcription of the *cIII* and *cI* genes, further decreasing the amount of cII and λ repressor. However, it increases its own synthesis as well as the synthesis of another regulatory protein called Q. When Q protein accumulates at a high enough level, it activates transcription of genes required for the lytic cycle. When that occurs, the infection process is committed to the lytic cycle. Ultimately the host is lysed and new virions are released.

We have now considered the regulatory processes that dictate whether lysogeny is established or the lytic cycle is pursued. However, how does induction reverse lysogeny? Induction usually occurs in response to environmental factors such as

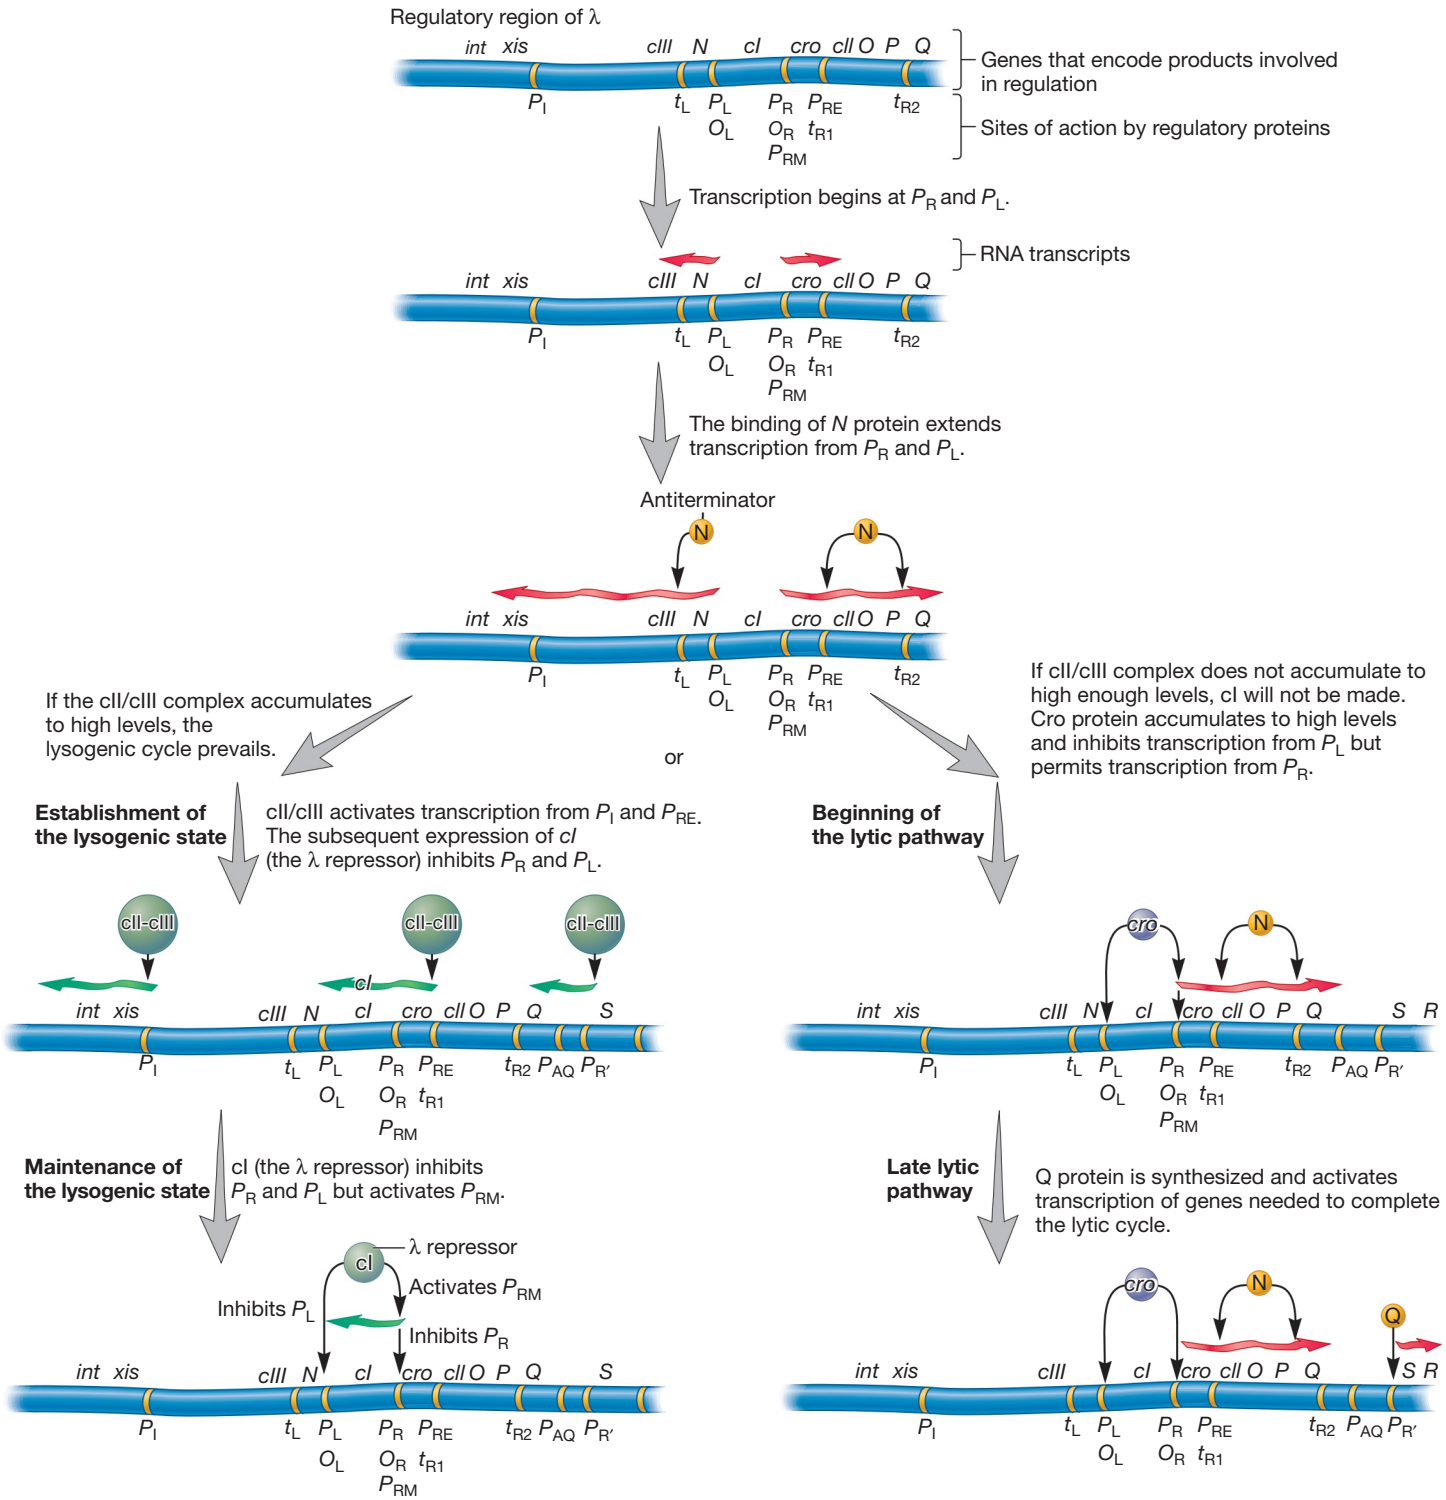

Figure 27.11 **The Decision-Making Process for Establishing Lysogeny or the Lytic Pathway.** The initial transcripts are synthesized by the host RNA polymerase. These encode the N protein and the Cro protein. The N protein is an antiterminator that allows transcription to proceed past the terminator sequences t_L, t_{R1}, and t_{R2}. This allows transcription of other regulatory genes, as well as the *xis* and *int* genes. The latter genes encode the enzymes excisionase and integrase, respectively. The left side of the figure illustrates what occurs if lysogeny is established. The right side of the figure shows the lytic pathway.

ultraviolet light or chemical mutagens that damage DNA. This damage alters the activity of the host cell's **RecA** protein. As we describe in chapter 16, RecA plays important roles in recombination and DNA repair. When activated by DNA damage, RecA interacts with λ repressor, causing the repressor to cleave itself. As more and more λ repressor proteins destroy themselves, transcription of the *cI* gene is decreased, further lowering the amount of λ repressor in the cell. Eventually the level becomes so low that transcription of the *xis, int,* and *cro* genes begins. The *xis* gene encodes the protein excisionase. It binds integrase, causing

Table 27.2 Functions of Lambda Promoters and Operators

Promoter or Operator	Name Derivation	Function
P_L	***P***romoter ***L***eftward	Promoter for transcription of *N, cIII, xis,* and *int* genes; important in establishing lysogeny
O_L	***O***perator ***L***eftward	Binding site for lambda repressor and Cro protein; binding by lambda repressor maintains lysogenic state; binding by Cro protein prevents establishment and maintenance of lysogeny
P_R	***P***romoter ***R***ightward	Promoter for transcription of *cro, cII, O, P,* and *Q* genes; Cro, O, P, and Q proteins are needed for lytic cycle; CII protein helps establish lysogeny
O_R	***O***perator ***R***ightward	Binding site for lambda repressor and Cro protein; binding by lambda repressor maintains lysogenic state; binding by Cro allows transcription to occur
P_{RE}	***P***romoter for Lambda ***R***epressor ***E***stablishment	Promoter for *cI* gene (lambda repressor gene); recognized by CII protein, a transcriptional activator; important in establishing lysogeny
P_I	***P***romoter for ***I***ntegrase Gene	Transcription from P_I generates mRNA for integrase protein but not excisionase; recognized by the transcriptional activator CII; important for establishing lysogeny
P_{AQ}	***P***romoter for ***A***nti-***Q*** mRNA	Transcription from P_{AQ} generates an antisense RNA that binds *Q* mRNA, preventing its translation; recognized by the transcriptional activator CII; important for establishing lysogeny
P_{RM}	***P***romoter for ***R***epressor ***M***aintenance	Promoter for transcription of lambda repressor gene (*cI*); activated by lambda repressor; important in maintaining lysogeny
$P_{R'}$	***P***romoter ***R***ightward′	Promoter for transcription of viral structural genes; activated by Q protein; important in lytic cycle

it to reverse the integration process, and the prophage is freed from the host chromosome. As λ repressor levels continue to decline, the Cro protein levels increase. Eventually synthesis of λ repressor is completely blocked, protein Q levels become high, and the lytic cycle proceeds to completion.

Our attention has been on λ phage, but there are many other temperate phages. Most, like λ, exist as integrated prophages in the lysogen. However, not all temperate phages integrate into the host chromosome at specific sites. Bacteriophage Mu integrates randomly into the genome. It then expresses a repressor protein that inhibits lytic growth. Furthermore, integration is not an absolute requirement for lysogeny. The *E. coli* phage P1 is similar to λ in that it circularizes after infection and begins to manufacture repressor. However, it remains as an independent circular DNA molecule in the lysogen and is replicated at the same time as the host chromosome. When *E. coli* divides, P1 DNA is apportioned between the daughter cells so that all lysogens contain one or two copies of the phage genome.

Retrieve, Infer, Apply

1. Explain why the T4 genome is circularly permuted.
2. Precisely how, in molecular terms, is a bacterial cell made lysogenic by a temperate phage such as λ?
3. How is a prophage induced to become active again?
4. Describe the roles of cII, CIII, λ repressor (CI), Cro, Q, RecA, integrase, and excisionase in lysogeny and induction.
5. How do the temperate phages Mu and P1 differ from λ?

Archaeal Viruses

Our understanding of archaeal viruses lags significantly behind that of bacterial viruses and animal viruses. However, as more archaeal viruses are isolated and studied, virologists are beginning to develop a clearer picture of the nature of these interesting biological entities. Nearly all known archaeal viruses have dsDNA genomes; the few exceptions have ssDNA genomes. However, metagenomic evidence suggests that RNA archaeal viruses exist; they have not yet been isolated. Archaeal virus genomes can be either linear or circular. Some archaeal viruses exhibit morphologies similar to that of other viruses. However, many others have unusual morphologies, such as bottle-shaped, droplet-shaped, and spindle-shaped (**figure 27.12**; *see also Microbial Diversity & Ecology 6.1 box figure*.) These unusually shaped viruses have defined several new virus families. Unlike most bacteriophages, many archaeal viruses are enveloped.

With a few exceptions, relatively little is known about archaeal virus life cycles. However, they do exhibit some interesting differences from those of bacteriophages. Thus far, most archaeal viruses studied establish chronic infections, whereby viruses are continuously produced and extruded from the host cell. This type of infection is similar to that of fd bacteriophage and other related ssDNA phages in the family *Inoviridae* (section 27.3). Some archaeal viruses have been shown to establish lysogeny by integrating their genomes into the host cell's chromosome.

Although relatively few archaeal viruses always cause lytic infections, one such virulent archaeal virus is of particular

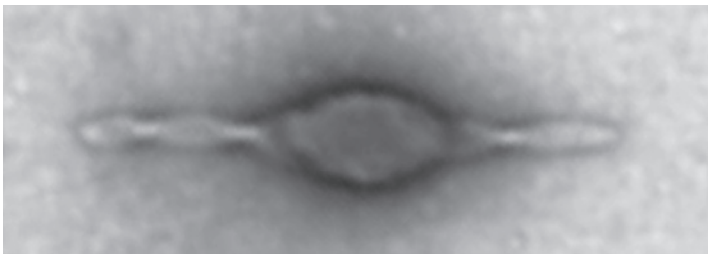
(b) Virions of *Sulfolobus shibatae* virus 2 (SSV-2-Ss)



(c) *Acidianus* two-tailed virus virion

Figure 27.12 Virion Morphology of Some Archaeal Viruses. (a) *Sulfolobus* turreted icosahedral virus (STIV) has a virion morphology similar to some bacterial and animal viruses. Scale bar = 500 nm. Transmission electron microscopy (TEM). (b) TEM image of *Sulfolobus shibatae* virus 2 (SSV-2-Ss) virions. These droplet-shaped virions have a short tail at one end. Virus particles often attach to membranes or each other by their tails. (c) TEM image of an *Acidianus* two-tailed virus virion.

interest. The *Sulfolobus* turreted icosahedral virus (STIV) is released from its host *Sulfolobus* spp. in an unusual way. After the genome enters the host cell (by an unknown mechanism), transcription of the viral genome begins. Some of the viral gene products regulate host cell genes, thus enabling the virus to control the replication process using the host's DNA replication, transcription, and translation machinery. Eventually the assembly phase begins. STIV virions have an icosahedral capsid that surrounds an internal lipid bilayer; the lipid bilayer encloses the virus's genome. Electron cryotomography studies suggest that during assembly, the capsid and internal membrane are assembled together, leading to the formation of an empty virion (procapsid) devoid of the viral genome. Once the procapsids (capsid plus membrane) are complete, the DNA is packaged by an unknown mechanism. Virion release results from the formation of pyramid-like structures on the surface of the host cell (**figure 27.13**). These virus-associated pyramids, as they are called, open up, much like the petals of a

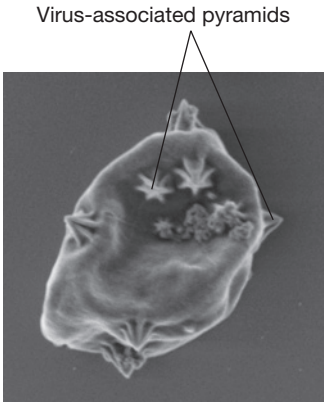


Figure 27.13 Virus-Associated Pyramids. Scanning electron micrograph of a *Sulfolobus solfataricus* cell infected with *Sulfolobus* turreted icosahedral virus (STIV). STIV virions are released from the cell by way of pyramid-like structures that form on the surface of the infected cell. The pyramids are seven-sided, and each face of the pyramid "peels back," providing an opening through which the virions escape.

flower bud open. This allows escape of the progeny virions, leaving the empty cell ghosts behind.

The CRISPR/Cas System: Bacteria and Archaea Fight Back

In our discussion of T4 bacteriophage, we introduce a defense mechanism—restriction—used by bacteria to protect themselves against attack from viruses. Many bacteria and archaea have another defense mechanism: the CRISPR/Cas system. This intriguing defense system has been likened to the adaptive immunity used by animals to protect themselves from microbial attack. The similarity is based on the observation that the CRISPR/Cas system uses parts of the invading virus's genome to "remember" an attack and prepare for a possible future attack, just as the adaptive immune system uses parts of an invading microbe to remember and prepare for the next invasion.

CRISPR/Cas was discovered when analyses of numerous bacterial and archaeal genomes identified sets of repeated nucleotide sequences separated by short spacers. These sets form a CRISPR system, CRISPR being short for *c*lustered, *r*egularly *i*nterspaced *s*hort *p*alindromic *r*epeats. The sequence of base pairs in the repeats are identical (or nearly so) within each CRISPR system. The spacers, however, differ considerably in sequence. Surprisingly, when the spacer sequences were used to probe nucleic acid databases, it was discovered that the spacers exhibit significant similarity to a variety of bacterial and archaeal virus genomes. CRISPR regions were later shown to be associated with a set of genes encoding proteins called Cas proteins (short for *C*RISPR-*a*ssociated *s*equences). Thus the new designation: a CRISPR/Cas system (**figure 27.14**).

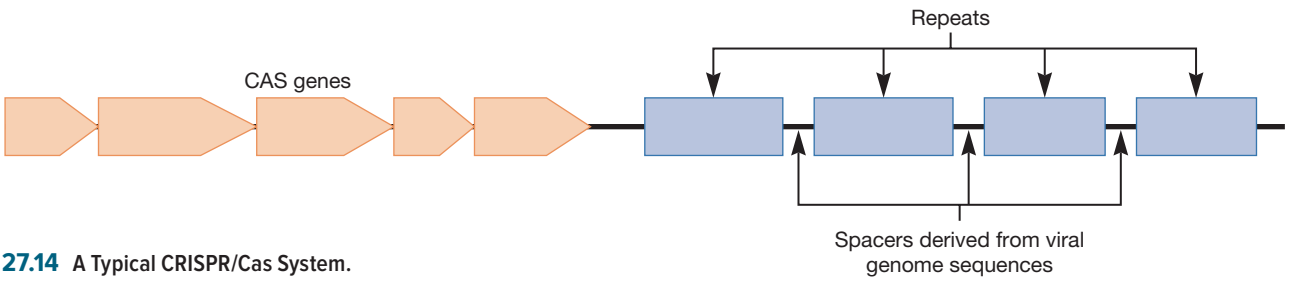

Figure 27.14 A Typical CRISPR/Cas System.

The surprising similarity between viral genes and CRISPR/Cas spacers led scientists to question how the spacers came to exist and what their role was in the host cell. The function of CRISPR/Cas systems is currently divided into three stages: acquisition, CRISPR RNA biogenesis, and interference. The acquisition stage occurs when a cell is infected by a virus. If the cell survives (e.g., because the virus is defective and can't successfully complete its life cycle), it adds portions of the viral genome to its CRISPR region. The addition is made at the end of the region closest to the CAS genes, and each new addition consists of a new repeat and a spacer consisting of DNA from the infecting virus. Thus the CRISPR sequences are akin to the growth rings on trees. Just as the history of the yearly growth of a tree can be ascertained by examining its growth rings, so too can the history of viral infections be determined. In any given bacterial or archaeal strain, a CRISPR sequence inserted during the oldest infection is located farthest from the Cas genes and the most recent is closest to the CAS genes.

During the CRISPR RNA (crRNA) biogenesis stage the CRISPR region is transcribed to yield a large RNA containing all repeats and spacers. Cas proteins associate with this full-length RNA and process it into mature crRNAs. Each of these consists of one repeat and one spacer. Cas proteins remain associated with the crRNAs, and during a subsequent infection, the Cas-crRNAs associate with either viral DNA or mRNA, leading to destruction of the molecule (interference). This prevents virus multiplication, and infection is thwarted. The interference stage bears significant similarity to silencing RNAs (siRNAs), as we describe in chapter 15.

Our focus has been on the use of CRISP/Cas systems by bacteria and archaea to defend against viral attacks. However, there is considerably more to these systems. It is now clear that bacteria and archaea use CRISPR/Cas for the more general process of protecting their genomes from foreign nucleic acids that might enter via conjugation or natural transformation. Furthermore, evidence suggests that crRNAs may regulate gene expression of host genes. Finally, viruses have been shown to evolve to evade their hosts' CRISPR/Cas defense, often by having a mutation in the target sequence. The host cell, in turn, responds by obtaining new spacers specific for that virus. It has been suggested that this back-and-forth interaction between virus and host plays an important role in the evolution of both. ⏮ *Bacterial conjugation requires cell-cell contact (section 16.6); Bacterial transformation is the uptake of free DNA from the environment (section 16.7)*

Herpesviruses

So far our discussion of dsDNA viruses has focused on bacteriophages and archaeal viruses. We now turn our attention to some important dsDNA viruses of eukaryotes, beginning with herpesviruses. As you will see, the life cycle of these viruses shares many features with that of bacteriophages such as T4. However, important distinctions in the life cycles exist because of the nature of their respective host cells.

Herpesviruses are members of the order *Herpesvirales*. This order includes herpes simplex virus type 1 (HSV-1; also called human herpesvirus 1) and herpes simplex virus type 2 (HSV-2; also called human herpesvirus 2), which cause cold sores and genital herpes, respectively (*see figures 38.13 and 38.16*); varicella-zoster virus (also called human herpesvirus 3), which causes chickenpox and shingles (*see figures 38.1 and 38.2*); cytomegaloviruses (species *Human herpesvirus 5*); Epstein-Barr virus (also called human herpesvirus 4), which causes infectious mononucleosis and has been implicated in some human cancers; and HHV 8 (species *Human herpesvirus 8*), the cause of Kaposi's sarcoma in AIDS patients. ⏭ *Cold sores (section 38.3); Genital herpes (section 38.3); Chickenpox (varicella) and shingles (herpes zoster) (section 38.1); Cytomegalovirus inclusion disease (section 38.3); Mononucleosis (infectious) (section 38.3); Acquired immune deficiency syndrome (AIDS) (section 38.3)*

Herpesvirus virions are 125 to 200 nm in diameter, somewhat pleomorphic, and enveloped (**figure 27.15**). The envelope contains distinct viral projections (called spikes) that are regularly dispersed over the surface. The envelope surrounds a layer of proteins called the tegument (Latin, *tegumentum,* to cover), which in turn surrounds the nucleocapsid. Herpesvirus genomes are linear, about 125 to 295 kilobase pairs (kb) long, and encode 70 to over 200 proteins. When herpesviruses target cells of vertebrate hosts, some bind to epithelial cells, others to neurons. Host cell selection is mediated by the binding of envelope spikes to specific host cell surface proteins termed receptors.

Herpesviruses cause both productive infections and latent infections. In a productive infection, the virus multiplies explosively; between 50,000 and 200,000 new virions are produced from each infected cell. As the virus multiplies, the host cell's metabolism is inhibited and the host's DNA is degraded. As a result, the cell dies. The first exposure to a herpesvirus usually causes this type of infection. Some of the cells infected in the initial infection develop a latent infection. During the latent infection, virions cannot be detected. However, the virus can be reactivated in the host cells, leading to a productive infection. The viral genome remains in the host cell after reactivation; thus once infected, the host can experience repeated productive infections.

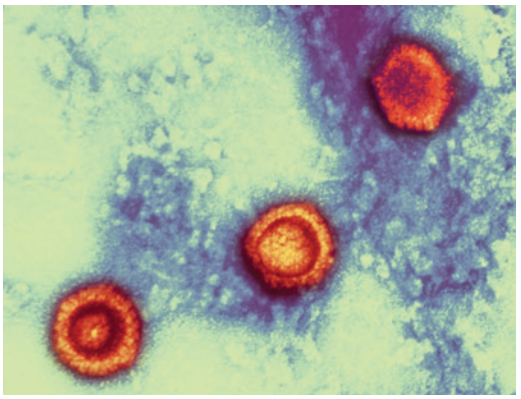

Figure 27.15 HSV-2. Herpes simplex virus type 2 inside an infected cell.

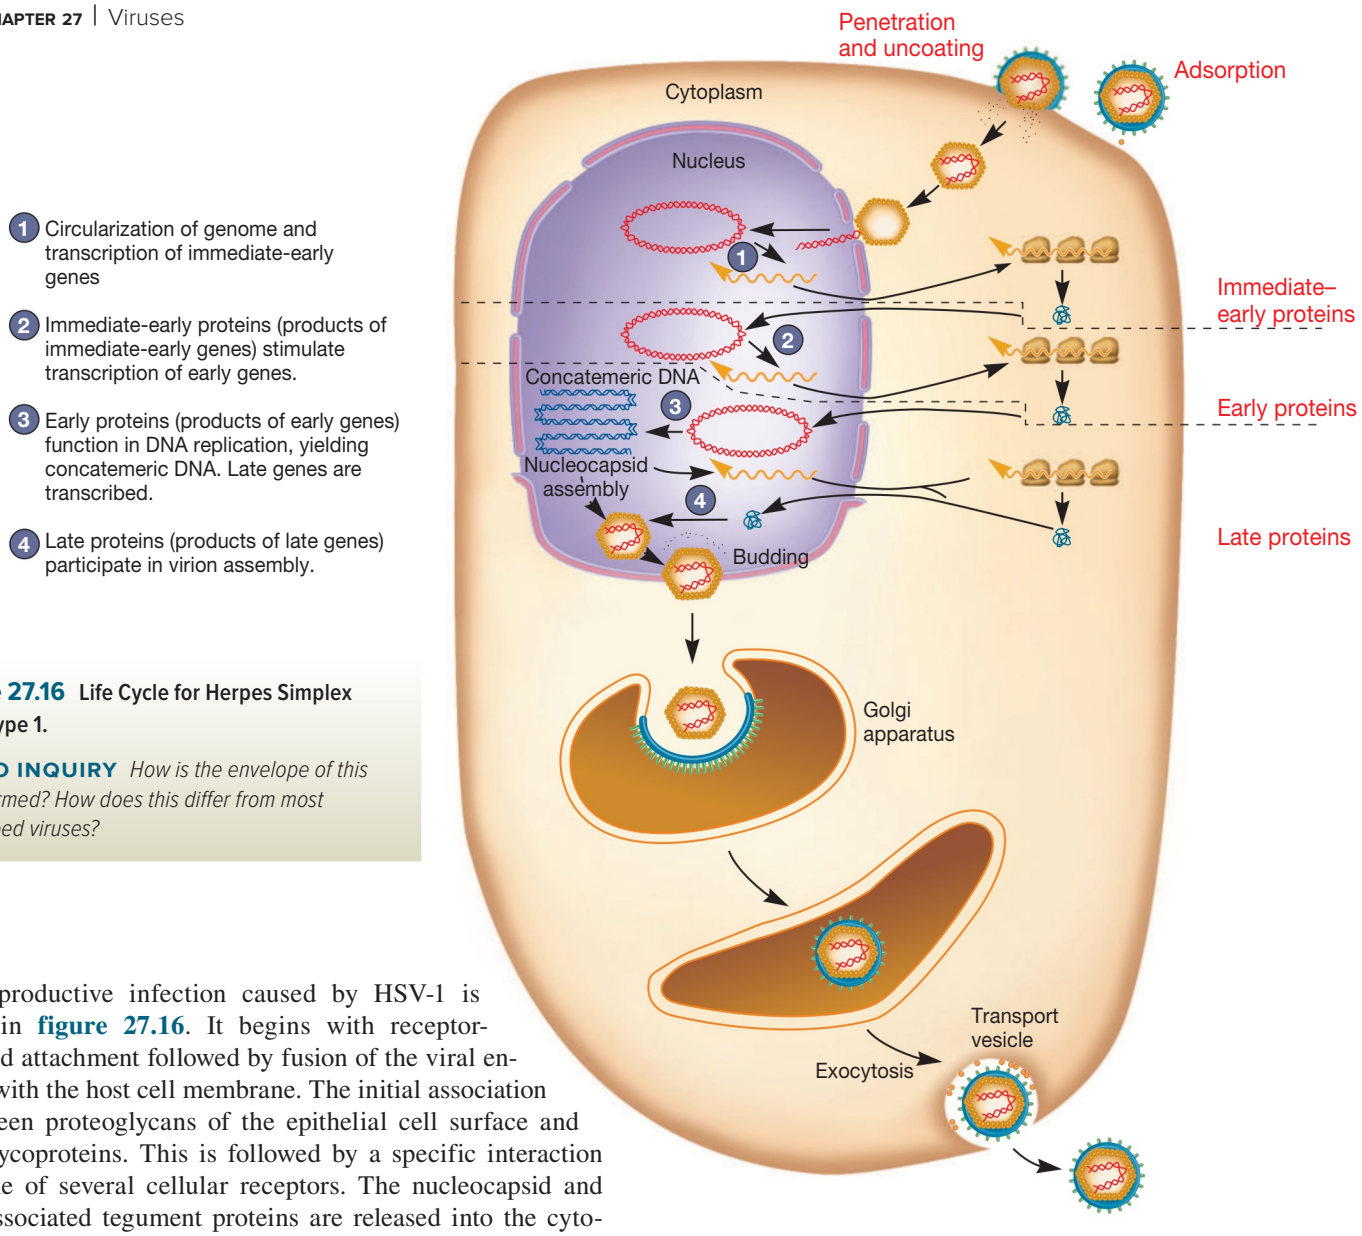

Figure 27.16 Life Cycle for Herpes Simplex Virus Type 1.

MICRO INQUIRY *How is the envelope of this virus formed? How does this differ from most enveloped viruses?*

A productive infection caused by HSV-1 is shown in **figure 27.16**. It begins with receptor-mediated attachment followed by fusion of the viral envelope with the host cell membrane. The initial association is between proteoglycans of the epithelial cell surface and viral glycoproteins. This is followed by a specific interaction with one of several cellular receptors. The nucleocapsid and some associated tegument proteins are released into the cytoplasm and transported by the host cell's microtubule/dyenin system to the nucleus. The linear dsDNA and some of the tegument proteins then enter the nucleus by way of a nuclear pore complex. Immediately upon entry of the viral DNA into the host nucleus, the DNA circularizes and is transcribed by host DNA-dependent RNA polymerase to form mRNAs, which are translated to yield several immediate early and early proteins. These are mostly regulatory proteins and enzymes required for replication of viral DNA (figure 27.16, steps 1 and 2). Replication of the genome with a virus-specific DNA-dependent DNA polymerase begins in the cell nucleus within 4 hours after infection (figure 27.16, step 3). Viral structural proteins are the products of the late genes. These proteins enter the nucleus, where they are assembled into nucleocapsids. Capsid formation and genome packaging are similar to that seen for bacteriophage T4.

The acquisition of the tegument and envelope, and exit from the host cell are interesting processes that require several steps to complete. Once the nucleocapsid is assembled, it makes contact with the inner membrane of the nucleus. It then buds into the space between the two nuclear membranes. This generates an envelope that is called the primary viral envelope. The primary envelope is lost when it fuses with the outer nuclear membrane, releasing the herpesvirus nucleocapsid into the cytoplasm. At this point in the life cycle, some tegument proteins associate with the nucleocapsid. Additional tegument proteins are added when the developing virion is enveloped by membranes of either the Golgi apparatus or endosomes. This yields a mature enveloped virion that is transported to the plasma membrane in a membrane vesicle. The membrane vesicle fuses with the plasma membrane and releases the mature virion from the host cell. Thus unlike many other enveloped viruses, the source of the HSV-1 envelope is an organelle membrane, rather than the plasma membrane.

Just as the life cycle of λ has been of interest as a model of regulatory processes, so too has the establishment of latency by herpesviruses. It appears that both viral and host proteins play a role in establishing a latent HSV-1 infection. Several studies have demonstrated that in epithelial cells, where productive infections occur, an HSV-1 protein called VP16 and a host protein called simply host cell factor (HCF) enter the nucleus with the viral genome. VP16 and HCF are needed for full expression of the

MICROBIAL DIVERSITY & ECOLOGY

27.1 What Is a Virus?

The discovery of mimivirus, a giant virus that infects the amoeba *Acanthamoeba polyphaga* and other megaviruses, has renewed a debate among biologists, chemists, virologists, and others: Are viruses alive? It has also introduced a new level of complexity to this debate: What makes a virus a virus? The confusion and debate stem from several sources. The first is that biologists have difficulty defining life. Instead, biologists have a list of attributes associated with life. Viruses share some of those attributes: they multiply, they evolve, they alter their gene expression in response to environmental stimuli (e.g., induction). However, there are others they lack: metabolic capabilities, especially energy-conserving processes, and an ability to carry out any of the processes associated with life outside a host cell. Another shift in thinking about viruses occurred when Wendell Stanley (1904–1971) and colleagues (all chemists) crystallized tobacco mosaic virus virions. The fact that they could be crystallized caused many to begin thinking of viruses simply as complexes of chemicals, rather than as biological entities.

The large size and coding capacity of megaviruses and the surprising discovery that they need not rely totally on their hosts for translation have fueled the debate. Indeed, the genomes of megaviruses are extensive enough to support the replication of their own viruses. In other words, some megaviruses are parasitized by viruses called virophages. Virophages use megavirus-encoded enzymes to complete their multiplication cycles. Surprisingly, one virophage genome is integrated into its megavirus "host."

In 2008 Didier Raoult and Patrick Forterre formalized their thoughts about what makes a virus a virus in a paper they published in *Nature Reviews Microbiology.* They proposed, first of all, that viruses are living organisms. They then argued that organisms should be divided into two groups: those that synthesize translational machinery (i.e., cellular organisms) and those that synthesize capsid (i.e., viruses). As you might imagine, this has caused considerable controversy.

These giant viruses have generated other controversies. Some scientists suggest that megaviruses be included in the tree of life as the fourth domain. Others argue that megaviruses may have given rise to the nucleus during the evolution of eukaryotic cells. There is also much debate about when and how megaviruses arose. Don't be surprised if more controversies arise as more is learned about these viruses.

virus's immediate early genes. However, VP16 and HCF do not enter the nucleus of infected neurons, and the expression of many immediate early genes is decreased. In addition, small noncoding RNAs produced by the virus further decrease expression of immediate early genes needed for a lytic infection. The inhibition of early gene expression helps establish latency. Interestingly, the production of VP16 in virus-infected neurons is an early event in the reactivation of the virus.

Nucleocytoplasmic Large DNA Viruses (Megaviruses)

Nucleocytoplasmic large DNA (NCLD) viruses are viruses of eukaryotic cells that are thought to have arisen from a common ancestor; a new virus order, *Megavirales,* has been proposed to encompass them. NCLD viruses, now often referred to as megaviruses, have similar life cycles in which most, if not all, of the events occur in the cytoplasm of their hosts. Most have large icosahedral capsids that enclose a lipid membrane. At the center of their virions is a large dsDNA genome (compare the 10-kilobase genome of an influenza virus to the 100- to 1,200-kilobase genomes of megaviruses). Thus both the virion itself and the genome are large, often rivaling the sizes of small bacteria and their genomes. Megaviruses infect a variety of eukaryotic hosts, including animals, algae, and protozoa.

The large genomes of megaviruses enable them to encode many proteins. Thus they are very self-sufficient and rely on their hosts for much less than do other viruses. They generally encode all the proteins needed for DNA replication, enzymes involved in recombination, RNA polymerases and associated transcription factors, and chaperone proteins. In addition, they encode some components of the translational machinery (tRNAs and aminoacyl-tRNA synthetases). Indeed, their coding capacity and size have led many virologists to rethink the definition of viruses and cells (**Microbial Diversity & Ecology 27.1**).

Retrieve, Infer, Apply

1. The CRISPR/Cas system has been a boon to biotechnology because it allows targeted silencing of specific genes. Explain how the CRISPR/Cas system can be modified to target eukaryotic genes.
2. Why do cold sores recur throughout the lifetime of an HSV-1–infected individual?
3. In what part of the host cell does a herpesvirus genome replicate? Where does the viral genome reside during a latent infection?
4. Many small DNA viruses rely on host enzymes for replication and transcription. Why are megaviruses able to use their own DNA-dependent RNA polymerases and DNA polymerases?

27.3 Single-Stranded DNA Viruses Use a Double-Stranded Intermediate in Their Life Cycles

After reading this section, you should be able to:

- Describe in general terms the strategy used by single-stranded (ss) DNA viruses to synthesize their nucleic acids and proteins
- Choose one specific bacterial and eukaryal ssDNA virus and illustrate the major events in their life cycles, noting, when possible, the specific mechanisms used to accomplish each step

Most DNA viruses are double-stranded, but several important viruses with single-stranded (ss) DNA genomes have been described. The life cycles of ssDNA viruses are similar to those of dsDNA viruses with one major exception. An additional step must occur in the synthesis stage because the ssDNA genome needs to be converted to a dsDNA molecule. A few ssDNA viruses are discussed next.

Bacteriophages ϕX174 and fd

The life cycle of ϕX174 (family *Microviridae,* species *Enterobacteria phage phiX174*) begins with attachment to the cell wall of its *E. coli* host. The circular ssDNA genome enters the cell with the help of a pilot protein called protein H. Protein H is thought to form a tubelike structure through which the DNA passes; the protein capsid remains outside the cell. The ϕX174 ssDNA genome has the same base sequence as viral mRNA and is therefore **plus-strand DNA.** For either transcription or genome replication to occur, the phage DNA must be converted to a double-stranded **replicative form (RF)** (**figure 27.17**). This is catalyzed by the host's DNA polymerase. The RF directs the synthesis of more RF copies and plus-strand DNA, both by rolling-circle replication (*see figure 16.21*). Assembly of ϕX174 virions begins with formation of a procapsid. This involves scaffolding proteins that interact with capsid proteins, causing them to undergo conformational changes and form a procapsid with the proper morphology. Once the procapsid is generated, the ssDNA genome is inserted, creating the mature virion. After assembly of virions, the host is lysed by a viral enzyme (enzyme E) that blocks peptidoglycan synthesis. Enzyme E inhibits the activity of the bacterial protein MraY, which catalyzes the transfer of peptidoglycan precursors to lipid carriers (*see figure 12.9*). Blocking cell wall synthesis weakens the host cell wall, causing the cell to lyse and release the progeny virions.

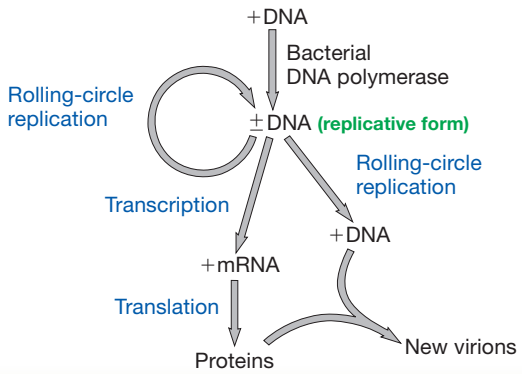

Figure 27.17 The Multiplication Strategy of ϕX174, a Plus-Strand DNA Phage.

MICRO INQUIRY *Why is the ϕX174 genome considered plus stranded?*

We include *Escherichia coli* phage fd (family *Inoviridae*) in our discussion because of one striking feature: its ability to be released from its host without lysis; it is also a good example of viral self-assembly. It, like other filamentous phages (e.g., *Pseudomonas* phage Pf1), is released by a secretory process. Extrusion begins when phage coat proteins are inserted into the host cell's plasma membrane. The coat then assembles around the viral DNA as it is secreted through the host plasma membrane (**figure 27.18**). Although the host cell is not lysed, it grows and divides at a slightly reduced rate. This mechanism is rare among bacterial viruses but is more common among archaeal viruses, as we note in section 27.2.

Parvoviruses

Parvoviruses (family *Parvoviridae*) infect numerous animal hosts, including crustaceans, dogs, cats, mice, and humans. Since its discovery in 1974, human parvovirus B19 (genus *Erythrovirus*) has emerged as a significant human pathogen. Parvovirus virions are uniform, icosahedral, nonenveloped particles approximately

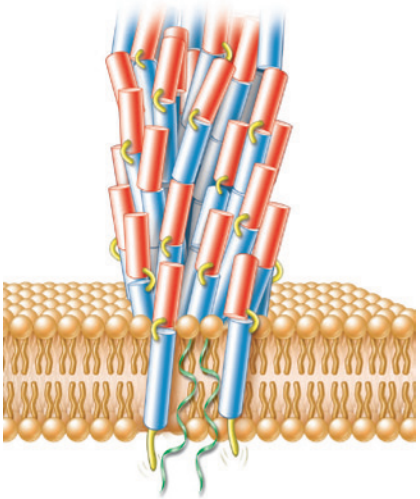

Figure 27.18 Release of Pf1 Phage. The filamentous Pf1 phage is released from *Pseudomonas aeruginosa* without lysis. In this illustration, the blue cylinders are hydrophobic α-helices that span the plasma membrane, and the red cylinders are amphipathic helices that lie on the membrane surface before virion assembly. In each protomer, the two helices are connected by a short, flexible peptide loop (yellow). It is thought that the blue helix binds with circular, single-stranded viral DNA (green) as it is extruded through the membrane. The red helix simultaneously attaches to the growing viral coat that projects from the membrane surface. Eventually the blue helix leaves the membrane and also becomes part of the capsid.

MICRO INQUIRY *What is the fate of the host cell infected with Pf1 phage?*

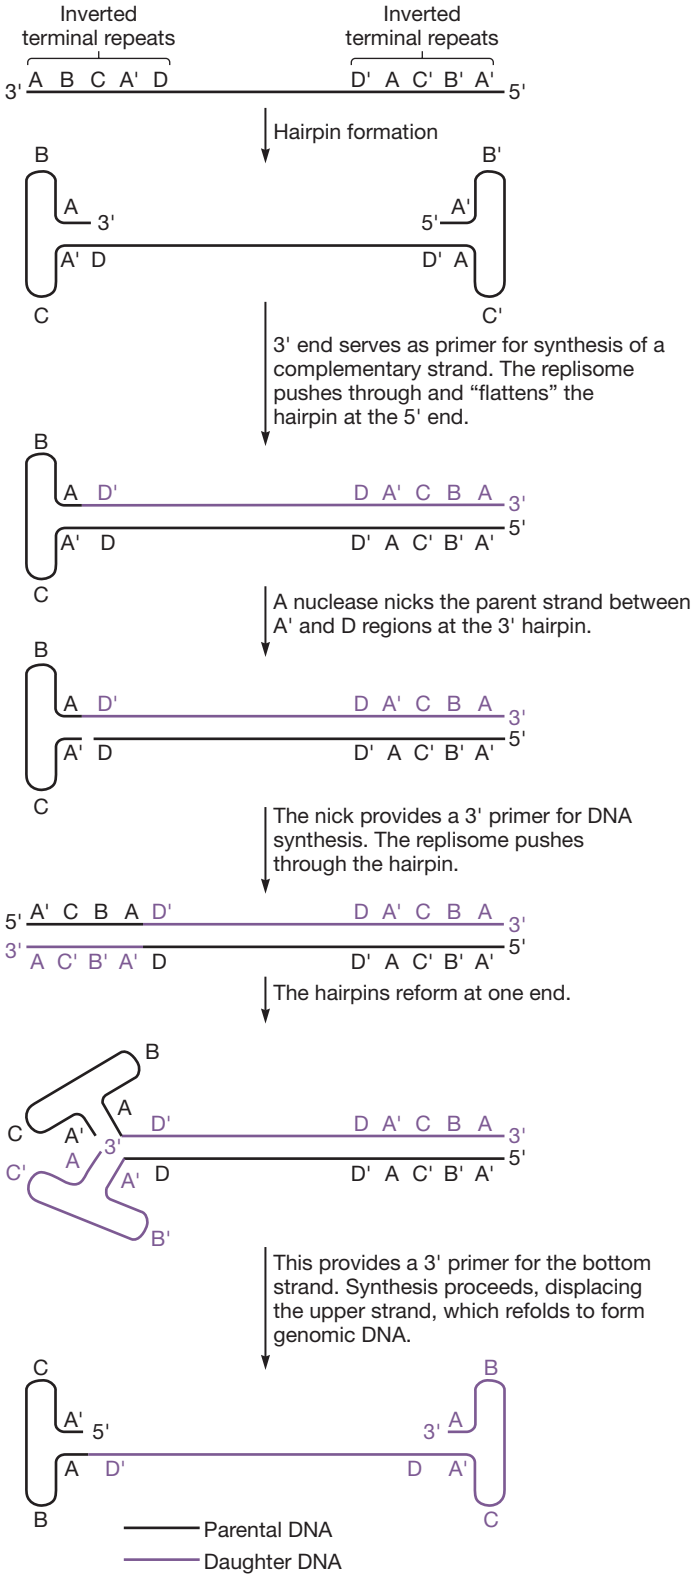

Figure 27.19 The Rolling-Hairpin Replication Used by Parvoviruses to Replicate Their DNA.

26 nm in diameter. Their genomes are composed of one ssDNA molecule of about 5,000 bases. Most of the genomes are **negative-strand DNA** molecules. That is, their sequence of nucleotides is complementary to that of the viral mRNA (figure 27.2). Parvoviruses are among the simplest of the DNA viruses. The genome is so small that it directs the synthesis of only three proteins and some smaller polypeptides. None has enzymatic activity. ▶▶| *Human parvovirus B19 infection (section 38.3)*

Each parvovirus uses a particular host cell molecule for attachment. For instance, the B19 virus uses a molecule found only on the surface of red blood cell progenitors. The virion then enters by receptor-mediated endocytosis. The virion escapes the endosome and is thought to be transported to the nucleus by the host cell's microtubules. The nucleocapsid enters the nucleus, followed by release of viral DNA from the capsid.

Since the parvovirus genome does not code for any enzymes, the virus must use host cell enzymes for all biosynthetic processes. Thus viral DNA can only be replicated in the nucleus during the S phase of the cell cycle, when the host cell replicates its own DNA. Because the genome is negative-strand DNA, it serves as the template for mRNA synthesis. Some of the RNA products encode polypeptides required for the interesting way the virus's genome is replicated. The ends of the parvovirus genome are palindromic sequences that can fold back on themselves. Formation of a hairpin at the 3′ end of the genome provides the primer needed for replication (**figure 27.19**). This is recognized by the host DNA polymerase, and DNA replication ensues by a process that is somewhat similar to rolling-circle replication. The parvovirus version of this replication method is often called rolling-hairpin replication because DNA polymerase seems to shuttle back and forth as it synthesizes genomes. The process involves a dsDNA intermediate, much like ϕX174.

Retrieve, Infer, Apply

1. Why is it necessary for some ssDNA viruses to manufacture a replicative form?
2. From the point of view of the virus, compare the advantages and disadvantages of host cell lysis, as seen in ϕX174, with the continuous release of phage without lysis, as with fd phage and other filamentous phages.
3. How do parvoviruses "trick" the host DNA polymerase into replicating their genomes? Why must this occur in the nucleus only during the S phase of the host's cell cycle?

27.4 Double-Stranded RNA Viruses: RNA-Dependent RNA Polymerase Replicates the Genome and Synthesizes mRNA

After reading this section, you should be able to:

- Distinguish RNA-dependent RNA polymerases from DNA-dependent RNA polymerases
- Describe what an RNA-dependent RNA polymerase is doing when functioning as a replicase and when functioning as a transcriptase
- Describe in general terms the strategy used by dsRNA viruses to synthesize their nucleic acids and proteins
- Describe the major events in the life cycles of ϕ6 and rotaviruses, noting, when possible, the specific mechanisms used to accomplish each step

The Baltimore system divides viruses with RNA genomes into four groups (table 27.1). However, they all share the same dilemma: their host cells have dsDNA genomes and thus lack a polymerase that can make RNA from an RNA template. Therefore RNA viruses classified in the Baltimore System as double-stranded, plus-strand, and negative-strand RNA viruses must produce an enzyme called **RNA-dependent RNA polymerase** (RdRp; an RNA polymerase that uses an RNA molecule as the template for RNA synthesis). When the RdRp is used to replicate the viral RNA genome, it is often referred to as a **replicase.** When it is used to synthesize mRNA, the RdRp is often said to have **transcriptase** activity. In most cases, an identical RdRp carries out both functions. Retroviruses use a very different approach: they first convert their ssRNA genomes into dsDNA, which is then recognized by the host cell's DNA-dependent RNA polymerase.

Among viruses with RNA genomes, those with dsRNA appear to be least abundant. These viruses share a common multiplication strategy (**figure 27.20**). Here we discuss two representative dsRNA viruses: a bacteriophage and a vertebrate virus. As you will see, these two viruses use one or more strategies to ensure that all needed viral proteins are made. Our discussions of other RNA viruses will introduce additional strategies. These strategies function at the levels of genome structure and organization, transcription, and translation.

Bacteriophage ϕ6

Several dsRNA phages have been discovered and assigned to the family *Cystoviridae*. The best studied, *Pseudomonas* phage phi6 (ϕ6), is unusual for several reasons. One is that it is an enveloped phage. The envelope encloses the nucleocapsid, which consists of an outer protein shell, composed of a viral protein called P8, and an inner core sometimes called the polymerase complex. It is so named because it consists of the virus's RNA-dependent RNA polymerase (RdRp) and three other proteins, and encloses the genome. The ϕ6 genome illustrates one of the methods used by RNA viruses to ensure synthesis of all viral proteins: it is a **segmented genome,** composed of more than one distinct RNA molecule. For most viruses, each segment encodes a single protein. However, ϕ6 deviates from this because each of its three dsRNA molecules generates a polycistronic mRNA and several proteins. Many other viruses also generate polycistronic mRNAs, much like the polycistronic mRNAs observed in bacteria and archaea (*see figure 13.22*).

The life cycle of the virus also has unusual features. Like some other phages, ϕ6 attaches to the side of a pilus. However, ϕ6 uses an envelope spike to facilitate adsorption. Retraction of the pilus brings the phage into contact with the outer membrane of its Gram-negative host. The viral envelope then fuses with the cell's outer membrane, a process mediated by another envelope spike. Fusion of the two membranes delivers the nucleocapsid into the periplasmic space. A protein associated with the nucleocapsid digests the peptidoglycan, allowing the nucleocapsid to cross this layer of the cell wall. Finally, the intact nucleocapsid enters the host cell by a process that resembles endocytosis. Evidence suggests that an interaction between the shell protein P8 and plasma membrane phospholipids mediates this mechanism of entry.

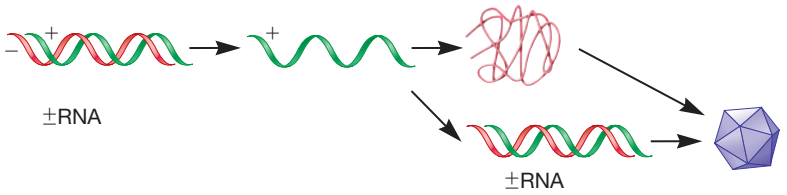

Figure 27.20 Multiplication Strategy of Double-Stranded RNA Viruses. Although we have designated plus and minus RNA strands, both strands may serve as templates for synthesis of mRNA by transcriptase, depending on the virus. For those viruses, each strand is said to be ambisense. The strand of the viral genome we have designated as the negative strand serves as the template for synthesis of positive strands by replicase. The positive strands are used by replicase to synthesize negative strands, thus replicating the dsRNA genome.

Once inside the host, the viral RNA polymerase acts as a transcriptase, catalyzing synthesis of viral mRNA from each dsRNA segment while they are still inside the capsid. The mRNAs leave the capsid and some are translated to early proteins. These assemble to form new, empty polymerase complexes (i.e., those lacking RNAs). Meanwhile, the virus's RNA polymerase acts as a replicase, synthesizing plus-strand RNA from each segment. The plus-strand RNAs become enclosed within the newly formed polymerase complexes, where they serve as templates for the synthesis of the complementary negative strand, regenerating the dsRNA genome. Proteins made later in the infection cycle include the proteins found in the outer shell. These associate with the polymerase complex, forming the nucleocapsid. Once the nucleocapsid is completed, a nonstructural viral protein called P12 surrounds the nucleocapsid with a plasma membrane-derived envelope while the nucleocapsid is within the host cytoplasm. Finally, additional viral proteins are added to the envelope and the host cell is lysed, releasing mature virions.

Rotaviruses

Human rotaviruses (family *Reoviridae*) are responsible for the deaths of over 600,000 children worldwide each year. They cause severe diarrhea, which rapidly causes dehydration and death if appropriate therapy is not provided. Because of their impact on humans, rotaviruses have been studied intensely to better understand their life cycles and pathogenesis. ▶▶| *Gastroenteritis (viral) (section 38.4)*

Viewed by electron microscopy, rotavirus virions have a characteristic wheel-like appearance (rotavirus is derived from the Latin *rota,* meaning wheel). Virions are nonenveloped and are composed of 11 segments of dsRNA surrounded by three concentric layers of proteins (*see figure 38.21*). The RNA segments code for six structural and six nonstructural proteins.

When a rotavirus virion enters a host cell, it loses the outermost protein layer and is then referred to as a double-layered particle (DLP; **figure 27.21**). The genome is transcribed by the viral transcriptase while still inside the DLP. The mRNA passes through channels in the DLP and is released into the cytosol of the host cell. There the mRNAs are translated by the host cell's

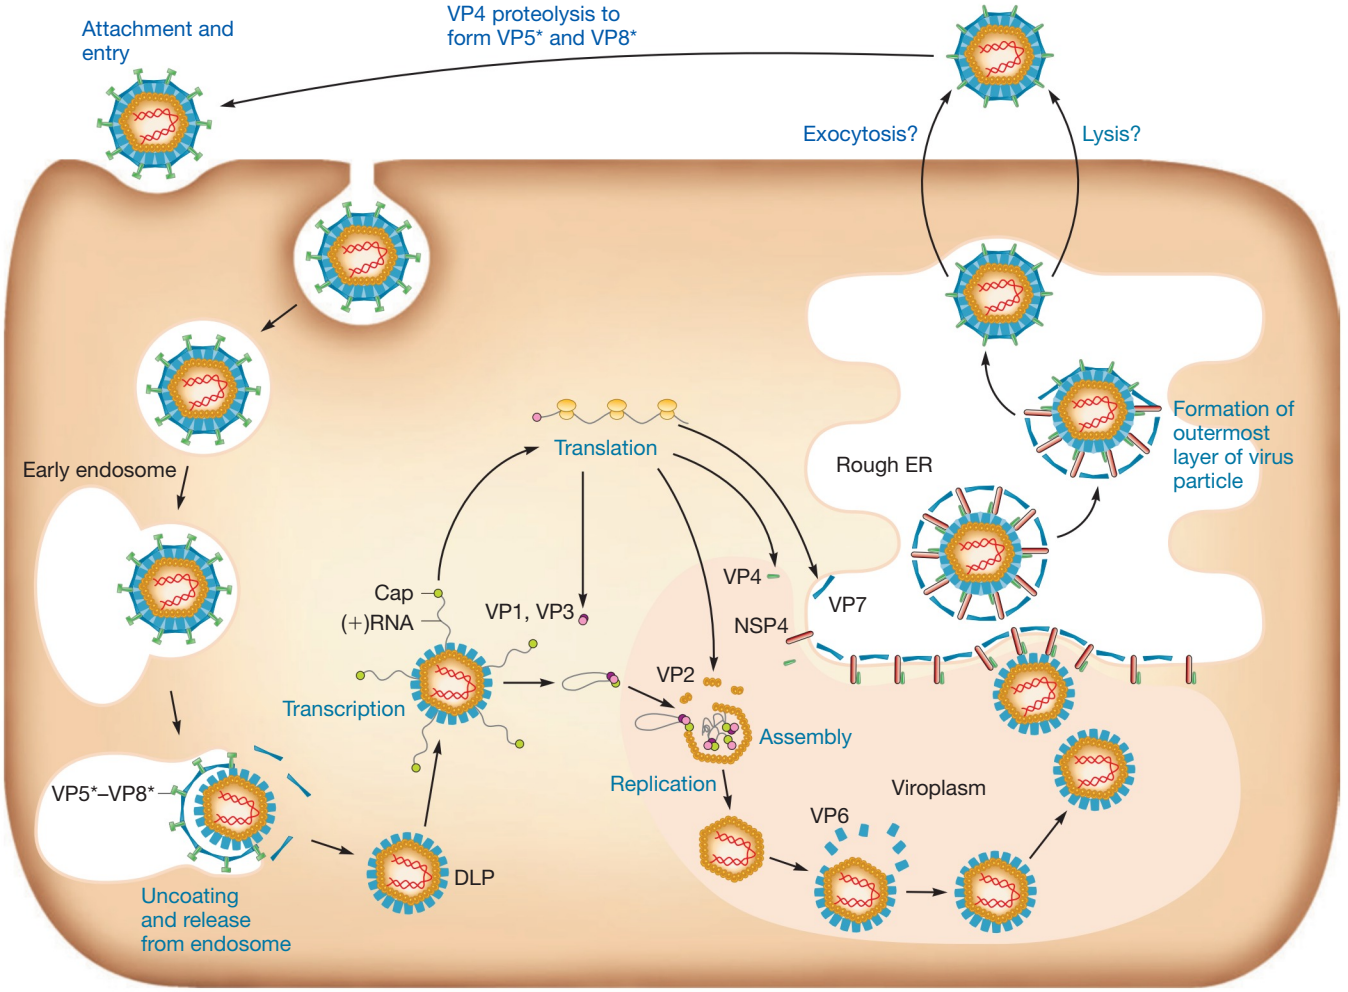

Figure 27.21 Life Cycle of a Rotavirus. VP1-8 are viral proteins that become part of the virion. NSP4 is a nonstructural protein that functions in virion assembly but is not incorporated into the virion. The method of release of progeny virions has not been definitively determined.

protein synthesis machinery. The newly formed proteins cluster together, forming an inclusion called a viroplasm. It is within the viroplasm that new DLPs are formed. Initially the DLPs contain plus-strand RNA, but this is soon used as a template for synthesis of the negative strand. Thus the dsRNA molecule is synthesized within the developing DLP.

DLPs containing dsRNA eventually leave the viroplasm and are enveloped by membranes of the endoplasmic reticulum. While in the endoplasmic reticulum, the outermost layer is added to the DLP, converting it to the mature triple-layered virion. The mature virion is released by an unknown mechanism.

27.5 Plus-Strand RNA Viruses: Genomes That Can Be Translated upon Entry

After reading this section, you should be able to:

- Describe in general terms the strategy used by plus-strand RNA viruses to synthesize their nucleic acids and proteins
- Outline the major events in the life cycles of poliovirus and tobacco mosaic virus, noting, when possible, the specific mechanisms used to accomplish each step

Plus-strand RNA viruses have genomes that can act as mRNA and be translated upon entry into the host cell. One of the first products is an RNA-dependent RNA polymerase, which catalyzes synthesis of negative-strand RNAs; these are then used to make more plus-strand RNAs (**figure 27.22**). In some cases, this occurs by way of a double-stranded replicative form (RF), just as seen with ssDNA viruses (section 27.3). In plant and animal viruses, viral genome replication occurs in a structure formed within the cytoplasm called a replication complex (*see figure 6.12*). These are compartments

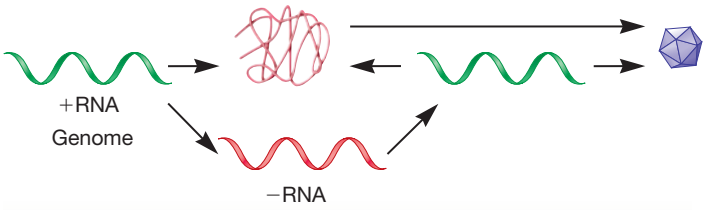

Figure 27.22 Multiplication Strategy of Plus-Strand RNA Viruses.
The plus-strand RNA genome can serve directly as mRNA. One of the first viral proteins synthesized is replicase, which replicates the genome, sometimes via a double-stranded replicative form. Transcriptase is responsible for synthesizing additional mRNA molecules.

MICRO INQUIRY *Where in the host does the plus-strand RNA genome replicate?*

formed in response to factors produced by the virus, and they are derived from the membranes of cell organelles (e.g., ER membrane); the source of the membrane depends on the virus. Assembly of progeny virions sometimes also occurs within the replication complex. There are a number of important positive-strand animal viruses (e.g., the viruses that cause polio, SARS, and hepatitis A), and most plant viruses have plus-stranded RNA genomes.

Poliovirus

Poliovirus (also called human enterovirus C), the causative agent of poliomyelitis, has caused disease in humans for centuries (*see Historical Highlights 38.1*). It primarily targets children, with paralysis being the tragic result in some cases. The life cycle of poliovirus illustrates another strategy used by RNA viruses to ensure synthesis of needed proteins: synthesis of a polyprotein. ▶▶| *Poliomyelitis (section 38.4)*

The biology of polioviruses (family *Picornaviridae*) has been intensely studied for decades. But many questions linger. This nonenveloped virus makes its way into a human host by ingestion. It attaches to a cell surface molecule called human PV receptor (PV for poliovirus). The nucleocapsid enters the host cell, and the plus-strand RNA genome is released into the cytosol while the virion is at the cell periphery and held within an endocytic vesicle (**figure 27.23**). The genome acts as mRNA and is translated by host cell ribosomes. This process has garnered considerable attention because the virus's RNA does not have the 5′ cap found on eukaryotic mRNAs, which is important for ribosome binding. Poliovirus "tricks" its host into translating its capless RNA using a 5′ region on the RNA called the internal ribosome entry site (IRES). In this region the ssRNA folds back on itself and forms extensive secondary structures (regions of dsRNA and numerous ssRNA loops), which are important for recognition of the RNA by ribosomes (**figure 27.24**).

Translation of the poliovirus genome yields a single polyprotein (**figure 27.25**). A **polyprotein** is a large protein that can be cleaved into smaller proteins by enzymes called proteases. The poliovirus polyprotein has protease activity and cleaves itself into three smaller proteins. Additional cuts in these proteins eventually yield all the structural proteins needed for capsid formation, as well as the virus's RNA-dependent RNA polymerase. The polymerase is used to generate negative-strand RNA molecules that serve as templates for synthesis of plus-strand RNAs. Some of these are translated, but eventually most will be used as new genomes and incorporated into capsids. All of the synthetic activity occurs in a replication complex. Mature particles are released from the cell by lysis. ◀◀| *Synthesis stage (section 6.3)*

Tobacco Mosaic Virus

Most plant viruses are RNA viruses, and of these, plus-strand RNA viruses are most common. Tobacco mosaic virus (TMV; family *Virgaviridae*) is the best-studied plus-strand RNA plant virus. TMV virions are filamentous with coat proteins arranged in a helical pattern. The TMV life cycle illustrates two new strategies to produce its needed proteins: subgenomic RNAs and readthrough. **Subgenomic RNAs** are mRNAs that are shorter than the genomic RNA. They can be synthesized in several ways, depending on the virus. Usually, synthesis of subgenomic RNAs is dictated by internal transcription start sites, internal transcription termination sites, or both. **Readthrough** occurs at the level of

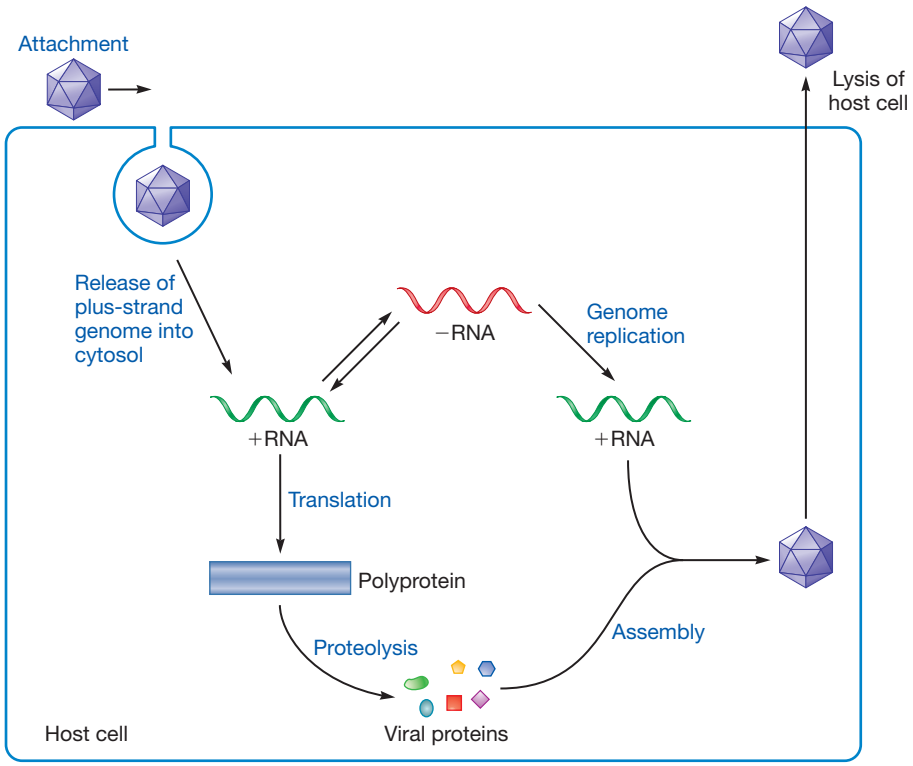

Figure 27.23 Poliovirus Life Cycle.

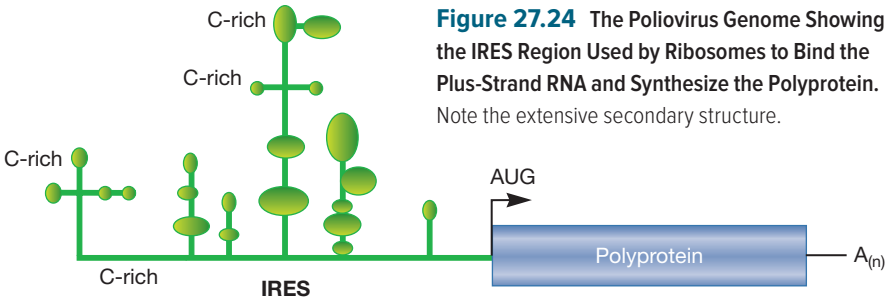

Figure 27.24 The Poliovirus Genome Showing the IRES Region Used by Ribosomes to Bind the Plus-Strand RNA and Synthesize the Polyprotein. Note the extensive secondary structure.

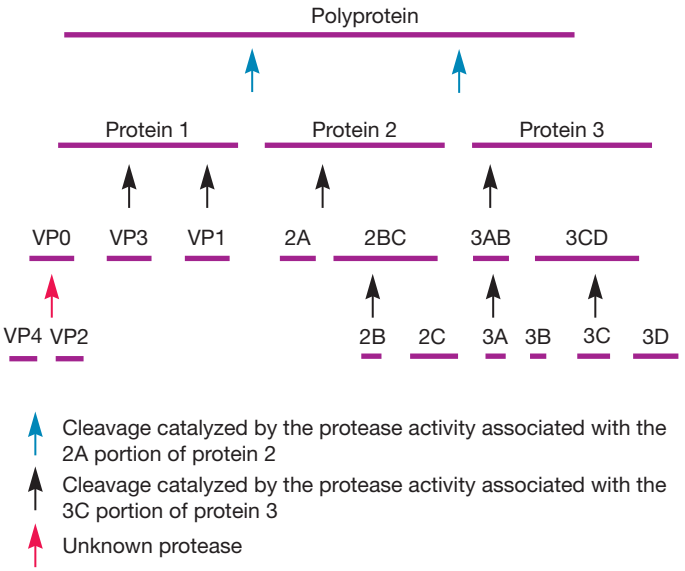

Figure 27.25 Cleavage of the Poliovirus Polyprotein. Proteins VP1-4 are structural proteins. Protein 3D is the RNA-dependent RNA polymerase.

translation. It occurs when the ribosome reaches a stop codon, ignores the stop signal, and continues translation.

Plant viruses, including TMV, usually enter the host through an abrasion or wound on the plant; biting insects are often involved in transmission of the virus. Following entry into its host, the TMV RNA genome is translated. Two proteins are produced, one smaller (about 125 kilodaltons; kD) and one larger (about 185 kD). The larger protein is produced by readthrough of the stop codon at the end of the coding region for the 125 kD protein. The 185 kD protein has RNA-dependent RNA polymerase activity and functions as both a transcriptase and a replicase. Soon thereafter, TMV uses membranes of the endoplasmic reticulum (ER) to form a replication complex. There, the RNA-dependent RNA polymerase synthesizes negative-strand RNA using the plus-strand genome as the template. It is not clear whether a double-stranded RF is created in vivo, but RFs have been observed in vitro. The negative-strand RNA serves as a template for synthesis of new genomes. It also serves as the template for synthesis of subgenomic mRNAs that are translated into a variety of proteins needed by the virus.

After the coat protein and RNA genome of TMV have been synthesized, they spontaneously assemble into complete TMV virions in a highly organized process (**figure 27.26**). The protomers come together to form disks composed of two layers of protomers arranged in a helical spiral. Association of coat protein with TMV RNA begins at a specific assembly initiation site close to the 3′ end of the genome. The helical capsid grows by the addition of protomers, probably as disks, to the end of the rod. As the rod lengthens, the RNA passes through a channel in its center

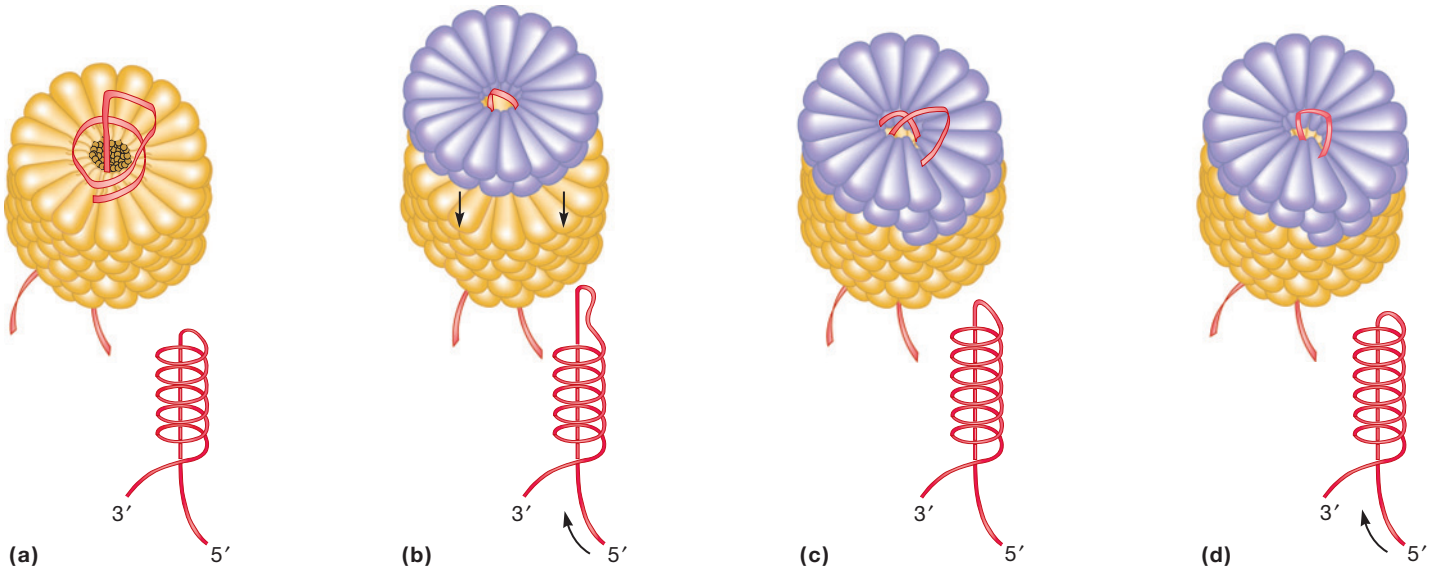

Figure 27.26 TMV Assembly. The elongation phase of tobacco mosaic virus nucleocapsid construction. The lengthening of the helical capsid through the addition of a protein disk to its end is shown in a sequence of four illustrations; line drawings depicting RNA behavior are included. The RNA genome inserts itself through the hole of an approaching disk and then binds to the groove in the disk as it locks into place at the end of the cylinder.

and forms a loop at the growing end. In this way, the RNA easily fits as a spiral into the interior of the helical capsid.

Multiplication of plant viruses within their host depends on the virus's ability to spread throughout the plant. Viruses can move to new sites in the plant through the plant vasculature; usually they travel in the phloem. They can also spread more locally in nonvascular tissue. Recall that plant cells have tough cell walls. Therefore, plant viruses move from cell to cell through plant cell plasmodesmata. These are slender bridges of cytoplasmic material, including extensions of the ER. Plasmodesmata extend through holes in cell walls to join adjacent plant cells. Viral "movement proteins" are required for transfer through the plasmodesmata. TMV movement proteins are closely associated with ER membranes and so are near the TMV replication complex where viral genomes are being synthesized. They bind the viral genomic RNA (vRNA) and also interact with components of the cytoskeleton. Therefore they facilitate the movement of vRNA from the replication complex to the plasmodesmata. TMV movement proteins also cause the plasmodesmata to increase in diameter, allowing the vRNA to pass through to the adjacent cell.

Several cytological changes can take place in TMV-infected cells. These include microscopically visible intracellular inclusions that are similar to the replication complexes observed in animal cells infected with plus-strand viruses. Hexagonal crystals of almost pure TMV virions sometimes develop in TMV-infected cells. In addition, host cell chloroplasts become abnormal and often degenerate, while new chloroplast synthesis is inhibited.

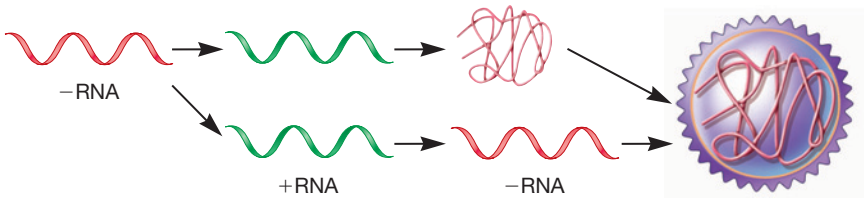

Figure 27.27 Multiplication Strategy of Negative-Strand RNA Viruses. An RNA-dependent RNA polymerase enters the host cell at the same time the negative-strand RNA genome enters. The genome serves as a template for synthesis of mRNA. Later in the infection, the negative-strand genome is used for plus-strand synthesis. These plus strands then act as templates for replication of the negative-strand genomes.

27.6 Minus-Strand RNA Viruses: RNA-Dependent RNA Polymerase Is Part of the Virion

After reading this section, you should be able to:

- Describe in general terms the strategy used by minus-strand RNA viruses to synthesize their nucleic acids and proteins
- Explain how having a segmented genome impacts synthesis of viral mRNA and proteins and the generation of new strains of a virus
- Create a flow chart that summarizes the life cycle of influenza virus, noting the specific mechanisms it uses to accomplish each step of its life cycle

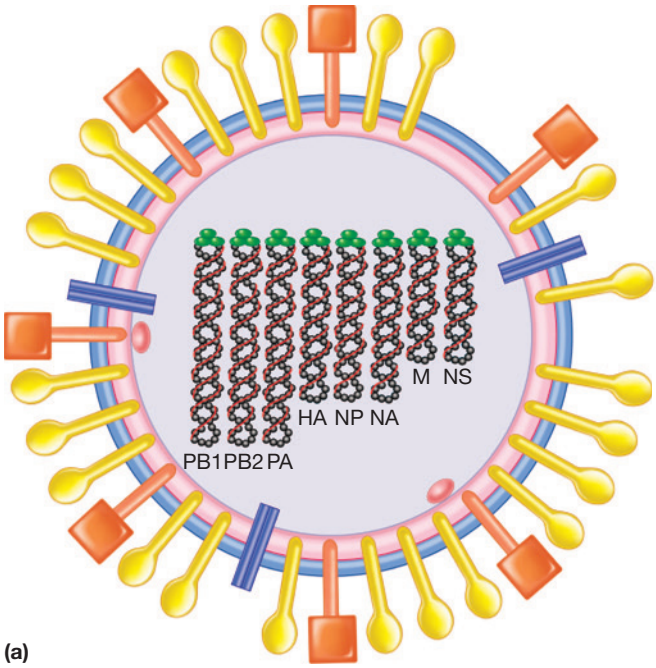
Negative-strand viruses are found in many families, including *Rhabdoviridae* (e.g., rabies virus), *Filoviridae* (e.g., Marburg and Ebola viruses), *Paramyxoviridae* (e.g., measles and mumps viruses), *Bunyaviridae* (e.g., hantaviruses), and *Orthomyxoviridae* (e.g., influenza viruses). Most negative-strand RNA viruses are enveloped viruses that infect plants and animals. They vary in morphology from spherical, to filamentous, rod-shaped, bullet-shaped, and pleomorphic. Members of four families have nonsegmented linear genomes and are grouped into the order *Mononegavirales*. The remaining negative-strand RNA viruses have segmented genomes that range from two to eight segments, each encoding usually one protein.

The genomes of negative-strand RNA viruses cannot function as mRNA. Therefore these viruses must bring at least one RNA-dependent RNA polymerase into the host cell during entry. Initially the viral genome serves as the template for mRNA synthesis (**figure 27.27**). Later the virus switches from mRNA synthesis to genome replication, as the RNA-dependent RNA polymerase synthesizes a distinct plus-strand RNA for replication. During this phase of the life cycle, the plus-strand RNA molecules synthesized from the minus-strand genome serve as templates for the manufacture of new negative-strand RNA genomes.

Our focus in this section is on influenza viruses. There are three types of influenza virus: influenza viruses A, B, and C. Influenza virus virions are composed of an envelope enclosing seven or eight nucleocapsids, depending on the type of influenza virus. Each nucleocapsid consists of a single, negative-strand RNA that exists as a double helical hairpin (**figure 27.28*a***). Formation and maintenance of the double helix does not involve base pairing. Rather, this is accomplished by numerous copies of the nucleocapsid protein (NP), which coat the RNA. The three proteins of the influenza polymerase (PA, PB1, PB2) are attached to the open end of the hairpin.

An influenza virion enters a host cell by receptor-mediated endocytosis. This encloses the virus in an endosome (figure 27.28*b*). When the endosomal pH decreases, a conformational change in the virion facilitates contact with the endosome membrane, allowing fusion of the endosome membrane and viral envelope to occur, releasing the nucleocapsids into the cytosol. ▶▶| *Influenza (flu; section 38.1)*

Once the RNA segments and associated RNA-dependent RNA polymerase enter the host cell nucleus, the genome segments serve as templates for mRNA synthesis (figure 27.28*b*,



(a)

Viral proteins

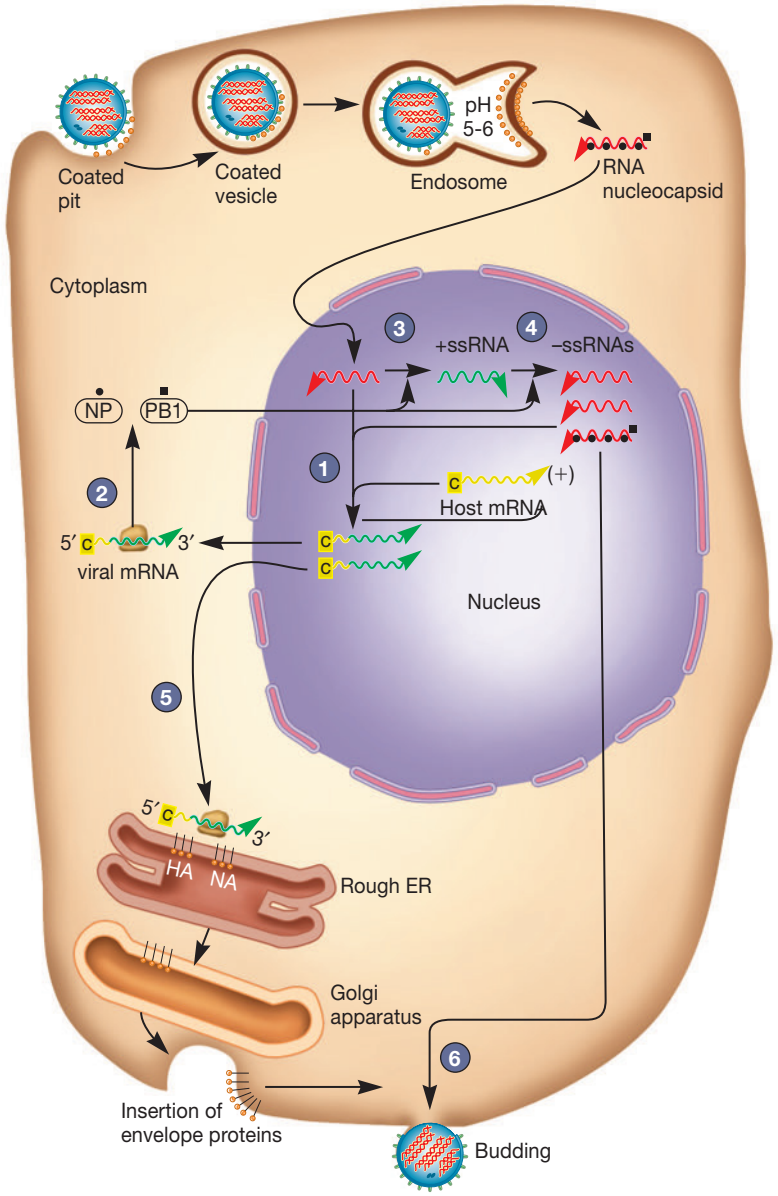
- Neuraminidase (NA)
- Nuclear export protein (NEP)
- Membrane protein (M2)



(b)

1. The PB2 protein cleaves the cap and about 10 nucleotides from the 5′ end of host mRNA (cap snatching). The fragment is used to prime viral mRNA synthesis by the RNA-dependent RNA polymerase activity of the PB1 protein.
2. Viral mRNA is translated. Early products include more NP and PB1 proteins.
3. PB1 synthesizes +ssRNA from genomic −ssRNA molecules.
4. PB1 synthesizes new copies of the genome using +ssRNA made in step 3 as templates. Some of these new genome segments serve as templates for the synthesis of more viral mRNA. Later in the infection, they will become progeny genomes.
5. Viral mRNA molecules transcribed from other genome segments encode structural proteins such as hemagglutinin (HA) and neuraminidase (NA). These messages are translated by ER-associated ribosomes and delivered to the cell membrane.
6. Viral genome segments are packaged as progeny virions bud from the host cell.

Figure 27.28 An Influenza Virus and Its Life Cycle. (a) Schematic representation of an influenza A virus showing the double helical hairpin RNA genome. The protein or proteins encoded by each RNA segment are shown below each nucleocapsid. A protein called M1 (lavender; M stands for matrix) lines the lipid bilayer envelope (dark blue). Another matrix protein (M2) is embedded in the envelope. NS proteins (NS1 and NS2) are nonstructural proteins that function in the life cycle of the virus but are not part of the virion. (b) This simplified version of the influenza life cycle omits several steps and represents the viral RNA molecules as simple lines. Negative-strand RNA is red and positive-strand RNA is green. After entry by receptor-mediated endocytosis, the virus envelope fuses with the endosome membrane, releasing the nucleocapsids into the cytosol. The nucleocapsids enter the nucleus, where synthesis of viral mRNA and genomes occurs. The influenza virus polymerase is composed of three subunits. PB1 has RNA-dependent RNA polymerase activity. PB2 is an endonuclease responsible for the cap snatching described in step 1. PA is a protease. Steps 1 through 6 illustrate the remaining steps of the virus's life cycle.

step 1). Later the virus switches from mRNA synthesis to genome replication. During this phase of the life cycle, the plus-strand RNA molecules synthesized from the minus-strand genome segments serve as templates for new negative-strand RNA genomes (figure 27.28, step 4). Virions exit the host cell by budding and thus acquire their envelope (figure 27.28*b*, step 6; *see also figure 6.15*).

2. Trace the multiplication of an influenza virus starting with host cell attachment and ending with the exit of virions.

27.7 Retroviruses: Plus-Strand Viruses That Use Reverse Transcriptase in Their Life Cycles

After reading this section, you should be able to:

- Describe in general terms the strategy used by retroviruses to synthesize their nucleic acids and proteins
- Differentiate a segmented genome from the genome of a retrovirus
- Describe the life cycle of HIV, noting the specific mechanisms it uses to accomplish each step
- Defend the statement "all three enzymatic activities of reverse transcriptase are required for dsDNA to be synthesized from RNA"
- Distinguish DNA-dependent DNA polymerases, DNA-dependent RNA polymerases, RNA-dependent RNA polymerases, and RNA-dependent DNA polymerases in terms of their templates, products synthesized, and proofreading activity, as discussed in this and previous sections

Retroviruses have positive-strand RNA genomes. However, their genomes do not function as mRNA (**figure 27.29**). Instead, retroviruses first convert their ssRNA genomes into dsDNA using a multifunctional enzyme called **reverse transcriptase.** The dsDNA then integrates into the host's DNA, where it can serve as a template for mRNA synthesis and synthesis of the plus-strand RNA genome. The host cell's DNA-dependent RNA polymerase catalyzes both of these processes.

Numerous retroviruses have been identified and studied. However, human immunodeficiency virus (HIV), the cause of AIDS (acquired immune deficiency syndrome), is of particular interest. AIDS is now recognized as the greatest pandemic of the second half of the twentieth century. Because of its global importance, we focus exclusively on HIV in this section. ▶▶| *Acquired immune deficiency syndrome (AIDS) (section 38.3)*

HIV is a member of the genus *Lentivirus* within the family *Retroviridae*. In the United States, AIDS is caused primarily by HIV-1. HIV-1 is an enveloped virus. The envelope surrounds an outer shell, which encloses a somewhat cone-shaped core (**figure 27.30**). The core contains two copies of the HIV RNA genome and several enzymes, including the enzymes reverse transcriptase and integrase. Thus far 10 virus-specific proteins have been discovered in the HIV virion.

After entering the body, the gp120 viral envelope protein binds to host cells that have a surface glycoprotein called CD4. The virus requires a coreceptor in addition to CD4, and this varies depending on the host cell infected (*see figure 38.10*). Still being debated is how HIV enters a host cell. Initially it was thought that the HIV envelope fused with the cell's plasma membrane and the virus released its core into the cytoplasm. However, evidence exists that virions enter by receptor-mediated endocytosis (figure 27.30). Some scientists suggest that virions may enter by either method. Inside the infected cell, the core protein dissociates from the RNA, and the RNA is copied into a single strand of DNA by the reverse transcriptase enzyme. The RNA is next degraded by reverse transcriptase, and the DNA strand is duplicated to form a double-stranded DNA copy of the original RNA genome (figure 27.29).

Reverse transcription is a critical step in the life cycle of HIV, and reverse transcriptase is a remarkable enzyme with multiple activities. It is an **RNA-dependent DNA polymerase,** a DNA-dependent DNA polymerase, and a ribonuclease. This latter function is referred to as RNaseH activity. Despite its versatility, reverse transcriptase lacks a function observed in other DNA polymerases: proofreading. Thus it makes many errors as it synthesizes DNA. Nonetheless, reverse transcription is an amazing process that involves the use of a host tRNA molecule as primer for initial steps in DNA synthesis (**figure 27.31**). In the process, a newly synthesized, small negative-strand DNA molecule is transferred

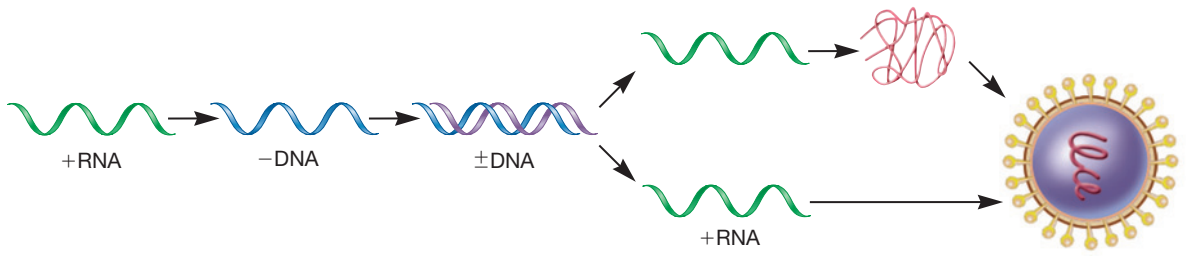

Figure 27.29 Multiplication Strategy of Retroviruses. Retroviruses have a plus-strand RNA genome that is first converted into dsDNA by the enzyme reverse transcriptase. The viral dsDNA integrates into the host chromosome, where it serves as the template for synthesis of viral mRNA and viral genomes. Both are synthesized using the host cell's DNA-dependent RNA polymerase.

from one end of the RNA template to the other to prime the synthesis of the rest of the minus-strand DNA. Later the full-length minus-strand DNA circularizes to allow completion of the plus-strand DNA.

Once dsDNA is formed, a complex of dsDNA (the provirus), integrase enzyme, and other factors (including some host molecules) moves into the nucleus, where the proviral DNA is integrated into the cell's DNA by integrase. Once integrated, the provirus can force the cell to synthesize viral mRNA (figure 27.30). Several different mRNAs are transcribed using the host cells DNA-dependent RNA polymerase. Some are full-length mRNAs and others are subgenomic mRNAs. The subgenomic mRNAs are formed by alternative splicing that brings different coding regions together, eliminating any intervening coding regions (rather than introns, as typically occurs during alternative splicing). Translation of two of the mRNAs yields polyproteins that are cleaved to give rise to numerous proteins. One of the polyproteins is synthesized by ribosomal frameshifting followed by readthrough. **Ribosomal frameshifting** is often used when viral genes overlap but are in different reading frames. It occurs at specific sites at which the ribosome pauses and then either continues in the same reading frame or shifts to the alternative reading frame. In the case of HIV, the ribosome reaches a stop codon, pauses, and either stops to yield one protein or shifts reading frame and continues translating the mRNA to yield the larger polyprotein. Some of the earliest proteins synthesized are used to regulate cellular activities so that HIV genes are preferentially expressed. Proteins needed to form HIV virions are made later. Eventually viral proteins and the complete HIV-1 RNA genome are assembled into new nucleocapsids that bud from the infected host cell (figure 27.30). After some time, the host cell dies, in part from repeated budding but by other processes as well.

2. CD4 is found on several different immune system cells. Consult chapter 34. Why is the presence of this molecule on the surface of many immune system cells important to the development of AIDS?
3. What role does alternative splicing play in the life cycle of HIV-1? For what purpose does the virus use ribosomal frameshifting and readthrough?

27.8 Reverse Transcribing DNA Viruses

After reading this section, you should be able to:

- Describe in general terms the strategy used by reverse transcribing DNA viruses to synthesize their nucleic acids and proteins
- Compare the role of reverse transcriptase in the life cycle of a retrovirus to that in the life cycle of a hepadnavirus

Reverse transcribing DNA viruses use reverse transcriptase to replicate their genomes. Members of four virus families fall into this category: *Caulimoviridae* (e.g., cauliflower mosaic virus and other plant viruses), *Metaviridae* (fungal, plant, and animal viruses), *Pseudoviridae* (fungal, plant, protist, and animal viruses), and *Hepadnaviridae* (e.g., hepatitis B virus and related animal viruses). Hepatitis B virus (HBV) is one of the best-studied reverse transcribing DNA viruses and is our focus here.

HBV virions are 42-nm spherical particles that contain the viral genome. The HBV genome is a circular dsDNA molecule that consists of one complete but nicked strand and a complementary strand that has a large gap; that is, it is incomplete (**figure 27.32**). The genome is 3.2 kb in length and consists of four partially overlapping, open reading frames that encode viral proteins. Production of new virions takes place predominantly in liver cells (hepatocytes).

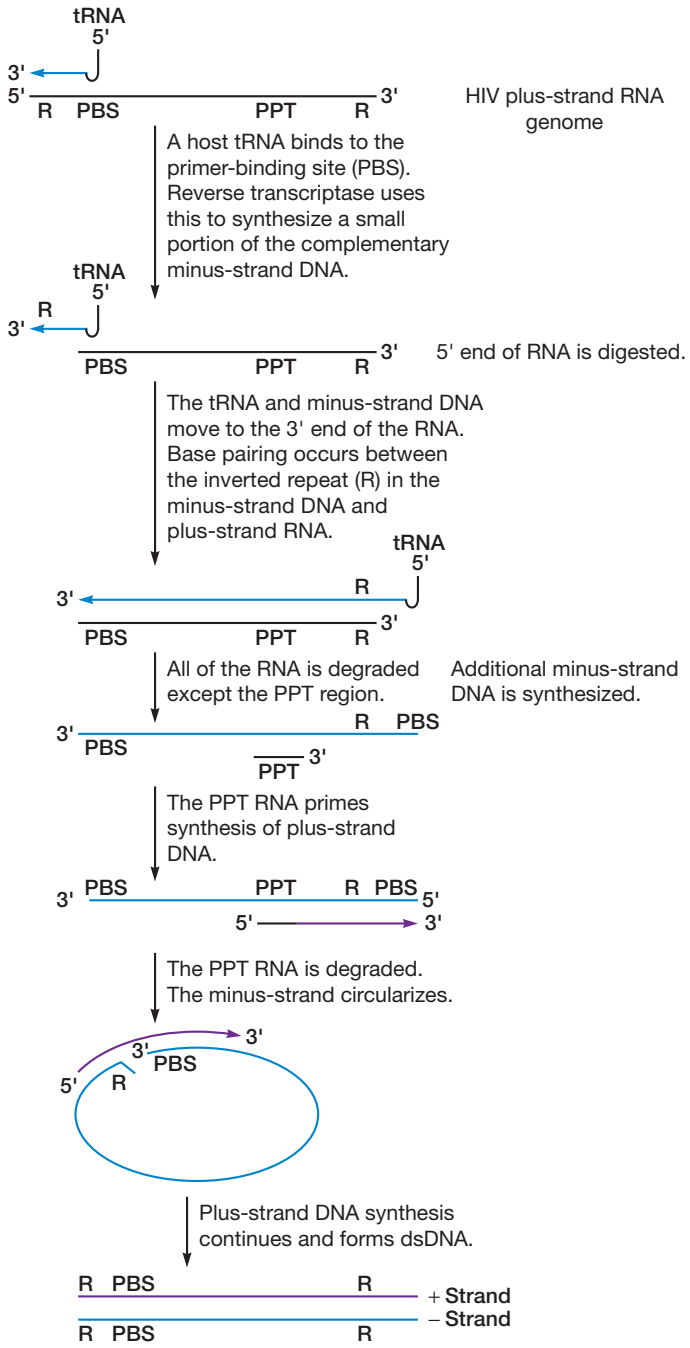

Figure 27.31 Reverse Transcription.

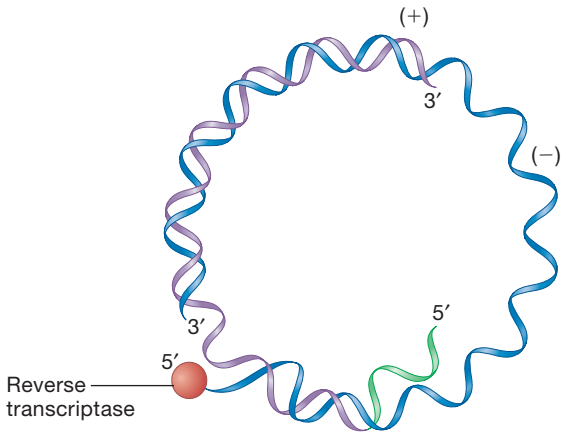

Figure 27.32 **The Gapped Genome of Hepadnaviruses.** The genomes of hepadnaviruses are unusual in several respects. The negative strand of the dsDNA molecule is complete but nicked. The enzyme reverse transcriptase is attached to its 5′ end. The positive strand is gapped; that is, it is incomplete (shown in purple). A short stretch of RNA is attached to its 5′ end (shown in green). Upon entry into the host nucleus, the nick in the negative strand is sealed and the gap in the positive strand is filled, yielding a covalently closed, circular dsDNA molecule.

After infecting a host cell, the viral-gapped DNA is released into the nucleus. There host repair enzymes fill the gap and seal the nick, yielding a covalently closed, circular DNA. Transcription of viral genes occurs in the nucleus using host RNA polymerase and yields several mRNAs, including a large 3.4-kb RNA known as the pregenome (a plus-strand RNA). The RNAs move to the cytoplasm, and the mRNAs are translated to produce viral proteins, including core protein and reverse transcriptase. Reverse transcriptase then associates with the plus-strand RNA pregenome and core protein to form an immature core particle. Reverse transcriptase subsequently reverse transcribes the RNA using a protein primer to form a minus-strand DNA from the pregenome RNA. After almost all the pregenome RNA has been degraded by the RNaseH activity of reverse transcriptase, the remaining RNA fragment serves as a primer for synthesis of the gapped dsDNA genome, using the minus-strand DNA as template. Finally, the nucleocapsid is completed and progeny virions are released.

2. Trace the HBV multiplication cycle, paying particular attention to localization within the host cell during the biosynthetic stage.

Key Concepts

27.1 Virus Phylogeny Is Difficult to Establish

- Currently viruses are classified with a taxonomic system placing primary emphasis on the type and strandedness of viral nucleic acids, and on the presence or absence of an envelope (**figure 27.1**).
- Increasingly, comparisons of viral genome sequences and the folding patterns of viral capsid proteins are being used to establish phylogenetic relationships among viruses.
- The Baltimore system is used by many virologists to organize viruses based on their genome type and the mechanisms used to synthesize mRNA and replicate their genomes (**table 27.1**).

27.2 Double-Stranded DNA Viruses Infect All Cell Types

- T4 is a virulent bacteriophage that causes lytic infections of *E. coli*. After attachment to a specific receptor site on the bacterial surface, T4 releases its dsDNA into the cell (**figures 27.4** and **27.5**). T4 DNA contains hydroxymethylcytosine (HMC) in place of cytosine, and glucose is often added to the HMC to protect the phage DNA from attack by host restriction enzymes (**figure 27.6**). T4 DNA replication produces concatemers, long strands of several genome copies linked together (**figure 27.7**).
- Lambda (λ) phage is a temperate bacteriophage. It can establish lysogeny, rather than pursuing a lytic infection. During lysogeny, the viral DNA, called a prophage, is replicated as the cell's genome is replicated. Lysogeny is reversible, and the prophage can be induced to become active again and lyse its host. This highly regulated process is an important model system for regulatory processes. The protein cII plays a central role in regulating the choice between lysogeny and a lytic cycle. If cII protein levels are high enough, lysogeny is established. If not, the lytic cycle is initiated (**figures 27.10** and **27.11**).
- Less is known about archaeal viruses. However, many of those discovered have interesting morphologies, which has led to the creation of several new viral families (**figure 27.12**). Many establish chronic infections, whereas others establish lysogenic and lytic infections (**figure 27.13**).
- The CRISPR/Cas system is a set of sequences found in many archaeal and bacterial genomes (**figure 27.14**). It is a defense system that protects the cells from viral attack. It functions in a manner similar to RNA silencing, an antiviral defense mechanism observed in eukaryotic cells.
- Herpesviruses are a large group of dsDNA viruses. They cause acute infections such as cold sores, genital herpes, chickenpox, and mononucleosis. This is followed by a lifelong latent infection in which the virus genome resides within neurons. The virus can be reactivated at later times to cause a productive infection.
- Nucleocytoplasmic large DNA (NCLD) viruses, also called megaviruses, are members of several virus families. They are thought to share an evolutionary history and are interesting due to their large genome and virion size. Furthermore, their genomes contain genes for translation-related functions that are not usually observed in viral genomes.

27.3 Single-Stranded DNA Viruses Use a Double-Stranded Intermediate in Their Life Cycles

- ϕX174 is an example of a ssDNA bacteriophage. Its replication involves the formation of a dsDNA replicative form (RF) (**figure 27.17**).
- fd phage is filamentous phage that upon infection is continuously released by the host without causing lysis.
- Parvoviruses cause a spectrum of diseases in a wide variety of animals. The parvovirus genome is replicated by host DNA polymerase in the host cell's nucleus using a process that is similar to rolling-circle replication (**figure 27.19**).

27.4 Double-Stranded RNA Viruses: RNA-Dependent RNA Polymerase Replicates the Genome and Synthesizes mRNA

- Double-stranded RNA viruses use a viral enzyme called RNA-dependent RNA polymerase to synthesize mRNA (transcriptase activity) and replicate their genomes (replicase activity) (**figure 27.20**).
- Bacteriophage ϕ6 is an unusual phage in that it is enveloped and enters the host bacterium through a process that resembles endocytosis. It has a segmented genome, in which each segment encodes a polycistronic mRNA that yields several proteins.
- Rotaviruses have segmented genomes, in which each segment codes for one or two proteins. They multiply in an inclusion called the viroplasm (**figure 27.21**).

27.5 Plus-Strand RNA Viruses: Genomes That Can Be Translated upon Entry

- The genomes of plus-strand RNA viruses serve directly as mRNA molecules. Among the first viral proteins synthesized is an RNA-dependent RNA polymerase that replicates the plus-strand RNA genome, sometimes by forming a dsRNA replicative intermediate. The negative RNA strands produced by the RNA-dependent RNA polymerase can be used to make either more genomes or mRNA (**figure 27.22**).
- Poliovirus genomic RNA is translated into a single polyprotein that is cleaved to form all the proteins needed by the virus during its life cycle (**figures 27.23–27.25**).
- TMV is like most known plant viruses in that it has a plus-strand RNA genome. Translation of TMV genomic RNA yields two proteins, the larger of which is produced by a readthrough mechanism. The RNA-dependent RNA polymerase encoded by the genome synthesizes minus-strand RNAs that serve as templates for synthesis of subgenomic mRNAs that are translated to yield other proteins needed by the virus. The minus-strand RNAs also serve as templates for synthesis of new plus-strand RNA genomes. The TMV nucleocapsid forms spontaneously when disks of coat protein protomers complex with the RNA (**figure 27.26**).

27.6 Minus-Strand RNA Viruses: RNA-Dependent RNA Polymerase Is Part of the Virion

- For minus-strand RNA viruses to synthesize mRNA and replicate their genomes, their virions must carry an RNA-dependent RNA polymerase, which enters the host cells as the genome does. The polymerase first synthesizes mRNA from the negative-strand genome. Later it is used to replicate the genome by way of a plus-strand intermediate (**figure 27.27**).
- Influenza viruses have segmented genomes; most segments encode a single protein. The viruses exit by budding (**figure 27.28**).

27.7 Retroviruses: Plus-Strand Viruses That Use Reverse Transcriptase in Their Life Cycles

- Retroviruses replicate their genomes and synthesize mRNA via a dsDNA intermediate. The dsDNA is formed by a multifunctional enzyme called reverse transcriptase (**figure 27.29**).
- HIV is an enveloped retrovirus with a cone-shaped core that contains two copies of its genome and several enzymes, including reverse transcriptase. Upon infection, its ssRNA genome is converted to dsDNA, which is then integrated into the host genome (**figure 27.30**). HIV uses alternative splicing to generate numerous different mRNA molecules. One encodes two polyproteins. One of the polyproteins arises by a combined ribosomal frameshifting, readthrough mechanism.

27.8 Reverse Transcribing DNA Viruses

- There are four groups of DNA viruses that use reverse transcriptase in their life cycles. One group, hepadnaviruses, includes hepatitis B virus, which has a dsDNA genome that consist of one complete but nicked strand and an incomplete (i.e., gapped) complementary strand (**figure 27.32**).
- Upon infection with hepatitis B virus, the host cell repairs the gap and seals the nick to generate a covalently closed, circular viral genome. This serves as the template for the synthesis of pregenome RNA, which is the template for reverse transcription. Reverse transcription produces the dsDNA, gapped genome.

Compare, Hypothesize, Invent

1. No temperate RNA phages have yet been discovered. How might this absence be explained?
2. The choice between lysogeny and lysis is influenced by many factors. How would external conditions such as starvation or crowding be "sensed" and communicated to the transcriptional machinery and influence this choice?
3. The most straightforward explanation as to why the endolysin (i.e., the T4 lysozyme) of T4 is expressed so late in infection is that its promoter is recognized by the gp55 alternative sigma factor. Propose a different explanation.
4. You are studying RNA viruses and have discovered a new one that grows well in a culture of eukaryotic cells. You know that the virus is a single-stranded RNA virus, but you don't know if it is plus or minus stranded. Your lab-mate says, "Well, just treat your cell culture with cyclohexamide and see if the virus replicates its genome." You know that cyclohexamide inhibits protein elongation by binding to eukaryotic ribosomes. What is the basis of your lab-mate's suggestion?
5. White spot syndrome virus (WSSV) is an enveloped dsDNA virus that infects crustaceans. It is particularly problematic for shrimp farmers as white spot disease can cause 100% shrimp mortality within a week. During infection, WSSV produces a large amount of a protein known as ICP11. This protein is a DNA mimic; that is, its folded structure resembles the acidic double helical structure of DNA. ICP11 binds directly to the DNA-binding site of host histones. How can a protein look like DNA, given that each is a different macromolecule composed of distinct monomers? Do you think ICP11 alone could cause host cell death? If so, explain the specific steps that would lead to host cell mortality. If not, what other virus-mediated activities would be necessary?

   Read the original paper: Wang, H. C., et al. 2008. White spot syndrome virus protein ICP11: A histone-binding DNA mimic that disrupts nucleosome assembly. *Proc. Natl. Acad. Sci. USA*. 105:20758.
6. Upon infection of host epithelial cells, papillomavirus (family *Papillomaviridae*) genomes are stably maintained in the nuclei for many years. These viral genomes are extrachromosomal and lack the capacity to segregate during host cell division. To prevent their loss during host cell division, the viral genomes use a protein known as E2 to attach to host chromosomes. For instance, the E2 protein of bovine papillomavirus type 1 (BPV-1) binds the host protein Brd4, which helps the viral genome attach to host chromosomes during mitosis. By contrast, the E2 protein of human papillomavirus 8 (HPV-8) does not require other host factors and binds directly to specific regions of host DNA during mitosis. How do you think the viral genome is released from a host chromosome following cell division? How do you think it was established that the HPV-8 E2 functions independently of host proteins, whereas the E2 of BPV-1 requires Brd4? Do you think the E2 proteins could be exploited to develop antiviral drugs? If so, why? How would you determine that a drug that targets E2 is specific to the viral protein and does not interfere with host cell function?

   Read the original paper: Poddar, A., et al. 2009. The human papillomavirus type 8 E2 tethering protein targets the ribosomal DNA loci of host mitotic chromosomes. *J. Virol.* 83:640.
7. Associated with the envelope of herpesviruses are numerous proteins called tegument proteins. Upon fusion of the viral envelope with the cell's plasma membrane, some of the tegument proteins are released into the cytosol. The fate of these proteins is unknown, although many are thought to be degraded. Herpes simplex virus 1 (HSV-1) encodes a tegument protein called vhs. This protein is released into the cytosol as HSV-1 enters the cell, but it is not degraded. The vhs protein has been shown to make cuts in RNA molecules (i.e., it is an endoribonuclease). Suggest a role for vhs in the life cycle of HSV-1. Justify your suggestion.

   Read the original paper: Dauber, B., et al. 2011. The Herpes simplex virus 1 vhs protein enhances translation of viral true later mRNAs and virus production in a cell type-dependent manner. *J. Virol.* 85(11):5363.

Biogeochemical Cycling and Global Climate Change

Global climate change has already increased the range of a number of insect vectors that cause disease. As the incidence of certain infectious diseases continues to shift and possibly increase, outbreaks of certain arthropod-borne diseases, such dengue fever, which is transmitted by mosquitoes, will become more common.

Global Climate Change; Global Infectious Disease Change?

When most people think of the bubonic plague, they think of medieval Europe. Malaria brings to mind sub-Saharan Africa. And if they have even heard of dengue (aka breakbone) fever, they think of a jungle somewhere in the tropics. However, these are just three of the diseases that may threaten residents living in temperate climates thanks to global climate change, according to scientists and the World Health Organization.

The links between climate and infectious disease are complex, so the exact shifts in disease patterns are difficult to predict. But consider the following facts. Insects are the vectors for many of the world's worst scourges: plague, malaria, Lyme disease, yellow and dengue fevers (just to name a few). Warmer temperatures not only expand the geographical range of many insects, they also lengthen their breeding season, boost their reproductive rates, and drive them to feed (i.e., bite) more frequently. In addition to diseases carried by insects, about 600 of the known 14,000 infectious agents, such as the viruses causing Ebola and avian flu, are shared between humans and animals. Historically, changes in the environment have been associated with the emergence of new diseases or the reemergence of old diseases.

With these facts in mind, the effects of global climate change on infectious disease can be broadly divided into three categories: altered disease patterns that are already being witnessed, those that can be predicted with confidence, and those that will surprise us. Let's start with a disease whose range has already increased—plague. This bacterial disease is endemic in human and rodent populations in parts of New Mexico, where its prevalence is correlated with the timing and amount of rainfall. Cases of human plague have recently been diagnosed farther north than ever before; plague is predicted to move as far north as Wyoming and Idaho. Similar temperature-dependent shifts in the number of rodents carrying plague bacteria have been documented in Central Asia.

The patterns of insect-borne diseases are also likely to change. Mosquitoes have brought malaria to Texas, Michigan, New Jersey, and New York. Dengue fever–bearing mosquitoes have spread as far north as Chicago and the Netherlands. Lyme disease, a tick-borne disease, is expected to migrate into Canada. And as drenching rain and flooding becomes more common, the rates of cholera and other diarrheal diseases are expected to rise.

This leaves us with diseases that could surprise us. These could be completely new diseases or diseases that were thought to be well controlled. But whether the infectious diseases are new or old, their prevention and treatment will require the expertise of a new generation of epidemiologists, health care workers, and (of course) microbiologists.

It is obvious why microbiologists are involved in the study of the link between climate and infectious disease. What may be less obvious is the role of microbes in climate change. However, as this chapter illustrates, the cycling of all elements (not just those involved in climate change) is mediated by microorganisms. The sum of the microbial, physical, and chemical processes that drive the flow of elements between sediments, waters, and the atmosphere is known as **biogeochemical cycling.** We explore biogeochemical cycling by focusing on the flux of carbon, nitrogen, sulfur, phosphorus, iron, and magnesium. We then turn our attention to global climate change, which is driven by changes in the carbon and nitrogen cycles. Collectively, this is the realm of **environmental microbiology,** which is concerned with microbial processes that occur in ecosystems, rather than the individual microorganisms dwelling there. However, it is critical to understand that bacteria, archaea, fungi, and protists are the agents of change. With only about 1% of microbes currently in culture, the identities and specific physiological activities of most microbes await discovery. Chapter 29 describes some approaches microbial ecologists employ to make these discoveries.

Readiness Check:

Based on what you learned previously, you should be able to:

- ✔ Distinguish macroelements from micronutrients, list examples of each, and describe their cellular function (section 3.3)
- ✔ Explain how nutrient availability and environmental factors influence microbial growth (sections 3.3, 7.4, and 7.5)
- ✔ Compare and contrast the growth and physiology of obligate aerobes, facultative anaerobes, and strict anaerobes (section 7.4)

- ✔ Explain oxidation-reduction (redox) reactions (section 10.3)
- ✔ Diagram, in general terms, the standard reduction potentials of electron donors as compared to electron acceptors and relate this to standard free-energy change (sections 10.3 and 10.4)
- ✔ Describe the difference between heterotrophy and autotrophy (section 11.1)
- ✔ Compare anaerobic respiration, aerobic respiration, and fermentation (sections 11.3, 11.7, and 11.8)
- ✔ Define chemolithotrophy and identify an example electron donor and acceptor (section 11.10)
- ✔ Compare and contrast oxygenic and anoxygenic phototrophy (section 11.11)

28.1 Biogeochemical Cycling Sustains Life on Earth

After reading this section, you should be able to:

- Explain the term redox potential and how it influences the flux of elements found in specific habitats
- Sketch generalized carbon, nitrogen, phosphorus, sulfur, iron, and manganese cycles
- Identify, by metabolic type, the microorganisms responsible for carbon and nitrogen fixation, and the mineralization of organic carbon and nitrogen under oxic and anoxic conditions
- List environments in which methanogenesis and methane oxidation occur
- Trace the fate of the N atom during dissimilatory nitrate reduction, nitrification, denitrification, and the anammox reaction, and indicate whether each must occur in an oxic or anoxic environment
- Contrast and compare dissimilatory nitrate reduction with dissimilatory sulfate reduction, and assimilatory nitrate reduction with assimilatory sulfate reduction
- Identify, by metabolic type, microorganisms responsible for dissimilatory nitrate, sulfate, and iron reduction; nitrification; and sulfur and iron oxidation
- Contrast and compare the iron and manganese cycles
- Provide at least two examples of how the flux of one element influences the cycling of another
- Summarize the importance of biogeochemical cycling in maintaining life on Earth

The long success and vast diversity of microbes reflect the variety of habitats found on Earth. In addition to differences in temperature, pressure, salinity, pH, and nutrient availability, variation in redox potential is also extremely important in determining microbial activity. **Redox potential,** or more formally, oxidation-reduction potential, is a measure of the tendency of molecules in a system to accept or donate electrons. In chapter 10, we discuss redox potential as it relates to specific conjugate redox pairs *(see table 10.2)*. Here our focus is on redox potential in the context of microbial environments, such as soil, sludge, or sterile growth media. The redox potential of these environments can be quantified in volts or millivolts, but to do so, each environment must be compared to a standard. Because no "standard environment" exists, a hydrogen electrode set to zero volts is used. Thus the redox potential of an environment is determined by the electrical potential difference between the environment and a standard hydrogen electrode. The value is denoted as E_h. Environments composed principally of compounds with high redox potentials (more positive) will be more likely to accept electrons (i.e., become reduced) when a new compound is added. The newly added compound that donates electrons then becomes oxidized (**table 28.1**).

Table 28.1 Elements Important in Biogeochemical Cycling and Their Redox States

			MAJOR FORMS AND VALENCES			
Cycle	Significant Gaseous Component Present?	Reduced Form	Intermediate Oxidation State Forms			Oxidized Form
C	Yes	Methane: CH_4 (−4)	Carbon monoxide: CO (+2)			CO_2 (+4)
N	Yes	Ammonium: NH_4^+; organic N (−3)	Nitrogen gas: N_2 (0)	Nitrous oxide N_2O (+1)	Nitrite: NO_2^- (+3)	Nitrate: NO_3^- (+5)
S	Yes	Hydrogen sulfide: H_2S; SH groups in organic matter (−2)	Elemental sulfur: S^0 (0)	Thiosulfate: $S_2O_3^{2-}$ (+2)	Sulfite: SO_3^{2-} (+4)	Sulfate: SO_4^{2-} (+6)
Fe	No	Ferrous iron: Fe^{2+} (+2)				Ferric Iron: Fe^{3+} (+3)
P	No	None	Always present in maximally oxidized state			Phosphate: PO_4^- (+5)
Mn	No	Manganese ion: Mn^{2+} (+2)	Manganese oxide MnO (+2)			Manganese dioxide MnO_2 (+4)

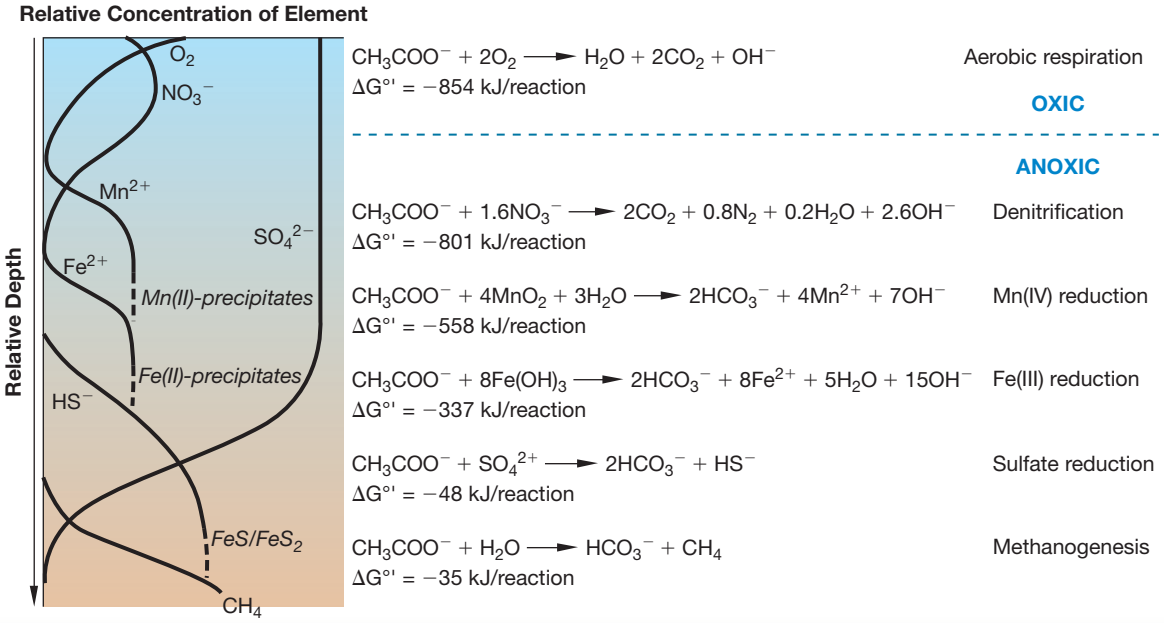

Figure 28.1 The Redox Potential, pH, and Oxygen Concentration Influence the Availability of Terminal Electron Acceptors. As oxygen concentration decreases with depth, other terminal electron acceptors are used in anaerobic respiration. The distribution of microbes in sediments or soils is dictated by the free energy yield for each respiratory process. The relative concentration of elements with depth is shown for marine sediments; freshwater sediments and soil have less sulfate, thus methanogenic archaea may be more abundant.

MICRO INQUIRY *Why do sulfate reduction and methanogenesis rarely occur at the same depth or in the same microhabitat?*

Why do microbiologists care about redox potentials? The redox state of the environment plays a critical role in determining the types of microbes present because it determines which oxidized compounds are available as terminal electron acceptors for anaerobic respiration and what reduced molecules are present for use as electron donors in chemolithotrophy. In general, electron acceptors used in anaerobic respiration follow a continuum defined by the free energy yield of each reaction. The terminal electron acceptors and their vertical zonation are shown in **figure 28.1**; however, microbial metabolic versatility is far more amazing than illustrated here. Redox cycling of many other elements such as arsenic, vanadium, uranium, and chromium can also be used to support microbial growth. ◀◀ *Redox reactions (section 10.3)*

Carbon Cycle

Carbon is the element that defines life, and as such it is everywhere. The carbon cycle is often regarded in terms of sources, sinks, and reservoirs of CO_2. Sources, such as heterotrophic microbes, release carbon as CO_2, whereas sinks include plants and phytoplankton, which take up CO_2 from the atmosphere. Reservoirs store carbon for geological periods of time. The exchange of elements between sources and sinks is referred to as flux. Carbon is present in reduced forms, such as methane (CH_4) and other, more complex organic matter, and in the oxidized, inorganic forms, carbon monoxide (CO) and carbon dioxide (CO_2). Although carbon is continuously transformed from one form to another, for the sake of clarity, we shall say that the cycle "begins" with carbon fixation—the conversion of CO_2 into organic matter (**figure 28.2**). Plants such as trees and crops are often regarded as the principal CO_2-fixing organisms, but at least half the carbon on Earth is fixed

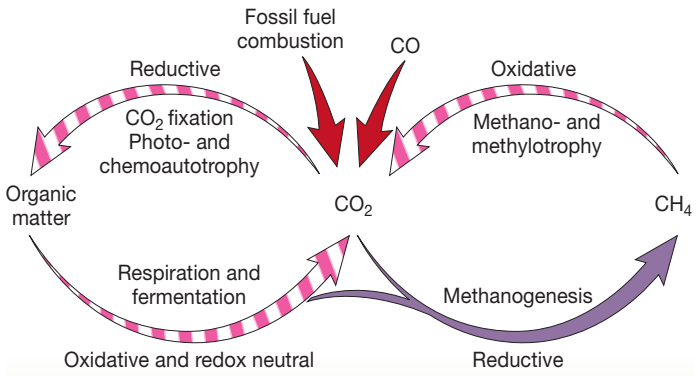

Figure 28.2 The Carbon Cycle. Carbon fixation occurs through the activities of photoautotrophic and chemoautotrophic microorganisms. Methane is produced from inorganic substrates ($CO_2 + H_2$) or from organic matter. Carbon monoxide (CO)—produced by sources such as automobiles and industry—is returned to the carbon cycle by CO-oxidizing bacteria. Aerobic processes are indicated by red arrows, those that occur under both oxic and anoxic conditions are noted with striped arrows, and a purple arrow leads to methanogenesis, an anaerobic process.

MICRO INQUIRY *What microbes are capable of methanogenesis and methane oxidation?*

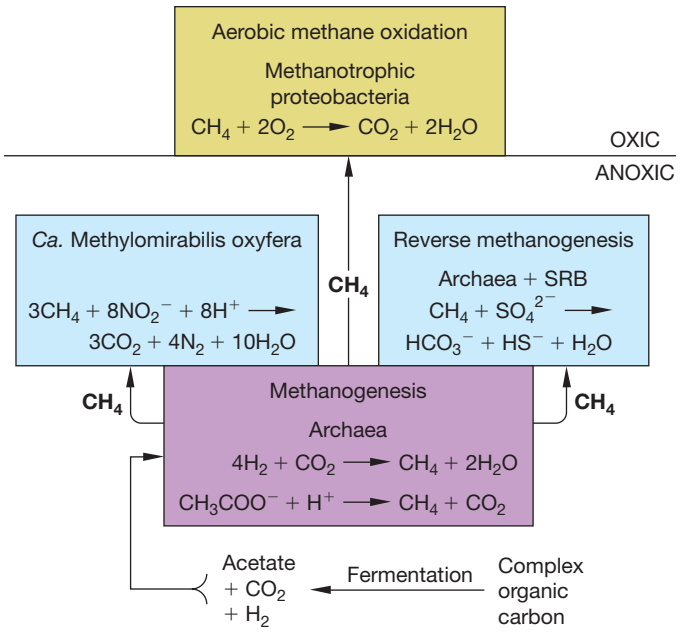

Figure 28.3 Methanogenesis and Methanotrophy. As methane is produced by archaea in terrestrial and marine anoxic sediments, it diffuses upward where it is oxidized by one of three general types of methanotrophs: the newly discovered proteobacterium *Candidatus* Methylomirabilis oxyfera, anaerobic archaea that reverse the methanogenic pathway in association with sulfate-reducing bacteria (SRB), and aerobic proteobacteria.

by microbes, particularly marine photosynthetic bacteria and protists (e.g., cyanobacteria in the genera *Prochlorococcus* and *Synechococcus,* and diatoms, respectively). Importantly, microbes also fix carbon in anoxic environments using anoxygenic photosynthesis as well as by chemolithoautotrophy in the absence of light. In fact, recent evidence suggests that bacterial chemolithoautotrophy in deep, dark subsurface sediments may constitute a significant fraction of global carbon fixation.

Alternatively, inorganic carbon (CO_2) can be reduced anaerobically to methane (CH_4). Recall that only archaea form methane from either $H_2 + CO_2$ or H_2 + acetate. As discussed in chapters 20 and 22, methane produced in sediments is then oxidized either aerobically by proteobacteria or anaerobically by archaea or newly discovered bacteria that couple methane oxidation with denitrification (**figure 28.3**). Large amounts of methane are also generated in the guts of ruminant animals. Globally, sediments found in rice paddies, coal mines, sewage treatment plants, landfills, marshes and mangrove swamps, and archaea found in the guts of ruminant animals and even termites are important sources of methane. ◀◀ *Methanogens and methanotrophs (section 20.4); Class* Alphaproteobacteria *includes many oligotrophs (section 22.1); Class* Gammaproteobacteria *is the largest bacterial class (section 22.3)*

All fixed carbon enters a common pool of organic matter that can then be oxidized back to CO_2 through aerobic or anaerobic respiration and fermentation (i.e., heterotrophy). In the carbon cycle depicted in figure 28.2, no distinction is made between the different types of organic matter formed and degraded. This is a marked oversimplification because organic matter varies widely in terms of elemental composition, structure of basic repeating units, and linkages between repeating units. Its degradation is also influenced by other factors, including (1) oxidation-reduction potential; (2) availability of competing nutrients; (3) abiotic conditions such as pH, temperature, O_2, and osmotic conditions; and (4) the microbial community present.

Many of the complex organic substrates used by microorganisms are summarized in **table 28.2**. Lignin, an important structural component in mature plant materials, is notoriously stable. Lignin is actually a family of complex amorphous polymers linked by carbon-carbon and carbon-ether bonds (*see figure 31.2*). Filamentous microorganisms—fungi and the streptomycetes—secrete hydrolytic enzymes that degrade lignin by oxidative depolymerization, a process that requires oxygen. A few microbes, such as the purple bacterium *Rhodopseudomonas palustris,* can

Table 28.2 Complex Organic Substrate Characteristics That Influence Decomposition and Degradability

			ELEMENTS PRESENT IN LARGE QUANTITY					DEGRADATION	
Substrate	Basic Subunit	Linkages (If Critical)	C	H	O	N	P	With O_2	Without O_2
Starch	Glucose	α(1→4) α(1→6)	+	+	+	–	–	+	+
Cellulose	Glucose	β(1→4)	+	+	+	–	–	+	+
Hemicellulose	C6 and C5 monosaccharides	β(1→4), β(1→3), β(1→6)	+	+	+	–	–	+	+

Chitin	*N*-acetylglucosamine	β(1→4)	+	+	+	+	–	+	+
Hydrocarbon	Aliphatic, cyclic, aromatic		+	+	–	–	–	+	+/–

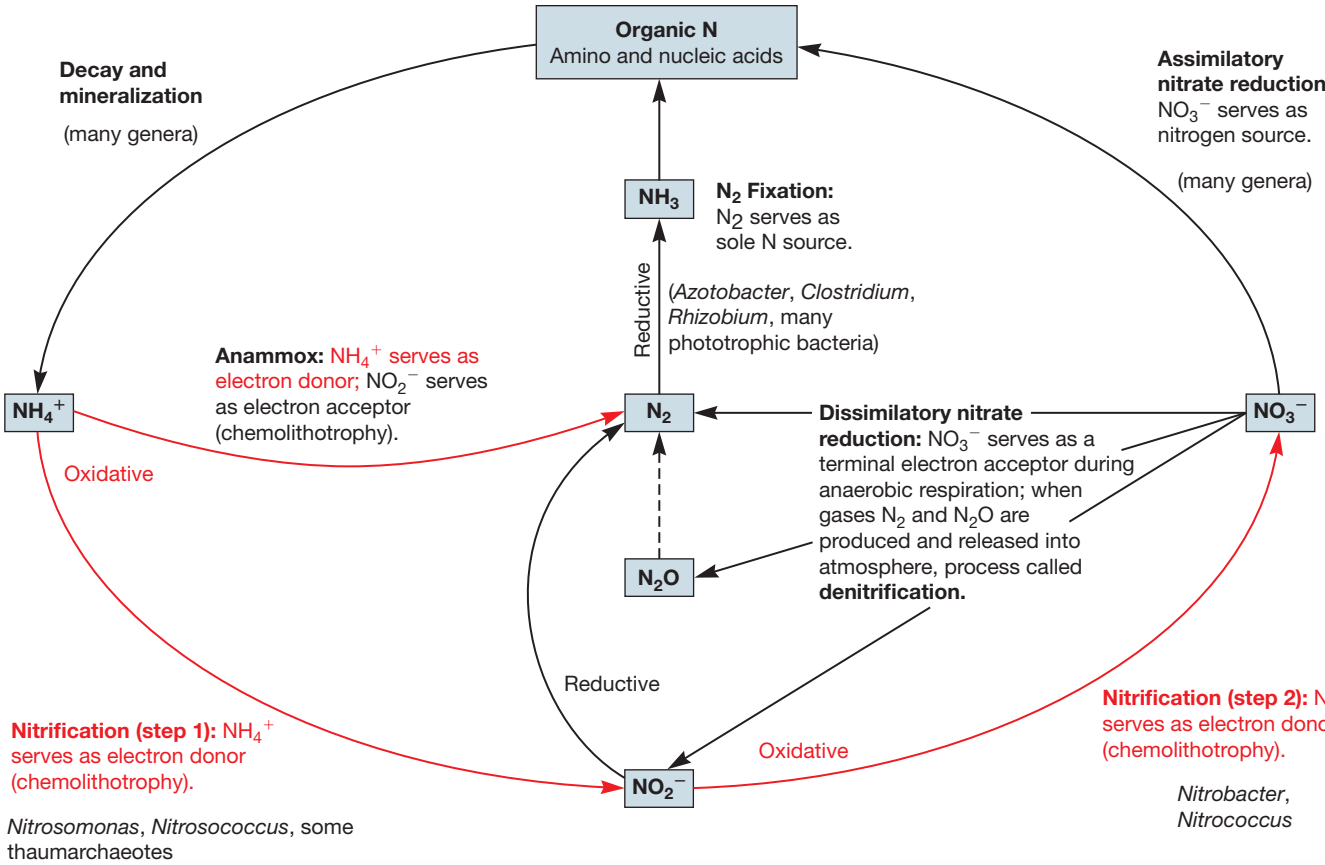

Figure 28.4 A Simplified Nitrogen Cycle. Depending on their oxidative state, some nitrogen species can function as either electron donors or electron acceptors and therefore play very different roles in the environment. NH_4^+ is fully reduced; therefore it can serve only as an electron donor. The fully oxidized species NO_3^- can function as a terminal electron acceptor, or plants and microbes can reduce it and incorporate it into biomass during assimilatory reduction.

MICRO INQUIRY *What are the products of denitrification, nitrification, dissimilatory nitrate reduction, and assimilatory nitrate reduction?*

degrade lignin anaerobically but very slowly. This diminished biodegradability under anoxic conditions results in accumulation of lignified materials, including the formation of peat bogs.

Two terms are helpful in considering the fate and availability of organic materials in nature: mineralization and immobilization. **Mineralization** describes the decomposition of organic matter to simpler, inorganic compounds (e.g., CO_2, NH_3, CH_4, H_2). These compounds may or may not be recycled within the same environment. By contrast, nutrients (including carbon) that are converted into biomass become temporarily unavailable for nutrient cycling; this is called nutrient **immobilization.** Saprophytes, which degrade dead organic material, as well as viruses, protists, and other predators are important in recycling immobilized organic compounds.

Many complex substrates contain only carbon, hydrogen, and oxygen. Growth using these substrates demands that microbes acquire the remaining nutrients (e.g., N, P, S, and Fe) elsewhere in the environment. This is often very difficult, as the concentration of nitrogen, phosphorus, and iron may be very low. When the supply of a macronutrient is insufficient to support maximal growth, that nutrient is said to be limiting. For instance, in open-ocean microbial communities, growth of many microbes is often nitrogen limited. In other words, if higher concentrations of usable nitrogen (e.g., NO_3^-, NH_4^+) were available, the rate of microbial growth would increase. This phenomenon is called Leibig's law of the minimum, named after the nineteenth-century chemist Justus van Leibig.

Retrieve, Infer, Apply

1. What are the possible fates of methane in anoxic zones?
2. When is a nutrient mineralized and when is it immobilized?
3. Where will lignin degrade faster: in a shallow riverbed or in a rice paddy? Explain.
4. What C, N, and S forms will accumulate after anaerobic degradation of organic matter? Compare these with the forms that accumulate after aerobic degradation.
5. What kinds of microbes would be able to recycle the carbon atoms in CO_2 and CH_4?

Nitrogen Cycle

Nitrogen exists in redox states from −3 to +5, and this is reflected in the transformations that drive nitrogen cycling (table 28.1). As shown in **figure 28.4**, depending on its level of oxidation, nitrogen

species can serve as electron acceptors in anaerobic respiration (e.g., NO_3^- and NO_2^-) or as electron donors (e.g., NO_2^- and NH_4^+) in chemolithotrophy. This can lead to some confusion, but the trick is to consider the oxidation state of the nitrogen species: is it fully oxidized (i.e., NO_3^-)? If so, it can only accept electrons. Conversely, if it is fully reduced (NH_4^+), its role is limited to electron donor. Nitrite (NO_2^-) is neither fully oxidized nor reduced, so it can function as either electron donor or acceptor.

We begin our discussion of this cycle with **nitrogen fixation**—the reduction of the inorganic gaseous molecule N_2 to its organic form (e.g., amino acids, purines, and pyrimidines). Nitrogen fixation is performed only by some bacteria and archaea. Although the nitrogenase enzyme is sensitive to oxygen, nitrogen fixation can be carried out under both oxic and anoxic conditions. Microbes such as *Azotobacter* spp. and cyanobacteria in the genus *Trichodesmium* fix nitrogen aerobically, while free-living anaerobes such as *Clostridium* spp. also fix nitrogen. Perhaps the best-studied nitrogen-fixing microbes are the bacterial symbionts of leguminous plants, including rhizobia, their α-proteobacterial relatives, and a few β-proteobacteria. Other bacterial symbionts fix nitrogen as well. For instance, actinomycete species in the genus *Frankia* fix nitrogen while colonizing many types of woody shrubs, and heterocyst-forming cyanobacteria *Anabaena* spp. fix nitrogen when in association with the water fern *Azolla* spp. ⏮ *Nitrogen fixation (section 12.5); Phylum* Cyanobacteria *(section 21.4); Order* Frankiales *(section 24.1)* ⏭ *Nitrogen-fixing bacteria are vital to agriculture (section 31.3)*

The product of N_2 fixation is ammonia (NH_3), which is immediately incorporated into organic matter as an amine. These amine N atoms are introduced into proteins, nucleic acids, and other biomolecules. Eventually these organic molecules are degraded (dissimilated) and mineralized, and the nitrogen is released as ammonium (NH_4^+). Many microbial genera are capable of dissimilation of organic nitrogen substrates, but complete mineralization requires an assemblage of microbes.

Because ammonium is fully reduced, it can only donate electrons, and this is what happens in the two-step chemolithotrophic process of **nitrification** (figure 28.4). In the first step, ammonium is oxidized to nitrite (NO_2^-), and in the second step, NO_2^- is oxidized to nitrate (NO_3^-). No single microbial genus can perform both steps of nitrification. For example, some mesophilic archaea and bacteria in the genera *Nitrosomonas* and *Nitrosococcus* play important roles in ammonia oxidation, while *Nitrobacter* spp. and related bacteria carry out nitrite oxidation. Both steps of nitrification are usually aerobic, with O_2 as the terminal electron acceptor. An exception is the β-proteobacterium *Nitrosomonas eutropha,* which oxidizes ammonium anaerobically to nitrite and nitric oxide (NO) using nitrogen dioxide (NO_2) as an acceptor in a denitrification-related reaction (*see figure 22.15*).

The production of nitrate is important because it can be reduced and incorporated into microbial and plant cell biomass in a process known as **assimilatory nitrate reduction.** Alternatively, some microorganisms use nitrate as a terminal electron acceptor during anaerobic respiration. When respired, the nitrogen is not incorporated into cellular material, so this is called **dissimilatory nitrate reduction.** A variety of microbes, including *Geobacter metallireducens* and *Desulfovibrio* spp., are capable of dissimilatory nitrate reduction. When nitrate is fully reduced to dinitrogen gas (N_2), nitrogen is removed from the ecosystem and returned to the atmosphere through a series of reactions collectively known as **denitrification.** This dissimilatory process is performed by a variety of heterotrophic bacteria, such as *Pseudomonas denitrificans.* The major products of dissimilatory nitrate reduction include nitrogen gas (N_2) and nitrous oxide (N_2O), although nitrite (NO_2^-) also can accumulate *(see figure 11.18)*. N_2O, an important greenhouse gas, is also produced during ammonia oxidation to nitrite; that is, the first step of nitrification. This is particularly true of marine ammonia oxidizing archaea. ⏮ *Anaerobic respiration uses the same three steps as aerobic respiration (section 11.7); Inorganic nitrogen assimilation (section 12.5)*

The **anammox reaction** (*an*oxic *amm*onium *ox*idation) is an anaerobic reaction performed by chemolithotrophs in the phylum *Planctomycetes.* Here ammonium ion (NH_4^+) serves as the electron donor and nitrite (NO_2^-) as the terminal electron acceptor; it is reduced to nitrogen gas (N_2) (*see figure 21.16*). In effect, the anammox reaction is a shortcut to N_2, proceeding directly from ammonium and nitrite, without having to cycle first through nitrate (figure 28.4). The discovery that planctomycete bacteria oxidize considerable amounts of NH_4^+ to N_2, thereby removing ammonia from the environment, has sparked keen interest in the wastewater management field, where high levels of ammonia are undesirable. ⏮ *Phylum* Planctomycetes *(section 21.5)*

Retrieve, Infer, Apply

1. Organic nitrogen that is introduced into an ecosystem directly by nitrogen fixation is sometimes called "new" nitrogen. Explain why.
2. Describe the two-step process that makes up nitrification. Could microbes performing nitrification and anammox live in the same environment? Explain your answer.
3. What is the difference between assimilatory nitrate reduction and denitrification? Which reaction is performed by many microbes, and which is a more specialized metabolic capability?
4. Refer to section 21.5 and figure 21.15 (*p. 496*). What nitrogenous intermediates are used in the anammox reaction? Why don't they accumulate in the environment?

Phosphorus Cycle

Biogeochemical cycling of phosphorus is important for a number of reasons. All living cells require phosphorus for nucleic acids, and some lipids and polysaccharides. However, unlike carbon and nitrogen, phosphorus exists in a single valence state of +5 and has no gaseous component (table 28.1). Indeed, all phosphorus is originally derived solely from the weathering of

phosphate-containing rocks (**figure 28.5**). However, recent evidence suggests that phosphonates, which bear a C—P bond and are thus organic, may be a significant source of phosphorus for some marine microorganisms. Nonetheless, phosphorus is present in low concentrations and frequently limits growth.

In soil, phosphorus exists in both inorganic and organic forms. Organic phosphorus includes not only that found in biomass but also that in materials such as humus and other organic compounds. The phosphorus in such organic materials is readily recycled by microbial activity. Inorganic phosphorus is negatively charged, so it complexes with positively charged elements in the environment, such as iron, aluminum, and calcium. These compounds are relatively insoluble, and their dissolution is pH dependent such that phosphate is most available to plants and microbes between pH 6 and 7. Microbes transform simple orthophosphate (PO_4^{3-}) to more complex forms. These include the polyphosphates present as inclusions as well as more familiar macromolecules such as nucleotides and phospholipids. ⏮ *Inclusions (section 3.6); Phosphorus assimilation (section 12.6)*

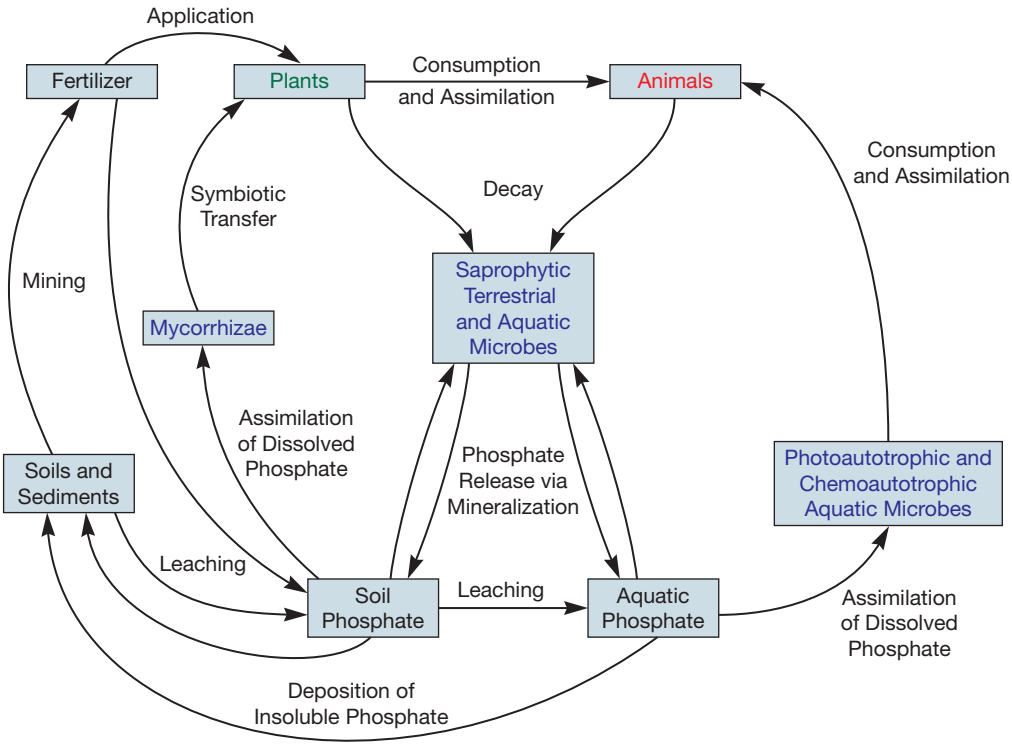

Figure 28.5 A Simplified Phosphorus Cycle. Phosphorus enters soil and water through the degradation of plants and animals, weathering of rocks, and fertilizer application. Phosphate in soil and waters is consumed by terrestrial and aquatic microbes and passed onto larger organisms. However, much of the soil phosphorus can leach great distances or, like phosphate in aquatic systems, complex with cations to form relatively insoluble compounds. Terrestrial chemolithotrophic microbes also take up soil phosphate but are not shown.

Sulfur Cycle

Microorganisms contribute greatly to the sulfur cycle; a simplified version is shown in **figure 28.6**. The sulfur cycle is similar to the nitrogen cycle in that, depending on the oxidation state of the sulfur species, it can serve as an electron acceptor, an electron donor, or both. Sulfate, the fully oxidized species, is reduced by plants and microbes for use in amino acid and protein biosynthesis; this is described as **assimilatory sulfate reduction.** By contrast, when sulfate diffuses into anoxic habitats, it provides an opportunity for microbial **dissimilatory sulfate reduction.** Here sulfate serves as a terminal electron acceptor during anaerobic respiration by a variety of microbes, including δ-proteobacteria such *Desulfovibrio* and *Desulfonema* spp. and archaea belonging to the genus *Archaeoglobus*. This results in sulfide accumulation. Sulfide, which is fully reduced, can then serve as an electron source for anoxygenic photosynthetic microorganisms and chemolithoautotrophs, including members of the phylum *Chlorobi* and the genus *Thiobacillus,* respectively. These microbes convert sulfide to elemental sulfur and sulfate. ⏮ *Proteobacteria (chapter 22)*

Other microorganisms have been found to carry out dissimilatory elemental sulfur (S^0) reduction. These include members of the genus *Desulfuromonas,* thermophilic archaea, and cyanobacteria in hypersaline sediments. Sulfite (SO_3^{2-}) is another critical intermediate that can be reduced to sulfide by a wide variety of microorganisms, including members of the genera *Alteromonas, Clostridium, Desulfovibrio,* and *Desulfotomaculum.*

Dimethylsulfoniopropionate (DMSP) is an important organic sulfur compound. It is produced by marine phytoplankton as a compatible solute. When these cells die and release DMSP, bacterioplankton (floating bacteria) use it as a sulfur and carbon source. In the process, it is metabolized to dimethylsulfide (DMS) and released into the atmosphere. There DMS is rapidly converted into a variety of sulfur compounds that serve as nuclei for water droplet formation, contributing to the formation of clouds. Because clouds help keep the Earth's surface cool, it is hypothesized that increased DMS production could help mitigate the effects of global climate change.

Iron Cycle

The iron cycle features the interchange of ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}) (**figure 28.7**). In environments that are fully aerated with a neutral pH, iron is present primarily as insoluble minerals of either oxidation state. The solubility of both reduced, ferrous iron

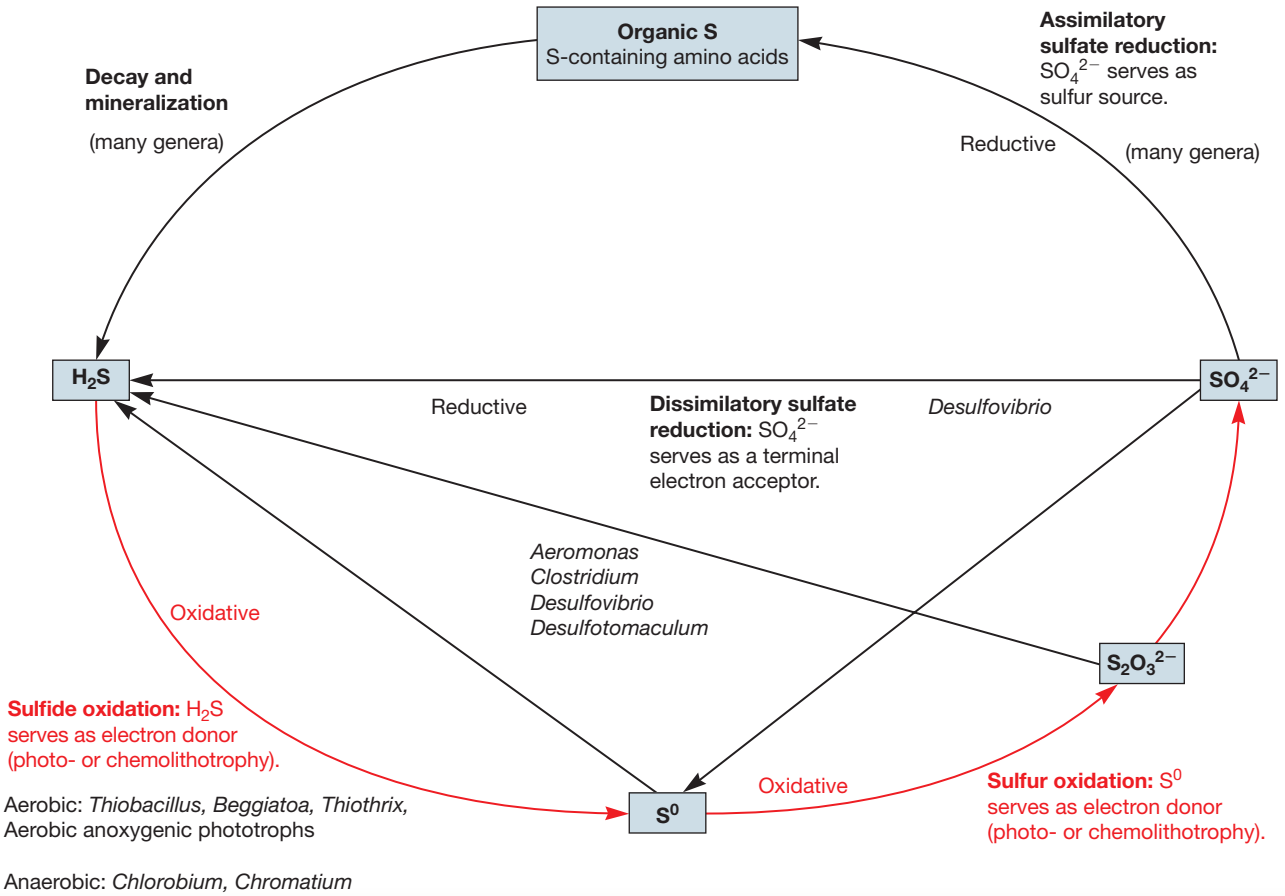

Figure 28.6 A Simplified Sulfur Cycle. Sulfate is fully oxidized, thus it serves as the terminal electron acceptor in anaerobic respiration, termed dissimilatory sulfate reduction. Alternatively, plants and microbes can donate the S atom to organic compounds during assimilatory sulfate reduction. H_2S is fully reduced, so it can serve as an electron donor during chemo- and photolithotrophy. Because elemental sulfur and thiosulfate are neither fully oxidized nor reduced, they can serve as either electron donors or acceptors.

MICRO INQUIRY *Which sulfur species is gaseous?*

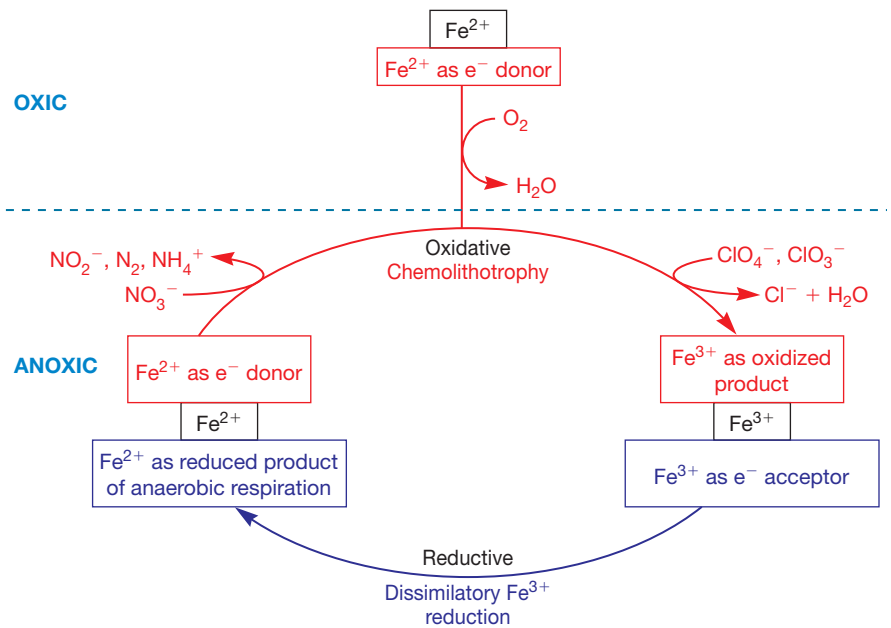

Figure 28.7 The Iron Cycle. Dissimilatory reduction of iron takes place when Fe^{3+} is used as a terminal electron acceptor during anaerobic respiration. This occurs only in anoxic environments. By contrast, oxidation of Fe^{2+} can occur under both oxic and anoxic conditions. Most well-known is the use of Fe^{2+} as an electron donor and O_2 as electron acceptor. Fe^{2+} can also be oxidized by lithotrophs that use NO_3^- or even the environmental contaminants chlorate (ClO_3^-) and perchlorate (ClO_4^-) as electron acceptors.

MICRO INQUIRY *Why is Fe^{2+} used as an electron donor chiefly in acidic environments?*

(Fe^{2+}) and oxidized, ferric iron (Fe^{3+}) increases with acidification, so that below pH 4, iron is found in the aqueous form. Its assimilation presents two challenges for most aerobic microorganisms. First, while iron is an essential element, free iron is usually present in very small quantities. Second, iron typically exists in the wrong oxidation state for uptake: Fe^{3+} dominates in oxic environments, but microbes generally incorporate Fe^{2+}. The use of siderophores solves both problems. Siderophores are low molecular weight organic molecules that bind Fe^{3+}, facilitating its transport into the cell, where it is reduced to Fe^{2+} (*see figure 3.15*). ◀◀ *Iron uptake (section 3.3)*

Once again, we see that dissimilatory reduction involves anaerobic respiration. In the case of dissimilatory iron reduction, ferric iron (Fe^{3+}) serves as a terminal electron acceptor during anaerobic respiration. In most environments, Fe^{3+} is found chiefly in a crystalline phase (e.g., hematite and magnetite) and as a component of sediment clays. As described more fully in chapter 22, some microbes donate electrons from the electron transport chain to these solid forms of Fe^{3+} outside the cell. Different microbes appear to use different strategies to transfer electrons to these external electron acceptors. For instance, δ-proteobacteria in the genus *Geobacter* and γ-proteobacteria in the genus *Shewanella* use electrically conductive threadlike structures called nanowires to transfer electrons from a reductase in the outer membrane to particulate Fe^{3+} (*see figure 22.28*). *Shewanella* spp. also produce redox-active flavins that shuttle electrons from the outer membrane to crystalline Fe^{3+} oxides. ◀◀ *Anaerobic respiration uses the same three steps as aerobic respiration (section 11.7)*; *Order* Alteromonadales *includes anaerobes that use a range of electron acceptors (section 22.3)*

A wide range of archaea and bacteria are capable of dissimilatory Fe^{3+} reduction. This includes archaeal genera from *Euryarchaeota* and *Crenarchaeota,* as well as all five classes of *Proteobacteria, Firmicutes, Deferribacteraceae, Acidobacteria, Thermotoga,* and *Thermus.* This phylogenetic diversity may reflect the antiquity of Fe^{3+} reduction. It is believed that life began 3.5 billion to 3.8 billion years ago in an environment that was rich in Fe^{2+}. The photooxidation of Fe^{2+} to Fe^{3+} and H_2 would have provided an electron acceptor and energy source, respectively, to early cellular forms. Banded iron formation that occurred when atmospheric oxygen levels were beginning to increase at the end of the Precambrian era may be evidence of increased bacterial iron metabolism. ◀◀ *Microbes have evolved and diversified for billions of years (section 1.2)*

In addition to ferric iron (Fe^{3+}) as a terminal electron acceptor, some magnetotactic bacteria such as *Aquaspirillum magnetotacticum* transform extracellular iron to the mixed valence iron oxide mineral magnetite (Fe_3O_4) and construct intracellular magnetic compasses (*see figure 3.37*). Magnetotactic bacteria may be described as magnetoaerotactic bacteria because they are thought to use magnetic fields to migrate to the position in a bog or swamp where the oxygen level best meets their needs. Furthermore, some dissimilatory iron-reducing bacteria accumulate magnetite as an extracellular product. ◀◀ *Inclusions (section 3.6)*

Because it is in the reduced state, ferrous iron (Fe^{2+}) can be used as an electron donor by lithotrophic microbes in acidic, oxic environments where it is soluble and oxygen can serve as the terminal electron acceptor. This has been well characterized in the α-proteobacterium *Acidithiobacillus ferrooxidans* and thermophilic crenarchaeotes in the genus *Sulfolobus.* In addition, it is now known that a number of microbes oxidize Fe^{2+} at neutral pH under oxic conditions. Best studied are γ-proteobacteria in the genus *Marinobacter* and β-proteobacteria in the genera *Leptothrix* and *Gallionella.* Ferrous iron can also be oxidized under anoxic conditions with nitrate as the electron acceptor. One interesting anaerobic microbe is *Dechlorosoma suillum,* which oxidizes Fe^{2+} using perchlorate (ClO_4^-) and chlorate (ClO_3^-) as electron acceptors. Because perchlorate is a major component of explosives and rocket propellants, it is a frequent contaminant at retired munitions facilities and military bases. Thus *D. suillum* may be used in the bioremediation (biological cleanup) of such sites. This process also occurs in aquatic sediments with depressed levels of oxygen and may be another route by which large zones of oxidized iron have accumulated in environments with lower oxygen levels. ▶▶ *Biodegradation and bioremediation harness microbes to clean the environment (section 43.4)*

Manganese and Mercury Cycles

Much like the iron cycle, the manganese cycle involves the transformation of the reduced form, manganous ion (Mn^{2+}), to the oxidized species, MnO_2 (equivalent to manganic ion [Mn^{4+}]). This occurs at the oxic-anoxic interface in hydrothermal vents, bogs, and stratified lakes (**figure 28.8**). Phylogenetically diverse bacteria are able to use Mn^{2+} as an electron donor with oxygen or

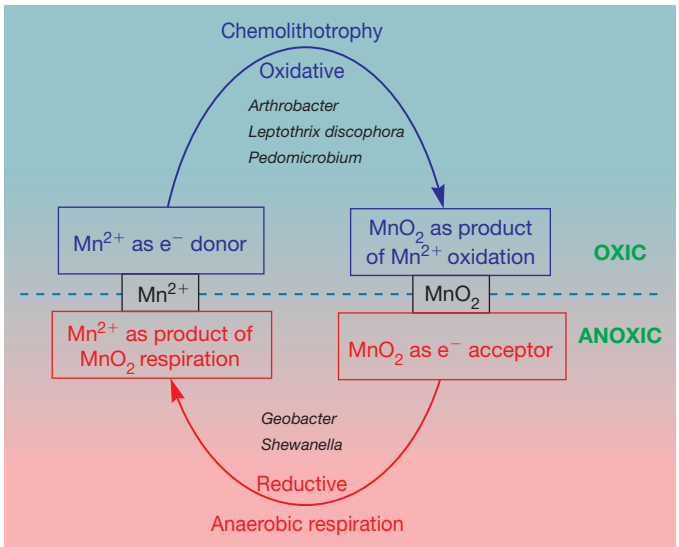

Figure 28.8 The Manganese Cycle, Illustrated in a Stratified Lake. Microorganisms make many important contributions to the manganese cycle. After diffusing from anoxic (pink) to oxic (blue) zones, manganous ion (Mn^{2+}) is oxidized chemically and by many morphologically distinct microorganisms in the oxic water column to manganic oxide—MnO_2(IV), valence equivalent to 4+. When the MnO_2(IV) diffuses into the anoxic zone, bacteria such as *Geobacter* spp. and *Shewanella* spp. carry out the complementary reduction process. Similar processes occur across oxic/anoxic transitions in soils, muds, and other environments.

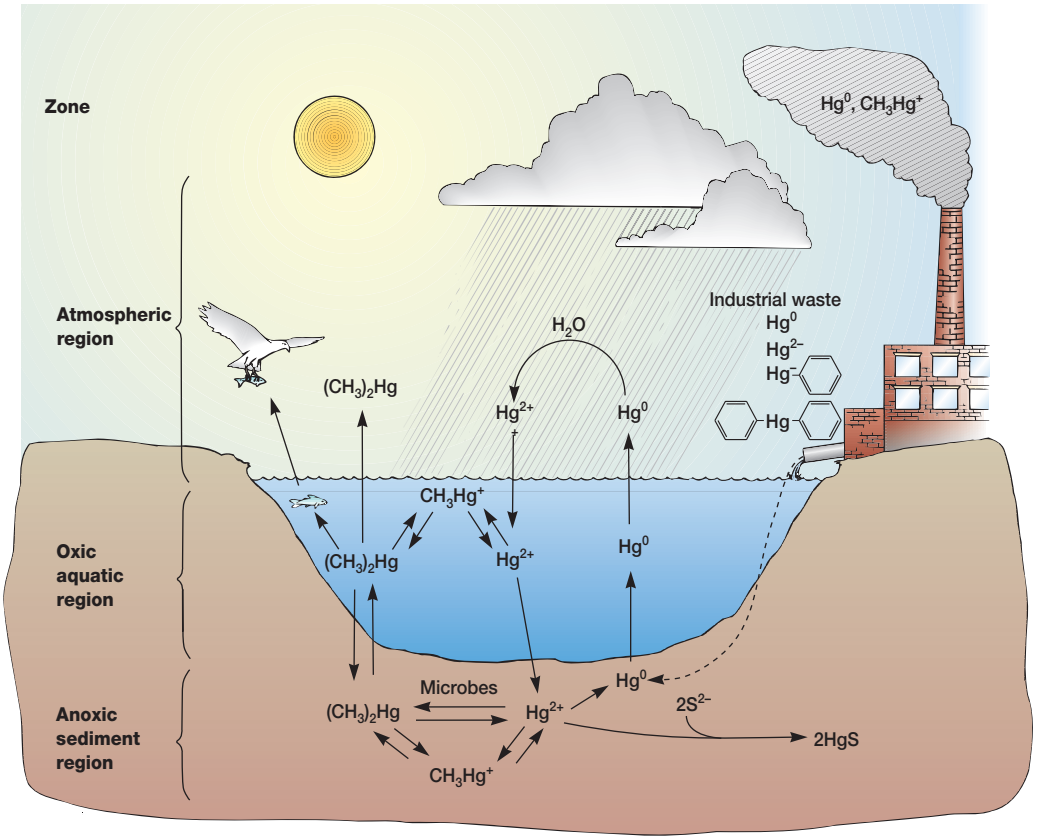

Figure 28.9 The Mercury Cycle. Interactions between the atmosphere, oxic water, and anoxic sediment are critical. Microorganisms in anoxic sediments, primarily *Desulfovibrio* spp., can transform mercury to methylated forms that can be transported to water and the atmosphere. These methylated forms also undergo biomagnification. The production of volatile elemental mercury (Hg^0) releases this metal to waters and the atmosphere. Sulfide, if present in the anoxic sediment, can react with ionic mercury to produce less soluble HgS.

nitrate at the terminal electron acceptor. *Shewanella* spp., *Geobacter* spp., and other chemoorganotrophs can carry out the complementary manganese reduction process, using MnO_2 as an electron acceptor. ▶▶| *Microorganisms in lakes can cause seasonal blooms (section 30.3)*

The mercury cycle illustrates many characteristics of metals that can be methylated. Mercury compounds were once widely used in industrial processes. A devastating situation developed in southwestern Japan when large-scale mercury poisoning occurred in the Minamata Bay region because industrial mercury was released into the marine environment. Inorganic mercury that accumulated in bottom muds of the bay was methylated by anaerobic bacteria of the genus *Desulfovibrio* (**figure 28.9**). Methylated mercury forms are volatile and lipid soluble, and mercury concentrations increase with each link of the food web in a process known as **biomagnification.** Fish containing high levels of methylated mercury were ultimately ingested by humans—the "top consumers"—leading to severe neurological disorders, particularly in children. Clearly, microbial interactions with metals such as methylated mercury can have far-reaching consequences.

Interaction Between Elemental Cycles

So far, we have presented biogeochemical cycling as discrete nutrient fluxes. However, it is important to understand that biogeochemical cycling involves dynamic, interconnected processes that over geologic time keep the biosphere in a self-sustaining steady state. Although links between cycles occur at a global scale, it is easiest to consider such links at the level of a single type of microbe. Here we present two illustrative examples: chemolithotrophy and nitrogen fixation.

When a community of chemolithotrophic microbes uses ammonium (NH_4^+) and nitrite (NO_2^-) as its source of electrons and CO_2 as its sole source of carbon, it contributes to both the flux of carbon and nitrogen by producing organic carbon and nitrate, which can be taken up by assimilatory nitrate reduction or returned to the atmosphere following denitrification (**figure 28.10**). Because

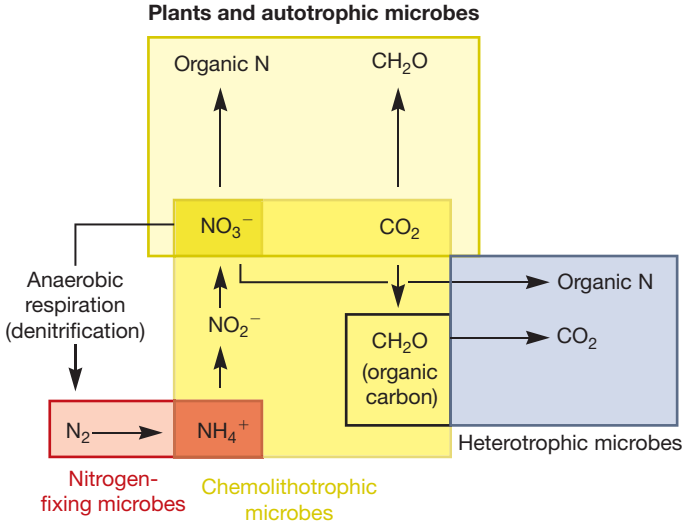

Figure 28.10 Examples of Interaction Between the N and C Cycles. The activities of microbes with different metabolic strategies result in linkage between elemental cycles. Common pools of organic carbon and nitrogen are typically created in an ecosystem; however, they are shown separately here for clarity.

chemolithoautotrophs fix CO_2 and use reduced inorganic compounds such as ammonium or ferrous iron as a source of electrons, they must oxidize large amounts of these compounds to generate enough ATP and reducing equivalents for carbon fixation. This reflects the relatively small amount of energy released during the oxidation of most inorganic chemicals. Thus chemolithotrophs not only link the carbon cycle to either the nitrogen, sulfur, or iron (or other metal) cycles, they also significantly impact the global flux of these elements.

In the case of nitrogen fixation, bacteria and archaea convert N_2 to ammonia, which is then incorporated into organic nitrogen molecules such as amino and nucleic acids. In many environments, the amount of carbon that is taken up by plants and microbes (either as CO_2 or as dissolved organic carbon) is dictated by how much nitrogen is available to support growth. Thus by introducing "new" nitrogen into the system, nitrogen-fixing microbes can also increase the rate of carbon flux.

Although we present only two examples, links between nutrient cycles abound, and new interactions are being discovered. For example, recent advances in microbial ecology have revealed that microbial methane oxidation links the carbon cycle to the nitrogen and sulfur cycles (figure 28.3).

3. What are some important microbial genera that contribute to manganese cycling?
4. How can microbial activity render some metals more or less toxic to warm-blooded animals?
5. Suggest how a chemolithoautotroph might link the carbon and sulfur cycles.

28.2 Global Climate Change: Biogeochemical Cycling Out of Balance

After reading this section, you should be able to:

- Differentiate between the terms "global warming" and "global climate change" and identify greenhouse gases
- Explain the link between greenhouse gas accumulation and microbial cycling of carbon and nitrogen
- Discuss the origin of the greenhouse gases CO_2, methane, and nitrogen oxide species

Microbial activity is critical in maintaining the dynamic equilibrium that defines our biosphere. The capacity of microbes to thrive in seemingly every niche on Earth is the result of 3.5 billion years of microbial evolution. Importantly, changes in the physical and chemical environment to which microbes have adapted generally occurred over geological time scales. However, since the beginning of the twentieth century, the rate at which CO_2 and other so-called greenhouse gases have entered the atmosphere has been much faster than at any other time in the known history of life on Earth. Atmospheric gases such as CO_2, CH_4, and nitrogen oxides are called **greenhouse gases** because they trap the heat that is reflected from Earth's surface in the atmosphere, rather than allowing it to radiate into space. The rate at which these gases are entering the atmosphere exceeds the rate by which the natural carbon and nitrogen cycles can recycle them, thus they accumulate. It is the ever-increasing atmospheric concentration of these gases that has resulted in what is often called global warming. However, the term global climate change more accurately reflects the changes in patterns of wind, precipitation, and ocean temperatures we are now experiencing.

The most abundant greenhouse gas is CO_2. Since the onset of the industrial era, about 150 years ago, global CO_2 levels have risen from 278 ppm (parts per million) to a current level over 400 ppm (**figure 28.11**). Most of this can be attributed to the

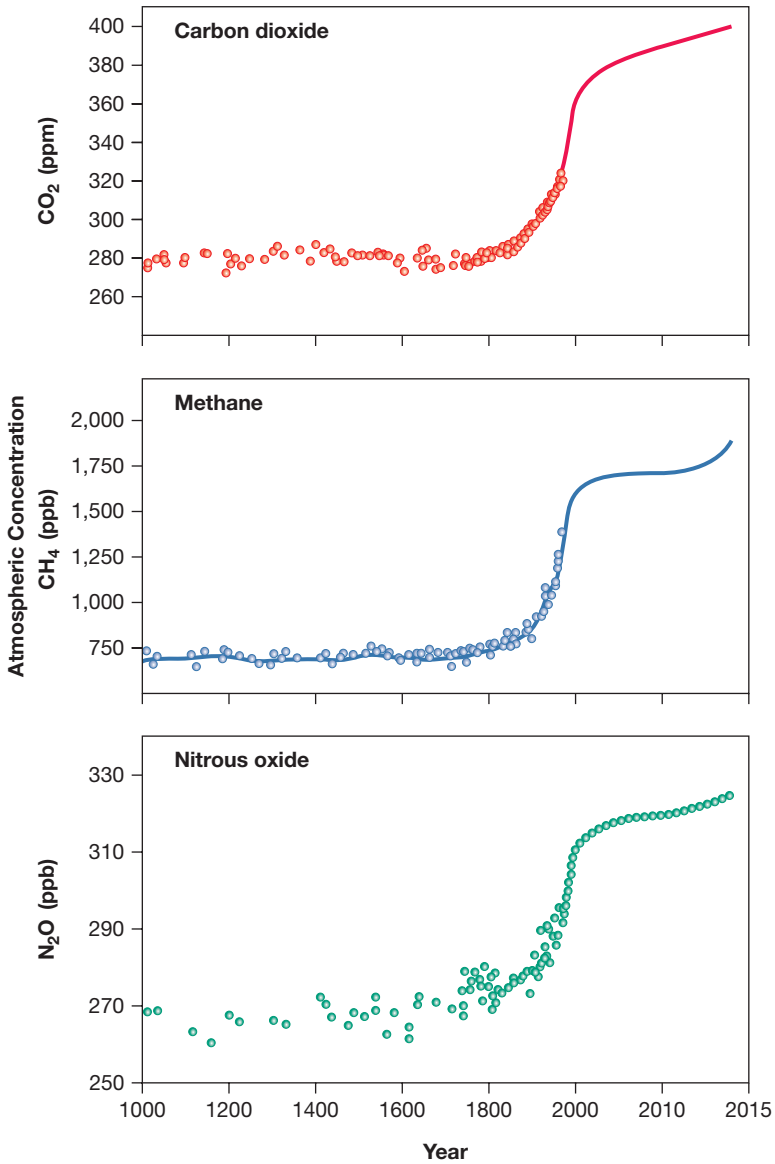

Figure 28.11 Global Atmospheric Concentrations of Greenhouse Gases. ppm = parts per million, ppb = parts per billion.

burning of fossil fuel, which releases about 10 billion tons of CO_2 each year. Changes in land use management, principally through deforestation, account for another 1.2 billion tons of CO_2 annually. To understand why these activities result in the release of CO_2, consider that fossil fuel (e.g., oil) is formed from decaying organic matter. This organic matter arose through millions of years of CO_2 fixation (i.e., removal of CO_2 from the atmosphere). It has been locked deep within the Earth for almost as long. When fossil fuels are burned, the energy of combustion oxidizes this material back to CO_2 in a tiny fraction of the time it took to accumulate.

The situation is different with deforestation. Forests are generally regarded as CO_2 sinks because the abundance of photoautotrophic plants pulls a great deal of CO_2 out of the atmosphere and converts it to biomass. Indeed, during the 1990s terrestrial ecosystems sequestered about 3 gigatons of carbon per year (a gigaton is 1 billion metric tons). Thus when forests are cut down for firewood or agricultural reasons, the Earth loses a carbon sink. While some speculate that other, remaining plants will assimilate the extra CO_2 and simply grow faster, changes in the rate of soil microbial respiration complicate matters. Recall that as respiration rates increase, so does the quantity of CO_2, CH_4, and N_2O released. In fact, recent analysis shows that warming permafrost in subarctic regions has dramatically increased soil microbial respiration. Thus the balance of CO_2 and other greenhouse gases in terrestrial ecosystems remains unclear. The important role oceans play in maintaining atmospheric CO_2 is discussed in chapter 30.

Methane is a greenhouse gas of increasing concern because it has about 25 times the global warming potential of CO_2. This means that a single molecule of CH_4 released into the atmosphere has the same thermal retention capacity as 25 CO_2 molecules. Based on analyses of gas bubbles in glacier ice cores, the levels of methane in the atmosphere remained essentially constant until about 150 years ago. Since then, methane levels have increased 2.5 times to the present level of about 1,890 parts per billion (ppb) (figure 28.11). Considering these trends, there is a worldwide interest in understanding the factors that control methane production and oxidation by microorganisms.

To understand the chief source of the nitrogen oxide greenhouse gases NO and N_2O, collectively referred to as "Nox," we need to examine food production. The "green revolution" of the mid-twentieth century ensured that agricultural output, boosted by the application of human-made fertilizer, could keep pace with population growth. The manufacture of fertilizer is an energy-intensive process that uses hydrogen gas to reduce N_2 to NH_4^+ at high temperature and pressure. This process was first described by Fritz Haber and Karl Bosch in 1913, but it was not until the middle of the twentieth century that the Haber-Bosch reaction was used at an industrial level. Current fertilizer production is about 1.3×10^{14} g per year, or about 400 times greater now than it was in 1940. In contrast to the positive outcome of increased agricultural output, the addition of so much ammonium to the soil has altered the balance of the nitrogen cycle.

What becomes of the extra NH_4^+? That which is not taken up by plants generally has one of two fates: runoff or nitrification followed by denitrification (**figure 28.12**). Ammonium runoff leaches into lakes and streams, frequently causing **eutrophication**—an increase in nutrient levels that stimulates the growth of a limited number of organisms, thereby disturbing the ecology of these aquatic ecosystems. By contrast, microbial nitrification results in the oxidation of ammonium to more nitrate than can be immobilized by plants and microbes, because organisms need a specific ratio of C:N:P, *(see page 669)*. The process of denitrification converts this extra nitrate to N_2 and the reactive greenhouse nitrogen oxides. This cycle of nitrification/denitrification

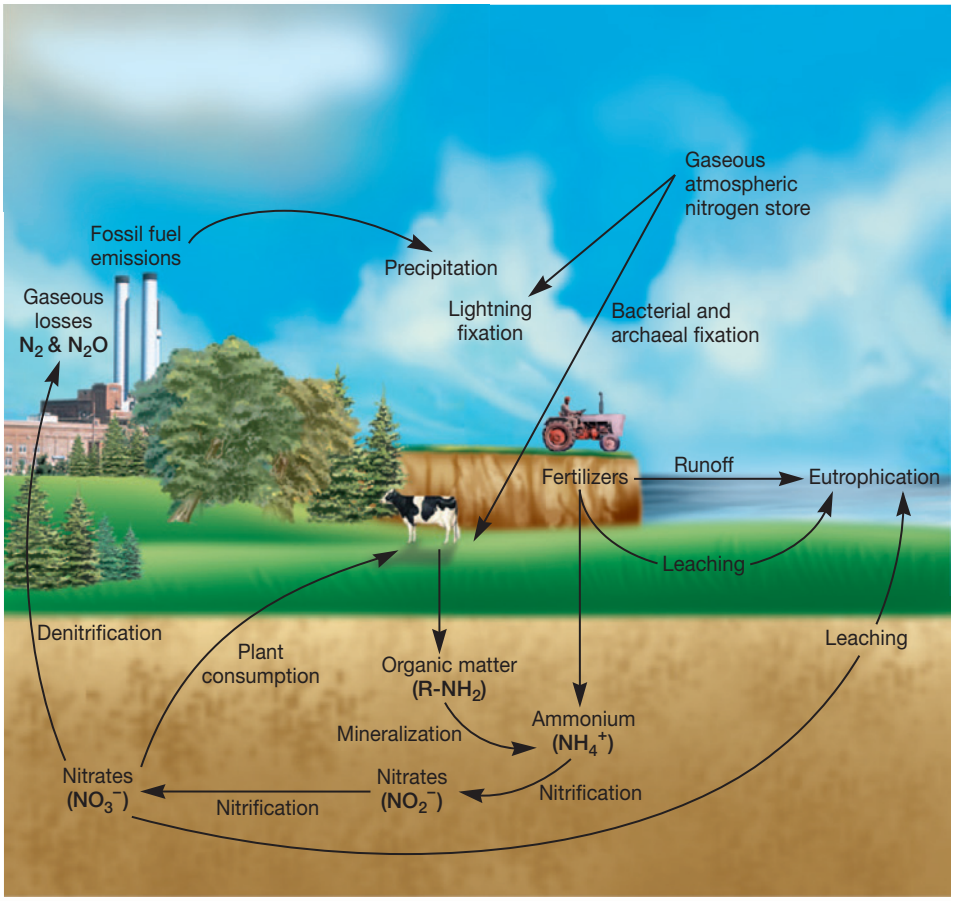

Figure 28.12 **Natural and Human-Made Influences on the Nitrogen Cycle.**

MICRO INQUIRY *What organisms benefit from nitrification?*

fueled by NH_4^+ introduced as fertilizer is responsible for the highest N_2O levels in 650,000 years.

What are the consequences of disrupting the carbon and nitrogen cycles? Global climate change is the most obvious example. It is important to keep in mind that weather is not the same as climate. While North America has suffered some of the hottest summers on record in the past decade, a single day or week in July that is particularly hot is not, by itself, evidence of global climate change. Global climate change is measured over decades and includes many parameters such as surface temperature on land and sea, and in the atmosphere and troposphere; rates of precipitation; and frequency of extreme weather. Based on these analyses, the average global temperature has increased 0.74°C since the early twentieth century, and this rise is directly correlated with fossil fuel combustion to CO_2 (**figure 28.13**). Depending on the rate of continued increase in greenhouse gases, the average global surface temperature is predicted to rise between 1.1 and 6.4°C by 2100.

An important question is how will microbes respond to a changing world. Because for the vast majority of Earth's history, microorganisms have been the drivers of elemental cycling, changes in microbial activities will have a major impact on the rate and magnitude of greenhouse gas accumulation and global climate change. The role microbes play in balancing carbon and nitrogen fluxes has opened new avenues of research in microbial ecology.

Retrieve, Infer, Apply

1. List three greenhouse gases. Discuss their origins.
2. Discuss the possible role of forests in the control of CO_2.
3. How do changes in the nitrogen cycle caused by fertilization influence the carbon cycle?
4. Given that each microbial group has an optimum temperature range for growth, how might you predict changes to a soil microbial community living in your geographic area?

Key Concepts

28.1 Biogeochemical Cycling Sustains Life on Earth

- The redox potential of the environment has a major impact on the type of metabolic processes that can occur (**figure 28.1**).
- The cycling between inorganic (CO_2) and organic carbon occurs aerobically and anaerobically by all types of microbes. Only methanogenic archaea can produce methane, an anaerobic process. Methane can be oxidized by bacteria in the presence of oxygen, or anaerobically by archaea (**figure 28.3**).
- Assimilatory processes involve incorporation of nutrients into the organism's biomass during metabolism; dissimilatory processes involve the release of nutrients to the environment after metabolism. Dissimilatory reduction usually involves the use of the oxidized compound (e.g., NO_3^- or SO_4^{2-}) as the terminal electron acceptor during anaerobic respiration (**figures 28.4** and **28.6**).
- Chemolithotrophs use reduced elements as electron donors and generate the oxidized form, which can then be used for assimilatory or dissimilatory processes (**figures 28.4** and **28.6**).
- Phosphorus is cycled in its oxidized state, phosphate. Unlike other elements, there is no gaseous form. Phosphate must be leached from rocks and soils. (**figure 28.5**).
- Iron and manganese cycle between their oxidized and reduced forms without the accumulation of intermediates (**figures 28.7** and **28.8**).
- Mercury cycling is complex but can have significant effects on the health of higher organisms (**figure 28.9**).
- Although it is convenient to consider a single element cycling, in nature there are extensive and complex interactions between nutrient cycles (**figure 28.10**).

28.2 Global Climate Change: Biogeochemical Cycling Out of Balance

- Microbes have evolved slowly over time; this has given rise to the biogeochemical cycles that sustain life on Earth. However, since the beginning of the twentieth century, the rate at which CO_2, CH_4, and nitrogen oxides have been released into the atmosphere has outpaced the rate at which they can be recycled. Thus these greenhouse gases are accumulating in Earth's atmosphere (**figures 28.11** and **28.12**).
- The increase in greenhouse gases is correlated with an increase in the global annual-mean surface air temperature (**figure 28.13**).

Compare, Hypothesize, Invent

1. Compare the production of N_2 gas by denitrification and anammox. Are they both aerobic processes? What are the implications for a given pool of NO_2^- and NO_3^-?
2. Examine figure 28.12. Farmers in Argentina use a crop/cattle rotation system in which cattle graze on pastures for about 5 years, then are moved to a different area and crops are planted where they had grazed. Crops are grown for 3 years, and then cattle are rotated back and the field reverts to a pasture. This dramatically reduces the amount of nitrogen fertilizer that must be added when crops are grown. Why is this the case? Why is it argued that this practice also minimizes fossil fuel emissions?
3. A bacterium isolated from sewage sludge was recently found to be capable of anoxygenic photosynthesis using nitrite as the electron donor, converting it to nitrate. Compare this form of nitrification to that which is well characterized. By removing nitrite from the environment for reductant, what other processes within the nitrogen cycle might this bacterium be influencing?
4. It is well documented that aquatic ecosystems have been negatively impacted by the influx of nitrogen from anthropogenic sources, including fertilizer and fossil fuel combustion. Although some of this N is removed by nitrification and immobilization, a better understanding of removal processes is needed for appropriate management. To that end, globally distributed lakes were analyzed and surprisingly showed that the availability of phosphorus promotes nitrogen removal. This has real-world implications, as many communities have implemented management plans to reduce phosphorus influx to natural waters. Explain how an increase in one element, phosphorus, could lead to the removal of another, nitrogen. Think about the carbon cycle. How could an increase in another element in a given ecosystem alter the loss of carbon as CO_2?

Methods in Microbial Ecology

Recent advances in the methods used by microbial ecologists have made it possible to explore the deep-sea sediment microbial community. Surprisingly, the benthos may be home to as many as half the microbes on the planet.

Scientists Search for Intraterrestrial Life—and Find It

In 1955 the "father of marine microbiology," Claude ZoBell, concluded that there was very little, if any, microbial life beneath the seabed. He based this assessment on the absence of bacterial growth in cultures from marine sediments deeper than about 10 meters. About a decade later, this notion was reinforced when the deep-sea submersible *Alvin* broke free of its tethers and sank. Although the scientists in the sub were rescued, a sandwich was not. Ten months later, *Alvin* was recovered and the sandwich was still intact. "Aha!" said scientists, "the ocean depths are too extreme to support microbial life!" Not surprisingly, this approach to studying deep-sea microbial ecology has not stood the test of time.

The modern age of subsurface microbiology was launched in the mid-1980s, when the U.S. Department of Energy drilled wells 200 m deep and a variety of microorganisms from subsurface aquifers were cultured. This was followed by a 1994 report of the growth of microorganisms from sediments collected 500 m below the seabed. In both cases, novel culture conditions were employed that more closely resembled the pressure, temperature, and redox potential of subsurface environments. Nonetheless, it was hard to convince the scientific community that these microbes weren't contaminants.

In the twenty-first century, advances in the tools available to microbial ecologists have propelled the "deep hot biosphere" to one of the most dynamic fields in microbiology and ecology. Technological advances including the advent of culture-independent methods have been crucial in probing what may be half of all microbial life on Earth. These techniques are designed to ask not just "Is there life?" but "Who is there?" "How fast are they growing?" and "What is their food?" Obtaining microorganisms in pure culture remains the most powerful tool available for understanding the taxonomy, genetics, and physiology of a single microbial strain. But just as it is impossible to learn everything about zebras by studying only those in zoos, microbiologists cannot fully understand microbes without exploring them in nature. In the past, investigations were often limited by technology; now this rarely seems to be the case. What would ZoBell think?

Recent estimates suggest that most microbial communities have between 10^{10} to 10^{17} individuals representing at least 10^{7} different taxa. How can such huge groups of organisms exist and, moreover, survive together in a productive fashion? To answer this question, one must know which microbes are present and how they interact. In other words, one must study **microbial ecology**—an interdependent series of inquiries that involves traditional, laboratory-based analyses, metagenomics, and in situ (Latin, in place) biogeochemical assessments (figure 29.1). The application of these techniques has brought an explosion of recent advances and generated a new appreciation of the vast diversity of microbes and their role in biogeochemical cycling.

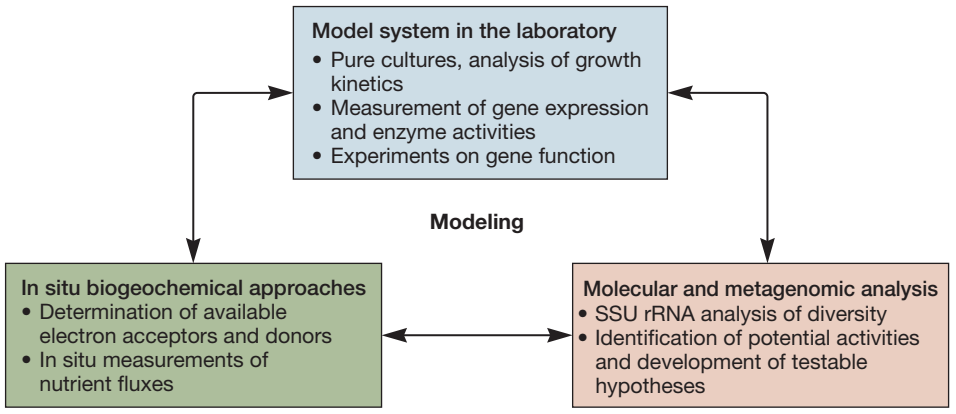

Figure 29.1 Microbial Ecology Is an Interdisciplinary Science. It relies on the interplay between a variety of approaches, which can be broadly classified as shown here.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Differentiate between defined and complex culture media (section 7.6)
- ✔ Describe conventional techniques used to isolate single colonies and establish a pure culture (section 7.6)
- ✔ List environmental factors that influence microbial growth (section 7.4)
- ✔ Explain why and how microbes frequently grow in biofilms (section 7.5)
- ✔ Evaluate the importance of intercellular molecular signaling to microbial growth in nature (section 7.5)
- ✔ Explain why PCR results in the amplification of a specific DNA sequence despite many competing sequences (section 17.2)
- ✔ Summarize the principle and application of gel electrophoresis (section 17.1)
- ✔ Review the theory and practice of metagenomics and functional genomics (sections 18.3 and 18.5)
- ✔ Compare and contrast different molecular approaches to microbial taxonomy and phylogeny (section 19.3)
- ✔ Explain why SSU rRNA is used as a taxonomic marker (section 19.3)
- ✔ Explain how the oxidation-reduction (redox) state of an environment impacts the types of microbial metabolic processes that might be found there (section 28.1)

29.1 Microbial Biology Relies on Cultures

After reading this section, you should be able to:

- Explain why, to the best of our knowledge, most microorganisms resist culturing in the laboratory
- Describe the use of enrichment cultures
- State when and how to apply the most probable number (MPN) method
- Describe at least two innovative approaches used to coax growth in the laboratory of previously uncultured microbes
- Explain the fundamentals of flow cytometry

It is now well understood that less than 5% of microbes have been grown under laboratory conditions. There are many reasons a particular microbe may resist culturing; a few are listed in **table 29.1**. The discrepancy between the number of microbial cells observed by microscopic examination and the number of colonies cultivated from the same natural sample has been called the **great plate count anomaly.** This has led to the description of such potentially viable microbes as being "nonculturable" *(see figure 7.35)*. A microbe is deemed **viable but nonculturable** (**VBNC**) if it fails to be cultivated but is determined to be viable by one of several methods. A common technique uses dyes that discriminate between live and dead cells that can be visualized microscopically (**figure 29.2**). A molecular approach, called viability polymerase chain reaction (PCR) also uses a dye to differentiate between live and dead cells. In this case, the dye enters dead cells whose membranes have become damaged. Upon photoactivation, the dye crosslinks the DNA, thereby preventing subsequent PCR amplification of target genes (e.g., SSU rRNA). In this way, the DNA of only viable cells is present in the pool of PCR templates and is therefore detected as amplified DNA product.

Although the "gold standard" is an **axenic culture** (i.e., a pure culture) of the microbe of interest, one typically has to purify the microbe from a natural microbial assemblage. In such cases, it is often best to increase the number of microbes of interest relative to others in the same sample. **Enrichment culture** techniques are based on recreating a microenvironment in the laboratory to promote the growth of a microorganism formerly restricted to a small ecological niche. At the same time, growth of other microbial types is inhibited. This approach often plays a central role in finding new microbes. As described in chapter 7, the success of an enrichment culture depends on a thorough understanding of the specific niche the microbe of interest inhabits and the physiological features that set that microbe apart from others. ⏮ *Enrichment cultures (section 7.6)*

Table 29.1 Reasons Microbes May Be "Unculturable"

Potential Problem	Example Method Designed to Overcome
Microbe is slow growing.	Incubation times of weeks to months
Microbe is present in very low abundance.	Extinction cultures, using many replicates
Different microbes in same habitat are physiologically very similar. OR Inhibition by other microbes in a mixed culture	Remove other microbes from the sample by physical methods such as filtration or density-gradient centrifugation, or use extinction cultures.
Fastidious growth requirement	Assess growth requirements of similar microbes, if known; use annotation of metagenomic sequences to infer nutritional capabilities and requirements; grow in diffusion chambers that allow influx of small molecules from natural environmental samples without microbial contamination.
Crossfeeding or communication signals from other microbes are needed.	Co-cultivate strains; use diffusion chambers; grow in conditioned spent medium of "helper" microbe.
Triggers for growth or exit from a dormant state are not present.	Add known growth triggers such as N-acetylmuramic acid.

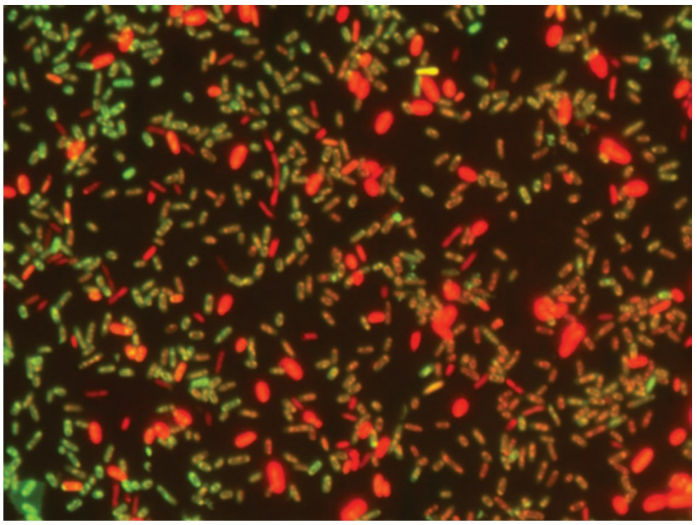

Figure 29.2 Assessment of Microbial Viability by Use of Direct Staining. By using differential staining methods, it is possible to estimate the portion of cells in a given population that are viable. In the LIVE/DEAD *Bac*Light Bacterial Viability procedure, two stains are used: a membrane-permeable green fluorescent nucleic acid stain and propidium iodide (red), which penetrates only cells with damaged membranes. In this *Escherichia coli* culture, living cells stain green, while dead and dying cells stain red.

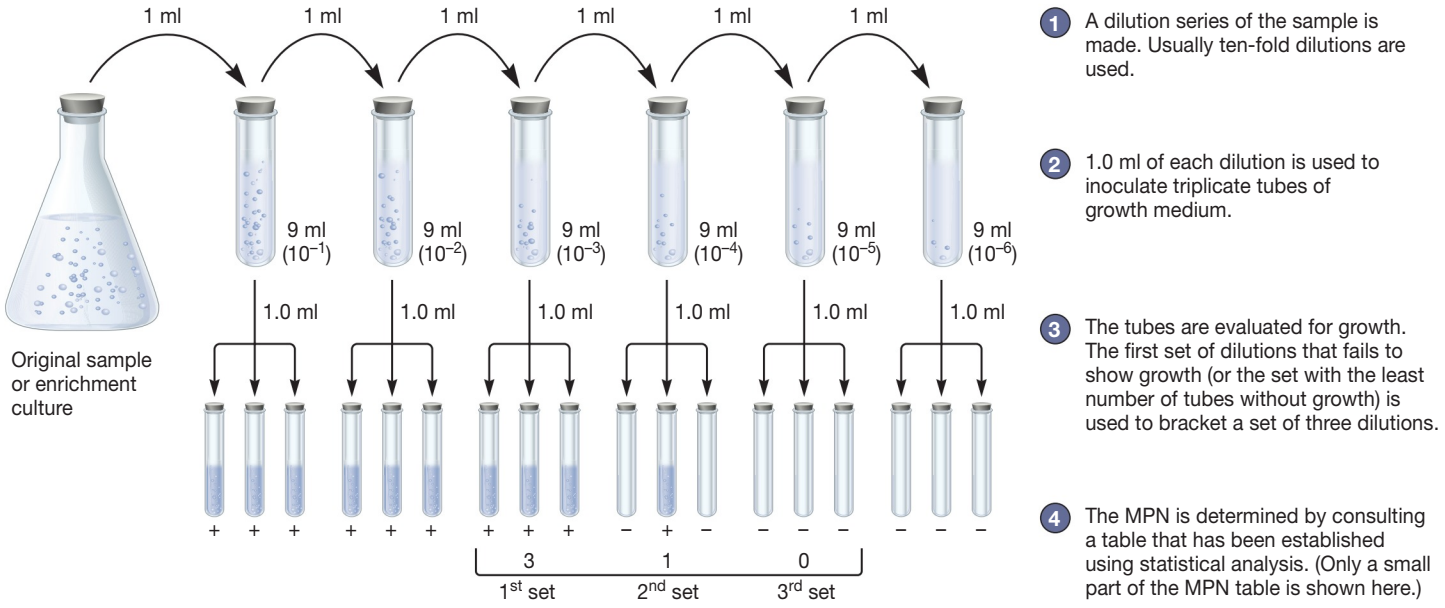
If the microbes of interest can be cultured, the number of microbes in the sample can be estimated by using the **most probable number** (**MPN**) technique. This can be used to quantify specific types of microbes in natural samples, enrichment cultures, or, as is often the case, in food or water samples. The MPN technique involves establishing serial, ten-fold dilutions of the sample. Triplicate tubes of each dilution are usually established, although sometimes five or six replicates of each dilution are used for more accurate results. The theoretical basis of the MPN approach is that even if only one cell is inoculated into a tube, growth will occur. As shown in **figure 29.3**, after incubation at the appropriate temperature and duration, the tubes are examined for growth. Ideally, beyond a certain dilution, tubes fail to show growth because no cells were introduced into the medium. This is seen in the 10^{-5} and 10^{-6} triplicates in figure 29.3. In this case, the first dilution without growth would be marked as the last dilution in a set of three that includes the two dilutions that precede it. The number of tubes in the first set (10^{-3}, in this case) and the middle set is recorded. In our example, we see that this gives us a pattern of three tubes with growth in the 10^{-3} dilution tubes, one tube with growth in 10^{-4}, and zero tubes in 10^{-5}. A table based on statistical and theoretical considerations is consulted (figure 29.3*b*), and we see that the pattern 3-1-0 gives a MPN of 0.43. What does this mean? The most probable outcome is that an average of



(a) Procedure for MPN analysis

Number of positive tubes in:			MPN
1st set	2nd set	3rd set	
3	0	3	0.95
3	1	0	0.43
3	1	1	0.75

MPN equals 4.3×10^3 microbes per 1.0 ml of sample

(b) MPN table

Figure 29.3 Most Probable Number Technique.

0.43 organisms were inoculated into each of the tubes of the middle set (in this case, 10^{-4}). From this, we conclude that the most-probable number of organisms per 1 milliliter of the original, undiluted sample would be 0.43×10^4 or 4.3×10^3.

Inspection of the MPN table in figure 29.3 reveals that the results do not always show the expected lack of growth only in the lowest dilution tubes. This can happen if the microbes were not randomly distributed within the sample or if they grew in clumps or chains. When this occurs, less than ideal results are obtained, and it may be best to use more replicates or a plating technique so that individual colonies can be counted.

Clearly, the MPN technique is only valid if the microbe of interest can be grown in the laboratory. Although this is not true of most microorganisms found in nature, it would be premature to claim that microbes currently unculturable will never be cultivated. Traditional growth media are now giving way to novel media and incubation conditions. One approach is to use unusual electron donors and acceptors. For instance, a novel isolate from Mono Lake (California) sediments was cultivated only when anoxic conditions with arsenite as the electron donor and nitrate as the electron acceptor were provided. It has also become clear that growing "unculturable" microbes requires patience. Microbiologists are most familiar with doubling times in the order of hours or, at the most, a few days, when in fact, this is not always the case. For example, newly described anaerobic soil isolates were discovered only when solid cultures were incubated over a 3-month period. Indeed, 20% of the colonies did not appear until after the second month. Furthermore, microbiologists have been trained to equate turbidity in liquid culture with growth. This is not always true, as some bacteria may stop dividing (i.e., reach stationary phase) at cell densities too low to appear turbid.

A variety of new culture techniques have been applied that address specific needs of microorganisms growing in diverse environments. Efficiency can be greatly improved by using "high-throughput" methods. One popular approach is the **extinction culture technique,** so named because natural samples are first microscopically examined and then diluted to a density of one to 10 cells, that is, diluted to extinction, much like in the MPN assay. Multiple 1-milliliter cultures are established in 48 well microtiter dishes. After incubating for the desired time under appropriate conditions, the samples are stained and examined microscopically to screen for growth. In many cases, cultures that do not appear turbid will nonetheless show signs of viable microbial growth and can be transferred to fresh medium. It is important that the initial culture has fewer than 10 cells; additional transfers and dilutions can ensure that a culture arising from a single cell (i.e., clonal growth) eventually is obtained.

Recent progress in cataloging microbes that make up the human microbiome has impelled the development of a high-throughput cultivation technique called culturomics. **Culturomics** involves at least three steps: first, samples of a mixed assemblage of microbes are used as inoculum for hundreds of different culture media incubated under a variety of physical conditions (e.g., temperature, pH, and oxygen concentration). Microorganisms from colonies that grow are then identified by mass spectrometry (*see page 447*) and small subunit (SSU; 16S for bacteria and archaea, 18S for eukaryotic microorganisms) rRNA gene sequencing. From these initial cultures, larger cultures can be started—that is, cultures are "scaled up," and in some cases organisms are grown in pure culture. Even if pure culture is not possible, these microbes can be the source for genome sequencing by single-cell genomics (*see page 426*). In this way, it is possible to grow and identify thousands of microorganisms and purify hundreds of microbial isolates, including bacteria, archaea, and fungi.

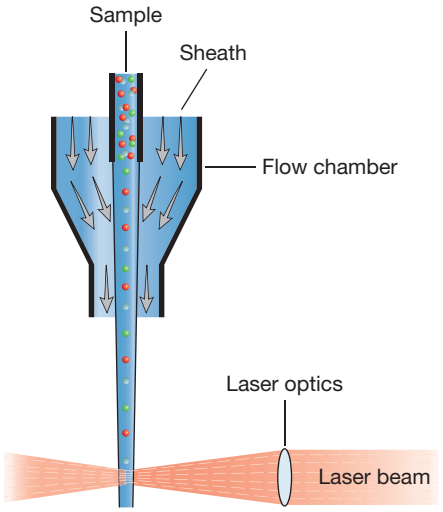


Figure 29.4 Flow Cytometry. Fluorescently labeled cell samples are injected into a fluid stream that narrows using a technique called hydrodynamic focusing. This forces only one cell at a time to pass a laser beam and scatter light in all directions. Forward-scattering light is a function of cell size, while the nature of laterally scattered light is determined by morphological complexity. This information is detected, measured, and converted to an electrical signal that reports the number and types of cells present.

MICRO INQUIRY *What happens to the flow stream in fluorescence activated cell sorting (FACS)?*

Two different techniques are commonly used to isolate single cells from a mixed population: flow cytometry and optical tweezers. In **flow cytometry,** cells are tagged with a fluorescent dye and injected into a flowing stream of fluid. As shown in **figure 29.4**, the diameter of the stream narrows, forcing one cell at a time through a laser beam that scatters its fluorescence. A detector collects and measures the light scattered in the forward direction and converts it to a voltage pulse that is proportional to the size of the cell. Light that scatters to the side is a function of morphological complexity of the cell, and this also is detected and quantified. Thus based on cell size and morphology, flow cytometry can detect different populations of cells. This enables an additional function, **fluorescence activated cell sorting (FACS**). Here, as the stream leaves the detector, vibration causes the fluid to break into single droplets with no more than one fluorescent cell per drop. The detector software identifies the specific fluorescent signal that depends on the size and complexity of the cell. Cells become electrostatically charged as they pass the detector. The charge is used to guide the cell into a

collection vessel. Thousands of cells per second pass through the laser beam, making "flow" an extremely efficient means to count and sort cells.

A less efficient but more visually rewarding approach of isolating single cells is accomplished by **optical tweezers**. This technique uses a highly focused laser beam to manipulate microbial cells. As the laser beam is focused, it passes through a very strong electric field gradient. Cells are dielectric (i.e., they can be polarized in an electric field), so they are attracted to the center of the light beam within the gradient. Because light is a collection of particles (photons) that interact with matter in its path, the traveling laser beam impinges on cells as they travel through the electric current, moving the cells toward the narrowest point of the focused beam. In this way, an optical trap is made that can be used to move microbial cells (and other small, dielectric particles, including DNA and proteins) in a directed fashion. When coupled with micromanipulation, a desired cell or cellular organelle can be drawn up into a micropipette. As with flow cytometry, once the microbe is isolated, it can be used as inoculum for the development of an axenic culture. Alternatively, PCR amplification of DNA from the individual cell can provide sequence data for phylogenetic analysis or single cell genomic sequencing.

29.2 Genetic Methods Are Used to Assess Microbial Diversity

After reading this section, you should be able to:

- Explain why microbial communities are often investigated in situ
- Describe why, when, and how FISH and CARD-FISH are used
- Summarize how PCR is used to take a microbial census
- Explain why and how DGGE is used
- Assess the advantages and disadvantages of DNA association studies
- Compare and contrast the use of phylochips with other microarray-based technologies designed to assess microbial communities
- Predict which techniques would be appropriate for assessing the microbial community in a gram of forest soil and in a milliliter of seawater

Microbial ecologists study natural microbial communities that exist in soils or waters, or in association with other organisms, including humans. In all cases, scientists seek to assess microbial diversity. Diversity can be a measure of the number of genera, species, or ecotypes in an ecosystem. Alternatively, diversity can reflect the various types of metabolic strategies used in a single habitat: What carbon sources, and electron donors and acceptors are used by the different microbes? A microbial **population** is defined as a group of microorganisms within an ecosystem that are the same species. When a group of microbes is defined by its physiological activity, it is called a **guild,** in the same way that guild of people often represents their occupation, for example, a carpenter's guild. A microbial example would be a guild of nitrifying microbes in a soil sample.

Staining Techniques

The most direct way to assess microbial diversity is to observe microbes in nature. This can be carried out in situ using immersed microscope slides or electron microscope grids placed in a location of interest, which are then recovered later for observation. Samples taken from the environment often are examined in the laboratory using classical cellular stains or fluorescent dyes that stain specific molecules. Individual cells can then be counted and their concentration calculated. The fluorescent stains DAPI (4′,6-*dia*mido-2-*p*heny*l*indole) and acridine orange are commonly used to visualize microbes in environmental, food, and clinical samples (**figure 29.5**). These dyes specifically label nucleic acids

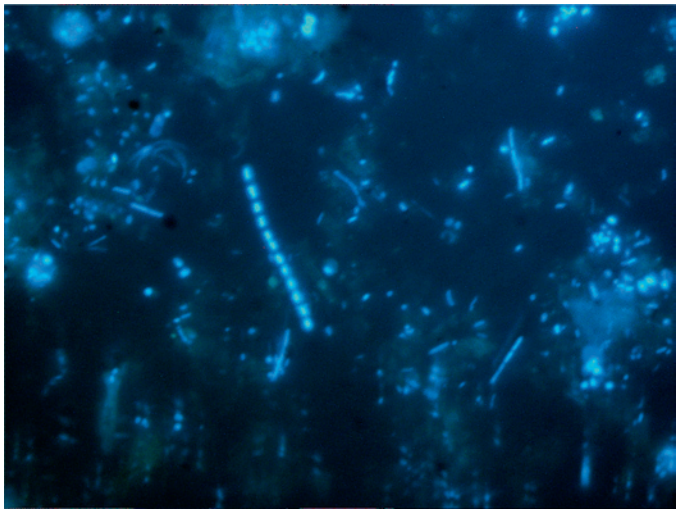

Figure 29.5 DAPI Stains Nucleic Acids. A microbial assemblage from the North Sea off the Belgian coast as visualized following DAPI staining.

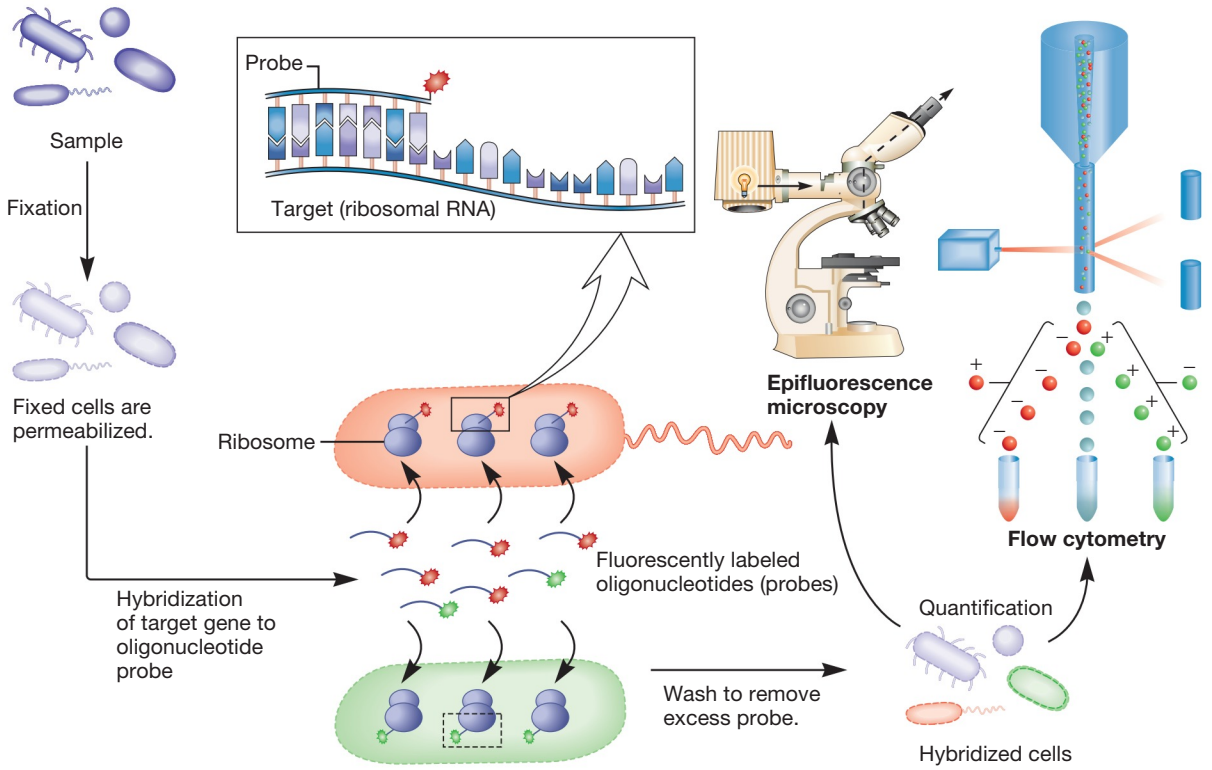

Figure 29.6 Fluorescence in Situ Hybridization (FISH).

(i.e., both DNA and RNA), and little sample preparation is required prior to their application. The nucleic acid dye SYBR Green is also used, in part because the signal is so bright virus particles can be seen.

Often microbiologists want to enumerate a specific genus or type of microbe. In these cases, a technique called ***f*luorescent *i*n *s*itu *h*ybridization** (**FISH**) can be used. Here fluorescently labeled oligonucleotides (small lengths of DNA) that are known to be specific to the microbe of interest are used to label natural samples (**figure 29.6**). These oligonucleotides are called **probes.** Sequences within the gene encoding SSU rRNA are commonly used probes (*see figure 19.3*). To perform FISH, microbial cell membranes are made permeable so the probe can be internalized. Once inside the cell, it hybridizes to complementary nucleotide sequences. Probe that does not bind is washed off, and probe fluorescence reveals the organisms of interest. Probe fluorescence is visualized by **epifluorescence microscopy,** in which the microscope is fitted with light filters that enable the excitation of the specimen with a specific wavelength. The fluorescent tag then emits light of a longer wavelength (**figure 29.7**). Alternatively, individual cells can be separated and counted (but not visualized) by flow cytometry (figure 29.4). ⏮ *Fluorescence microscopes use emitted light to create images (section 2.2)*

Depending on the probe used, FISH can identify a particular species, strain, or ecotype. This has made it a popular tool in clinical diagnostics and food microbiology, as well as microbial ecology. For example, FISH was used to discover the association between the archaea *Nanoarchaeum equitans* and *Ignicoccus hospitalis (see figure 20.10).* Two fluorescent tags—one green, the other red—were attached to 16S rRNA probes, each having a different genus-specific nucleotide sequence. In this way, it was found that

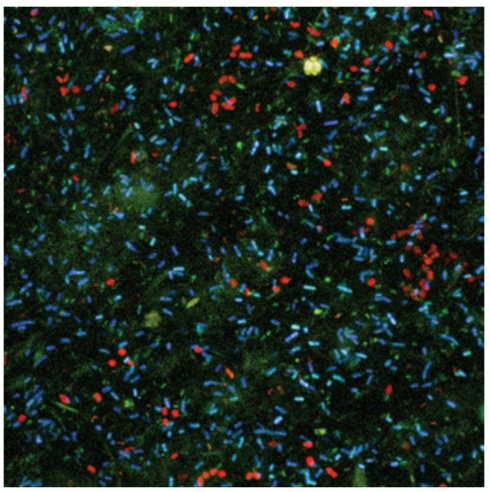

Figure 29.7 **The Use of FISH to Study Microbial Populations.** In this study, 16S rRNA probes tagged with different color fluorescent labels were used to study the microbial diversity within an earthworm gut.

MICRO INQUIRY *Under what circumstances would one use epifluorescence microscopy, rather than flow cytometry, and vice versa?*

N. equitans, which is only 0.4 μm in diameter, grows attached to the larger archae on as an obligate symbiont. Thus the combination of direct observation and molecular probes made it possible to document the lifestyle of this unusual archaeal symbiont and extend our understanding of archaeal diversity. ▶▶| *Identification of microorganisms from specimens (section 36.3)*

Sometimes when FISH is used in natural samples, the fluorescent signal is not bright enough to be detected microscopically. This is because microbes living in these environments often grow quite slowly, so each cell has relatively few ribosomes and little probe is bound. A clever modification of the FISH technique amplifies the signal produced by each cell. The trick is to label the fluorescent probe (i.e., label the label) with an enzyme that makes lots of fluorescent product when exposed to substrate. This is called *c*atalyzed *r*eported *d*eposition-FISH, or simply **CARD-FISH.** The enzyme attached to the oligonucleotide is usually horseradish peroxidase (HRP). After the oligonucleotides are hybridized to the sample, the HRP substrate tyramide is added. Tyramide is oxidized by HRP and the level of fluorescence is amplified. In this way, a single oligonucleotide bound to just one molecule of rRNA can generate an "enzyme boosted" fluorescent signal.

Molecular Techniques

Because so few microbes can be grown easily in culture, the importance of molecular techniques to identify and quantify microorganisms is paramount. Metagenomic analysis has become increasingly important in studying microbial diversity, particularly when coupled with next-generation sequencing. |◀◀ *Next-generation DNA sequencing (section 18.1); Metagenomics provides access to uncultured microbes (section 18.3)*

Microbial ecologists regularly use SSU rRNA analysis to identify the microbes that populate a community, although the **internal transcribed spacer region** (**ITS**) between the 16S and 23S rRNA genes may also be used. Sometimes other genes besides SSU rRNA analysis are used. When protein-coding genes are used to define phylotypes, the genes must meet three important criteria: they need to be found in all known microbes, they need to have only one copy in the genome, and they need to rarely show evidence of horizontal gene transfer.

Several approaches can be used to generate a molecular census. DNA from samples of soil, water, or other natural material (e.g., sputum or blood in a clinical setting) can be cloned into a plasmid vector to generate a metagenomic library. PCR is then used to amplify the gene or genes of interest. More often, PCR is used to amplify rRNA genes directly from natural samples without first constructing a metagenomic library. In this way, all the genomes recovered from the environment can be sequenced by a next-generation technique. Alternatively, single-cell genomic sequencing may be performed. |◀◀ *Polymerase chain reaction amplifies targeted DNA (section 17.2); Genomic libraries (section 17.5); Single-cell genomic sequencing (section 18.2)*

Despite the power of PCR, its use under these circumstances can be problematic because the rRNA genes of some microbes are more readily amplified than others. The most obvious reason for this is relative abundance of a microbe—a microbe present in great numbers typically generates more PCR product than a rare microbe—but this is not the only reason. Other factors include (but are not limited to) the G + C content of a microbe's genome, the amount of nucleic acid degradation that might have occurred, and the relative ease with which some microbes can be lysed and thus their nucleic acids extracted (e.g., spores vs. vegetative cells). The observation that certain nucleotide templates are more readily amplified than others is termed **PCR bias.** PCR bias is typically more of a problem when nucleotide fragments are cloned into a metagenomic library prior to nucleotide sequencing.

Once SSU rRNA nucleotide sequences are obtained, they can be compared with sequences isolated from other microbes that have been deposited in databases such as the Ribosomal Database Project. In this way, microbial ecologists can get a reasonable idea of the identity of the microbes that occupy a specific niche. Because whole organisms are not isolated and studied, it is said that specific **phylotypes** have been identified.

As discussed in chapter 19, it is sometimes desirable to avoid nucleic acid sequencing and obtain a DNA fingerprint instead. DNA fingerprints generate a barcodelike image that represents community diversity most commonly by separating the amplified rRNA gene fragments on an agarose gel (*see figure 19.4*). One microbial community can then be compared with another (differing in either time or space). Often a single pair of primers is used to amplify the same region of a SSU rRNA gene from a mixture of genomes. Despite different nucleotide sequences, the PCR products will have very similar molecular weights and thus appear as a single band on an agarose gel. To be of any use, such PCR products must be separated from one another. This is accomplished through **denaturing gradient gel electrophoresis (DGGE)** (**figure 29.8**).

DGGE relies on the fact that although the PCR fragments are about the same size, they differ in nucleotide sequence. Recall that the rate at which double-stranded DNA becomes single stranded varies with the G + C content; that is, it varies with DNA sequence. DGGE takes advantage of the observation that DNA of different nucleotide sequences will denature at varying rates and uses a gradient of chemicals to denature the DNA (usually urea and formamide). In this technique, DNA fragments generated by PCR are loaded in a single well in a gradient gel. As electrophoresis proceeds, fragments will migrate until they become denatured. What appeared to be a single DNA fragment (band) on a nongradient gel will resolve into separate fragments (multiple bands) by DGGE. Because DGGE can be limited by poor gel-to-gel reproducibility, its popularity has declined in recent years. |◀◀ *Gel electrophoresis (section 17.1); DNA sequencing methods (section 18.1)*

Microarray technology has also been applied as a means to assess microbial diversity in natural samples without nucleotide sequencing. These specialized microarrays are called **phylochips** (**figure 29.9**). As described more fully in chapter 18, microarrays are prepared robotically with single-stranded DNA "probes" attached in a gridlike pattern on a solid matrix, often a glass slide. Each DNA probe is a single gene (or part of a gene), and its identity and location on the slide is recorded. Single-stranded

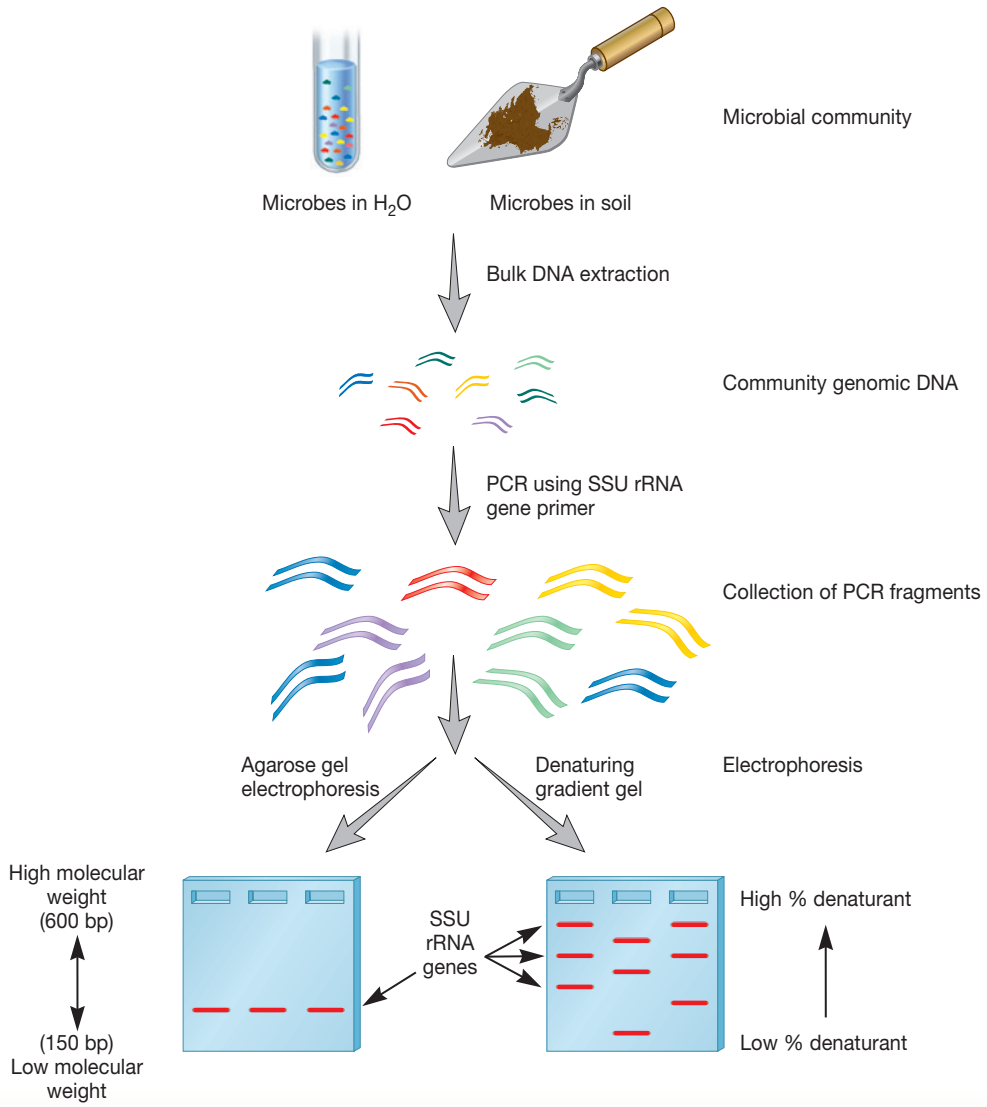

Figure 29.8 **Denaturing Gradient Gel Electrophoresis (DGGE).** The identification of phylotypes starts with the extraction of DNA from a microbial community and PCR amplification of the gene of choice, usually that which encodes SSU rRNA. Because the majority of amplified DNA fragments have about the same molecular weight, when visualized by agarose gel electrophoresis, they appear identical, as shown in the gel on the left. However, DGGE uses a gradient of DNA denaturing agents to separate the fragments based on the concentration at which they become single stranded. When a fragment is denatured, it stops migrating through the gel matrix (gel on right). Individual DNA fragments can then be cut out of the gel and cloned, and the nucleotide sequence determined.

MICRO INQUIRY *How many different phylotypes appear to be represented by this DGGE?*

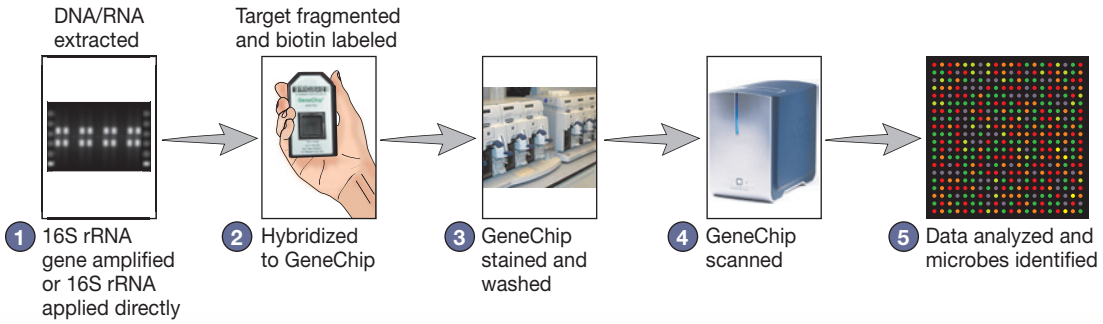

Figure 29.9 **Phylochip Analysis.** This form of microarray analysis enables the rapid evaluation of microbial diversity. (1) 16S rRNA genes or 16S rRNA molecules are obtained from the natural sample and labeled. (2) The 16S nucleic acids are hybridized to probes on a microarray called a phylochip. The probes consist of short regions of 16S rRNA genes obtained from preselected microbes. (3) The chip is washed to remove labeled 16S rRNA nucleic acids that could not hybridize because their complement is not found among the probes. (4) Laser beams scan the phylochip and (5) generate a series of spots of various colors and intensities that indicate the presence, absence, and, to a lesser extent, relative abundance of each microbe represented with an rRNA probe. This data is computer analyzed.

MICRO INQUIRY *How do phylochips differ from the microarrays discussed in chapter 18 (see p. 432)?*

nucleotides from an environmental sample are incubated with the phylochip so that complementary probe and sample sequences can hybridize. The level of hybridization to each probe (gene) is measured by laser beams. Analysis of DNA hybridization thus reveals the presence or absence of the specific genes in the environment. ◀◀ *Transcriptome analysis (section 18.5)*

29.3 Assessment of Microbial Community Activity Relies on Biochemistry and Genetics

After reading this section, you should be able to:

- Explain how microbial ecologists measure community activity
- Describe why microelectrode measurements are important tools in the study of microbial community activity
- Compare the application of traditional stable isotope analysis with stable isotope probing
- Assess the advantages and disadvantages of measuring in situ mRNA abundance
- List the type of data that can be generated by MAR-FISH and compare this with functional gene arrays
- Describe the construction and application of reporter microbes
- Differentiate metagenomics from metaproteomics

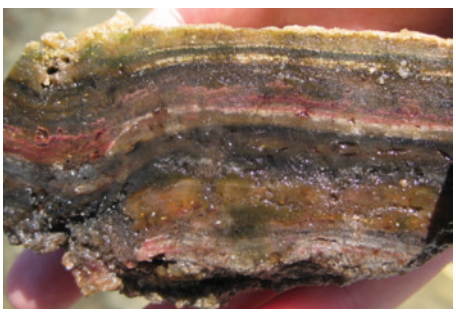
Microbial ecologists want to understand how microbes drive and respond to the biogeochemical cycles that are essential for life on Earth. Thus they seek to identify and measure the flux of nutrients, the interactions between microbes that make these fluxes possible, and the influences of abiotic factors. Here we divide methods into biogeochemical and molecular techniques, but it should become clear that the results of one type of approach are often used to formulate hypotheses that will be tested by another (figure 29.1). This illustrates why microbial ecology might be considered the most multidisciplinary branch of microbiology. ◀◀ *Biogeochemical cycling sustains life on Earth (section 28.1)*

Biogeochemical Approaches

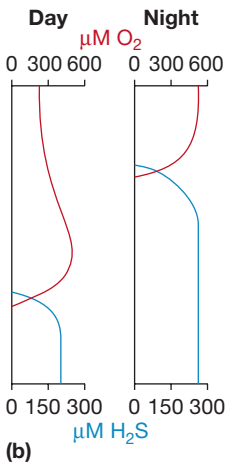
Microbial growth rates in complex systems can be measured directly. Changes in microbial numbers are followed over time, and the frequency of dividing cells is also used to estimate production. Alternatively, the incorporation of radiolabeled components such as thymidine (a DNA constituent, usually labeled with ^3H) into microbial biomass provides information about growth rates and microbial turnover. This approach is most easily applied to aquatic microorganisms; it is more difficult to directly observe terrestrial microbial communities.

Aquatic microorganisms can be recovered directly by filtration; the volume, dry weight, or chemical content of the microorganisms can then be measured. It is sometimes not possible to directly measure cell density. In that case, carbon, nitrogen, phosphorus, or an organic constituent of the cells (such as protein) can be determined. This will give a single-value estimate of the microbial community. Such chemical measurements are typically expressed as microbial biomass.

To determine community activity, it is necessary to have a good understanding of the microenvironment inhabited by the microbial community in question. In many ecosystems, these microhabitats are studied by **microelectrodes**—electrodes capable of measuring pH, oxygen tension, H_2, H_2S, or nitrogen species. The tips of these electrodes range from 2–5 μm wide and 100–200 μm long, enabling measurements to be taken as the tip penetrates the sample in increments of a millimeter or less. Because these parameters include electron donors (e.g., sulfide, ammonium) and acceptors (e.g., oxygen, nitrate, sulfate), microbial activities can be inferred. Microelectrodes have been widely used in the study of **microbial mats** (**figure 29.10**). These highly



(a)



(b)

Figure 29.10 Microelectrode Analysis of Microbial Mats. (a) Microorganisms, through their metabolic activities, can create environmental gradients resulting in layered ecosystems. A vertical section of a hot spring (55°C) microbial mat, showing the various layers of microorganisms. (b) The measurement of oxygen and H_2S with microelectrodes demonstrates the diurnal shift in gas production: during the day, oxygen produced by cyanobacteria in the upper layers inhibits anaerobic respiration, so sulfate reduction is confined to the lower (dark) strata. At night, atmospheric oxygen has a limited range of diffusion into the mat, and H_2S diffuses upward, where it can be used as an electron donor by purple photosynthetic bacteria.

striated communities of photoautotrophs and chemoheterotrophs develop in saline lakes, marine intertidal zones, and hot springs.

In determining community function, it is often instructive to explore the cycling of a particular elemental species. In aquatic and marine systems, the amount of carbon fixed by microbes is an important measurement. This is most commonly accomplished by measuring how much radioactive bicarbonate ($H^{14}CO_3$) is taken up by microbes. As we discuss in chapter 30, when bicarbonate dissolves in water, it dissociates to CO_2. Thus when added to a sample of microbes, its incorporation into particulate carbon (i.e., biomass) represents the gross primary production; that is, the total amount of carbon fixation without accounting for CO_2 lost through respiration. Specialized CO_2 traps can be added to the incubation vessel so that the amount of CO_2 lost by respiration is also measured. When CO_2 respired is subtracted from the amount of CO_2 fixed into biomass, net primary production has been assessed.

In addition to radioactive isotope incorporation, **stable isotope analysis** may be used. Isotopes are those forms of elements that differ in atomic weight because they bear different numbers of neutrons. Isotopes can be stable or unstable; only radioactive isotopes are unstable and decay. As shown in **table 29.2**, stable isotopes are rare when compared to their lighter counterparts. For example, both ^{14}N and ^{15}N occur in nature, but ^{14}N is found in much greater abundance. Organisms discriminate between stable isotopes, and for any given element, the lighter (in this case, ^{14}N) is preferentially incorporated into biomass, a phenomenon known as **isotope fractionation.** This discrimination can be used to follow the fate of a specific element by labeling the compound of interest with the heavier isotope. For instance, one might want to explore the fate of NO_3^- in soil. Samples of the soil would be incubated in the presence of $^{15}NO_3^-$. One would then sample the soil microorganisms and measure the amount of ^{15}N incorporated into biomass, released as $^{15}N_2$, and reduced to $^{15}NH_4^+$. However, because the absolute value of ^{15}N is so small, it cannot be directly measured. Instead, the ratio of ^{15}N to ^{14}N in the sample is compared to the standard ratio found in inorganic material. An organism that assimilates the $^{15}NO_3^-$ would contain more ^{15}N when compared to the standard. This difference, called delta (δ), is calculated as follows:

$$[(R_{sample} - R_{standard})/(R_{standard})] \times 1{,}000 = \delta_{sample\text{-}standard}$$

where R_{sample} is the ratio of heavy to light isotope in the sample and $R_{standard}$ is the ratio of heavy to light isotope in the standard. For instance, if our hypothetical soil community is found to have a $^{15}N/^{14}N$ ratio greater than the standard by 3 parts per thousand, this value is reported as $\delta\ ^{15}N = +3$ δ o/oo. The true value of stable isotope fractionation rests in the fact that different microbes discriminate between heavy and light isotopes differently. For instance, nitrate production can be discerned from N_2 formation because the isotopic enrichment factor for denitrification is less than that for nitrification (about −26 o/oo vs. −34 o/oo, respectively).

Another technique, called **stable isotope probing,** can be used to examine nutrient cycling in microbial communities as well as identify the microbes taking up the element of interest. As an example, this technique was employed to explore methanogenesis in a rice paddy soil ecosystem. Researchers built **microcosms**—small incubation chambers with conditions that mimic the natural setting. In this case, they simulated natural rice paddies and introduced $^{13}CO_2$. Gaseous $^{13}CH_4$ was collected and RNA was isolated from the soil. The ^{12}C-containing RNA was separated from the ^{13}C-RNA on the basis of differing densities. The ^{13}C-containing rRNA, which could only be synthesized by those bacteria that assimilated the $^{13}CO_2$, was then used to identify these archaea; recall that all methanogenic microbes are archaea. This study demonstrates the value and importance of culture-independent approaches that combine biogeochemistry and molecular biology to understand microbial community ecology and physiology. ◀◀ *Methanogens and methanotrophs (section 20.4)*

Molecular Approaches

As introduced in section 18.3, the use of metagenomics to investigate natural populations has revolutionized the depth to which community dynamics can be assessed. Metagenomics applied to diverse natural habitats can have several outcomes, including the identification of new genes and gene products from uncultured microbes, the assembly of whole genomes, and comparisons of community gene content from microbial assemblages of different origin. Metagenomic data can also be used to validate the measurement of gene expression when mRNA is extracted directly from the environment. Researchers are finding large numbers of new genes from metagenomic analysis, and it is agreed that the discovery of new genes is far from complete. In fact, the number of metagenomic sequences obtained from uncultivated microbes in mixed assemblages outnumbers data sets obtained from microbes grown in pure culture. Here we discuss a few metagenomic approaches that are most commonly used by microbial ecologists.

Recall that metagenomics involves the nucleotide sequencing of community DNA fragments. These nucleotide sequences can be used to infer community function. Metagenomes from a variety of biomes (e.g., mines, hypersaline ponds, marine water,

Table 29.3 Example Genes Used to Assess Community Function and Metabolic Diversity

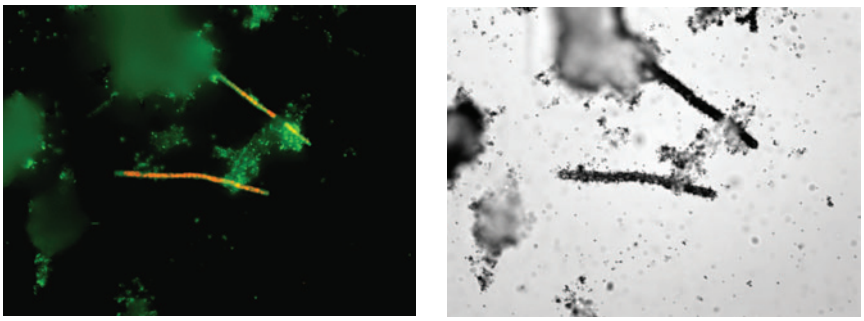
freshwater, etc.) can predict the biogeochemical conditions of a habitat. For instance, community metagenomes from a well-oxygenated coral reef are rich in genes encoding respiration proteins, while the metagenomes from the colons of terrestrial animals have a high number of genes coding for enzymes involved in fermentation.

mRNA present in the environment can also be monitored, a technique called **metatranscriptomics**. Here mRNA extracted from the natural environment is reverse transcribed to cDNA (*see figure 17.5*) and directly analyzed by next-generation sequencing. The presence of mRNA demonstrates that a gene is actively transcribed and the gene product is probably active. Thus, one can assess community activity at the time the sample was collected. However, rather than surveying the entire genetic landscape, a researcher may be interesting in a particular metabolic function. In this case, a specific gene or mRNA encoding enzymes of interest would be targeted by specific primers. Example genes are listed in **table 29.3**. Such studies have shown that both dissimilatory nitrate reduction and the anammox reaction account for loss of nitrogen in specific habitats.

Microarray analysis can also be used to assess community function. **Functional gene arrays (FGAs)** are prepared with sequences of genes known to be important in biogeochemical cycling processes (table 29.3). However, the use of microarrays to assess microbial communities is inherently problematic: only known genes can be used to make oligonucleotide probes. This generates an information bias such that no novel genes in the community can be detected. In addition, the interpretation of community-based microarrays is challenging because the mRNA pool is derived from multiple genera. This results in varying levels of homology to different probes. In turn, this can generate high background levels of fluorescence and obscure valid results. It is for these reasons that metatranscriptomics is becoming the preferred method for evaluating microbial gene expression in environmental samples. ⏮ *Transcriptome analysis (section 18.5)*

Unfortunately, most mRNAs are unstable, making recovery technically challenging. Instead of measuring mRNA, a **metaproteomics** approach can be used to identify each protein present at the time of sampling. There are two general approaches by which all the proteins in a community can be sampled and identified. The more labor-intensive technique uses 2D-polyacrylamide gel electrophoresis (2D-PAGE) so that each protein recovered from the environment is visualized (*see figure 18.16*). Individual proteins can be eluted from the gel and analyzed by mass spectroscopy (MS). Total peptide mass and amino acid sequence information is then used to search databases to identify the protein. This approach is best if the relative concentration of individual proteins is considered important. If a census of proteins is the goal, a more automated, high-throughput approach is taken. Here community proteins are extracted and digested with a protease to generate protein fragments called peptides. This mixture of peptides is separated by a technique known as 2D nano-liquid chromatography (nano-LC). Just as 2D gels separate proteins first by charge and then by molecular weight, 2D nano-LC separates peptides by two different properties: peptides are first separated by charge and then by hydrophobicity. The peptide masses are determined by advanced mass spectrometry, and finally, tandem MS is used to obtain amino acid sequence information. In both cases, the protein sequences obtained are compared to metagenomic data obtained from the same environment. Metaproteomics is limited by the complexity of the environment being assessed. Complex environments such as a pristine soil may have as many as a billion or more different proteins per gram. Even the most advanced and automated MS approaches are not yet able to resolve such a large and diverse group of proteins. ⏮ *Proteomics explores total cellular proteins (section 18.5)*

Both metatranscriptomics and metaproteomics seek to assess activities that are actually taking place in the environment. Another method that also measures active processes uses FISH to identify specific mRNAs (figure 29.7). This approach is called **in situ reverse transcriptase (ISRT)-FISH.** Recall that in situ means "in place," so this technique allows the microbial ecologist to examine specimens and determine if a gene of interest is being expressed, as well as visualize the microbes expressing it. Let's say that one is interested in recently identified archaea capable of nitrification (*see figure 22.15*). These microbes must express the *amoA* (ammonia monooxygenase) gene to oxidize ammonium to nitrite (table 29.3). One could design an *amoA* DNA probe—a short piece of DNA that is complementary to the *amoA* mRNA. Once the DNA probe has hybridized to the *amoA* mRNA in the natural sample, reverse transcriptase is used to generate a cDNA, which is then amplified by PCR. One now has an abundance of nucleotide fragments that can be fluorescently tagged in FISH. In our example of the archaeal nitrifier, we might want to determine where these archaea are metabolically active in the water column of an oceanic sampling station. Water samples of varying depths would be collected and filtered on board a research vessel. The filters would most likely be fixed



(a) (b)

Figure 29.11 MAR-FISH Technique Combines Microautoradiography with FISH in a Single Sample. Cells of interest are triple-labeled for identification and measurement of metabolic activity even if present in a complex microbial community. (a) The filamentous microbe of interest was identified using a FISH probe that generates an orange signal under fluorescence microscopy. The green fluorescence is the result of a dye (YO-PRO-1) that binds to double-stranded nucleic acid such as DNA of the bacteria. (b) MAR resulted in black staining of the filamentous bacteria when viewed under bright field microscopy, indicating that the microbes took up (assimilated) ^{3}H-labeled amino acids.

with preservative for later analysis (it is difficult to perform microscopy on a moving boat). The data collected by ISRT-FISH would indicate where archaeal nitrification was most active. This could then be correlated with physical parameters such as light penetration, oxygen concentration, and levels of nitrate, nitrite, ammonia, and dissolved organic nitrogen. In this way, the microbial ecologist can begin to build a hypothesis about the importance and distribution of these interesting microbes.

But what if one wanted to identify the microbe responsible for a specific metabolic activity? Recall that ISRT-FISH enables the visualization of the microbes expressing a specific gene but does not identify the microbe. To simultaneously assess metabolic activity and phylogenetic identity, a technique that combines an older method, **microautoradiography** (**MAR**), with FISH can be employed. This method is thus called MAR-FISH. To understand MAR-FISH, it is necessary to first explain MAR. In MAR, a radioactive substrate is mixed with the sample and incubated under specific conditions, usually closely resembling those in the field. At the completion of the incubation period, the sample is washed to remove any radioactive substrate not taken up by the cells. A sample attached to a microscope slide is treated with a photographic emulsion. The slide is carefully wrapped and stored in complete darkness. As the incorporated radioactive material decays, the silver grains in the photographic emulsion are exposed. When developed, this leaves a series of black dots around the cells that assimilated the radioactive substrate (**figure 29.11**). When MAR is combined with FISH, one can analyze the phylogenetic identity and the specific substrate uptake patterns of microbes of interest at the level of a single cell in complex microbial communities.

Retrieve, Infer, Apply

1. How do radioactive and stable isotopes differ? Design an experiment to determine whether or not denitrification is taking place in a soil ecosystem.
2. How might microelectrodes be used to gather data in preparation for a stable isotope study?
3. How do functional gene arrays differ from phylochips? When would one use a functional gene array, rather than a phylochip?
4. What is metaproteomics? How is it similar to metagenomics? How does it differ?
5. What is the difference between MAR and MAR-FISH? Suggest a microbial ecology question that could be answered by MAR and one that would require MAR-FISH.

Key Concepts

29.1 Microbial Biology Relies on Cultures

- Enrichment cultures are used to promote the growth of one type of microbe, while suppressing the growth of others. This is accomplished by designing media and culture conditions that favor the growth of the desired microorganisms but limit the growth of others.
- Although most microbes cannot be grown in pure culture, novel approaches have been developed that have resulted in the isolation of previously uncultured microorganisms.

29.2 Genetic Methods Are Used to Assess Microbial Diversity

- A variety of staining techniques are used to observe microbes in natural environments. Fluorescent in situ hybridization (FISH) labels specific microbes that possess a specific nucleotide sequence, usually a region of the SSU rRNA gene (**figures 29.5–29.7**).
- A survey of SSU rRNA is the most common approach for assessing microbial diversity. There are several approaches by which SSU rRNA can be recovered; those that do not use PCR to amplify rRNA genes are gaining popularity because they avoid PCR bias.
- Microarrays that have SSU rRNAs as probes, called phylochips, can quickly evaluate population and community diversity (**figure 29.9**).

29.3 Assessment of Microbial Community Activity Relies on Biochemistry and Genetics

- Microelectrodes can be used to determine physical and biological parameters such as pH, O_2, and H_2S concentrations in microniches (**figure 29.10**).

- Stable isotope analysis is based on the fact that organisms discriminate between heavy and light naturally occurring isotopes. It is often used to monitor nutrient flux through ecosystems.
- Metatranscriptomics assesses community activity by measuring microbial gene expression.
- Metaproteomics can be used to identify the proteins that are expressed by a microbial community. Because the number of proteins is so large, traditional 2D gel analysis is usually not practical and high-throughput chromatographic techniques are used instead.

Compare, Hypothesize, Invent

1. How might you attempt to grow in the laboratory a chemolithoautotroph that uses ferrous iron as an electron donor and oxygen as an electron acceptor?
2. What genes would you use as probes on a functional array designed to assess microbial activity in the plankton of a nitrogen-limited aquatic ecosystem? Would direct sequencing of the mRNA from these genes provide a more accurate assessment? Why or why not?
3. Both acetate and CO_2 can be used by methanogenic archaea to generate methane (CH_4). How would you determine the source of carbon for methanogenesis in a waterlogged peat?
4. Kindaichi and colleagues used FISH and microelectrodes to investigate the spatial organization of nitrifying and anammox microbes in a biofilm. Recall that nitrification is an aerobic process that involves ammonia oxidation to nitrite by both archaea and bacteria followed by nitrite oxidation to nitrate by bacteria. Gram-negative bacteria in the phylum *Planctomycetes* perform the anammox reaction—the anaerobic oxidation of ammonium with nitrite as the electron acceptor and N_2 as the major end product (*see figure 21.16*). Explain the purpose of each technique used by these investigators. How do you think these approaches would contribute to an understanding of the spatial distribution of each type of microbe as well as help document the metabolic process occurring in each microregion of the biofilm?

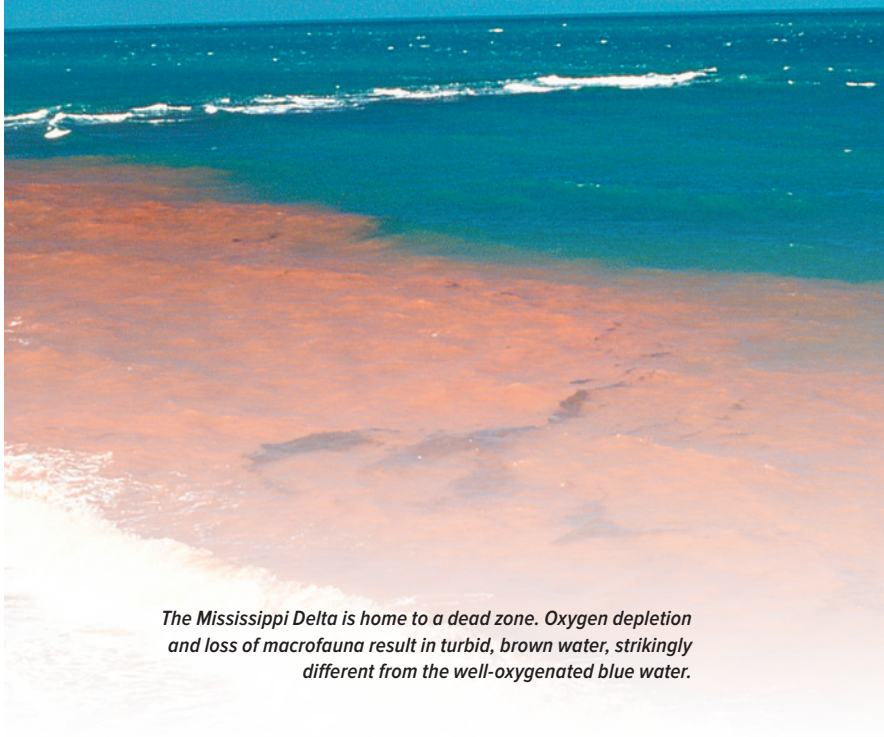
Microorganisms in Marine and Freshwater Ecosystems



The Mississippi Delta is home to a dead zone. Oxygen depletion and loss of macrofauna result in turbid, brown water, strikingly different from the well-oxygenated blue water.

Ocean Death Coming Soon to a Coast Near You

If you live near a coast, you probably live not far from an ocean dead zone. These regions, more technically called "oxygen minimum zones," have been increasing in size and distribution over the past decade and could occupy as much as 20% of the world's oceans by 2100.

Ocean dead zones are regions in which all plant and animal life dwelling below the surface has suffocated. The twenty-first century has brought the convergence of global climate change and water pollution (in the form of nitrogen and phosphorus fertilizer) to coastal ecosystems. Dead zones result when phytoplankton respond to increases in nutrients and temperature by growing (and growing and growing) and then sinking. Initially, phytoplankton on the ocean floor means more food for heterotrophic organisms. But as the number of oxygen-consuming animals and microbes increases, available oxygen dwindles. Invertebrates and fish die. Plants cannot grow because there is not enough light. The only organisms left are anaerobic chemolithoautotrophs—microbes that make a living fixing CO_2 and extracting energy from reduced inorganic compounds.

Of the more than 500 oxygen minimum zones globally covering over 245,000 square kilometers, the Baltic Sea is the largest, while the second largest dead zone is at the mouth of the Mississippi River. This mighty river dumps fertilizer collected from watersheds ranging from Montana to Louisiana. The addition of literally tons of extra nitrogen and phosphorus to the Gulf of Mexico has resulted in a dead zone that is 22,015 km^2, roughly the size of New Jersey. The presence of such a large dead zone has huge and obvious implications for fisheries, sea birds, tourism, and the overall health of the Gulf.

Are dead zones reversible? In some cases, yes. But like most problems, prevention is the best approach. Prudent use of fertilizer and limiting surface runoff are good places to start. Another area of concern is the deposition of animal waste into local waterways. Finally, proper sewage treatment (*section 43.2*) and the restoration of natural wetlands to filter and consume much of the nitrogen and phosphorus before it flows to the coast are projects worth pursuing.

In this chapter, we turn our attention to the microbial ecology of aquatic environments. The two main disciplines of aquatic biology are oceanography and limnology. **Oceanography** is the study of marine systems and the biological, physical, geological, and chemical factors that impact biogeochemical cycling, water circulation, and climate. Microbial oceanography seeks to understand marine microorganisms at the level of the individual taxon and at the same time elucidate how they influence biogeochemical cycling at a global level. **Limnology** is the investigation of aquatic systems within continental boundaries, including glaciers, groundwater, rivers, streams, and wetlands. All terrestrial life depends on the sustained provision of clean freshwater from these ecosystems. This chapter provides a brief introduction to these dynamic and interdisciplinary fields.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Explain the global impact that microbes have on carbon and nitrogen cycling (section 28.1)
- ✔ Diagram the viral life cycle (section 6.3)
- ✔ List environmental factors that influence microbial growth (section 7.4)
- ✔ Compare and contrast the growth and physiology of obligate aerobes, facultative anaerobes, and strict anaerobes (section 7.4)
- ✔ Explain why and how microbes frequently grow in biofilms (section 7.5)
- ✔ Explain how the oxidation-reduction (redox) state of an environment impacts the types of microbial metabolic processes that might be found there (section 28.1)
- ✔ Identify, by nutritional type, microorganisms responsible for carbon fixation, nitrogen fixation, nitrification, dissimilatory nitrate reduction, denitrification, nitrification, the anammox reaction, and sulfur reduction (sections 20.3, 21.4, 21.5, 22.1, 22.3, and 22.4)
- ✔ Review innovative methods for growing microbes isolated from nature in the laboratory (section 29.1)

30.1 Water Is the Largest Microbial Habitat

After reading this section, you should be able to:

- Explain the carbonate equilibrium system and why it is important in the study of marine microbial biology

Microbes drive marine and freshwater ecosystems. They are the most diverse and abundant organisms in these habitats. The importance of microbial activities in oceans, rivers, and lakes has been brought into sharp focus by global climate change. To understand the capacity of microbes to influence the worldwide flux of nutrients and greenhouse gases, we must first consider marine and freshwater habitats.

The nature of water as a microbial habitat depends on a number of physical factors such as temperature, pH, and light penetration. One of the most important factors is dissolved oxygen. The flux rate of oxygen through water is about 10,000 times less than its rate through air. However, in some aquatic habitats, the limits to oxygen diffusion can be offset by the increased solubility of oxygen at colder temperatures and increasing atmospheric pressures. For instance, in the very deep ocean, the dissolved oxygen concentration actually increases with depth, even though the air-water interface can be literally miles away. On the other hand, tropical lakes and summertime temperate lakes may become oxygen limited only meters below the surface.

As seen in the development of dead zones (chapter opening story), light is also critical for the health of marine and freshwater ecosystems. Like all life on Earth, all organisms in these environments depend on **primary producers**—autotrophic organisms—to fix CO_2, thereby providing organic carbon. In streams, lakes, and coastal marine systems, macroscopic algae and plants are the chief primary producers. Organic carbon also enters these systems in terrestrial runoff. The situation is very different in the open ocean, where all organic carbon is the product of microbial autotrophy. In fact, about half of all **primary production** (carbon fixation) on Earth is the result of this microbial carbon fixation.

Solar radiation warms the water, and this can lead to thermal stratification. Warm water is less dense than cool water, so as the sun heats the surface in tropical and temperate waters, a **thermocline** develops. A thermocline can be thought of as a mass of warmer water floating on top of cooler water. These two water masses remain separate until there is either a substantial mixing event, such as a severe storm, or in temperate climates, the onset of autumn. As the weather cools, the upper layer of warm water becomes cooled and the two water masses mix. This is often associated with a pulse of nutrients from the lower, darker waters to the surface. This pulse of nutrients can trigger a sudden and rapid increase in the population of certain microbes, and a bloom may develop. This is considered more fully in the discussion of microorganisms in coastal marine systems (p. 653) and lakes (p. 663).

Because CO_2 is critical in many chemical and biological processes, it is important to understand its fate in freshwater and marine ecosystems. The pH of unbuffered distilled water is determined by dissolved CO_2 in equilibrium with the air and is typically 5.0 to 5.5. The pH of freshwater systems such as lakes and streams, which are usually only weakly buffered, is therefore controlled by terrestrial input (e.g., minerals that may be either acidic or alkaline) and the rate at which CO_2 is removed by photoautotrophic organisms such as diatoms; CO_2 fixation can increase the pH of the water.

In contrast, seawater is strongly buffered by the balance of CO_2, bicarbonate (HCO_3^-), and carbonate (CO_3^{2-}). Atmospheric CO_2 enters the oceans and either is converted to organic carbon by photosynthesis or reacts with seawater to form carbonic acid (H_2CO_3), which quickly dissociates to form bicarbonate and carbonate (**figure 30.1**):

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \rightleftharpoons 2H^+ + CO_3^{2-}$$

The oceans are effectively buffered between pH 7.6 and 8.2 by this **carbonate equilibrium system.** Much like the buffer one might use in a chemistry experiment, the pH of seawater is determined by the relative concentrations of bicarbonate and carbonate.

The reactions of the carbonate equilibrium system have taken on new importance as increases in atmospheric CO_2 result in higher rates of CO_2 dissolution in seawater. In fact, the ocean is already absorbing about half the anthropogenically produced CO_2. This has led to **ocean acidification;** the average pH of the ocean has dropped by 0.1 unit (to 8.1) since the pre-industrial age. It is expected to decline another 0.35 to 0.50 by 2100, unless

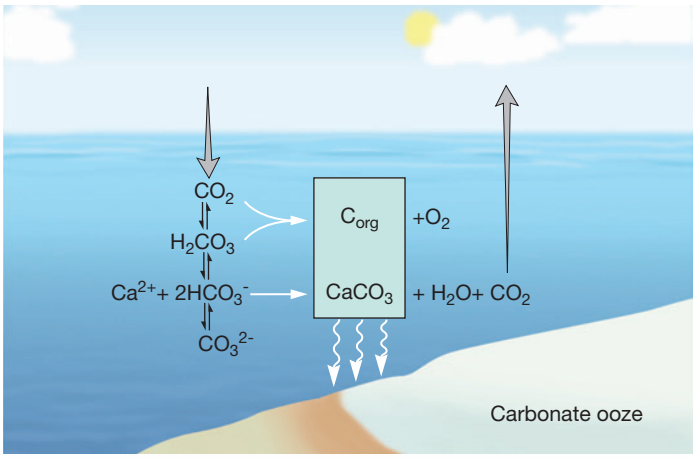


Figure 30.1 The Carbonate Equilibrium System. Atmospheric CO_2 enters seawater and is converted to organic carbon (C_{org}) or to carbonic acid (H_2CO_3) that rapidly dissociates into the weak acids bicarbonate (HCO_3^-) and carbonate (CO_3^{2-}). Calcium carbonate ($CaCO_3$), a solid, precipitates to the seafloor, where it helps form a carbonate ooze. This system keeps seawater buffered at about pH 8.0.

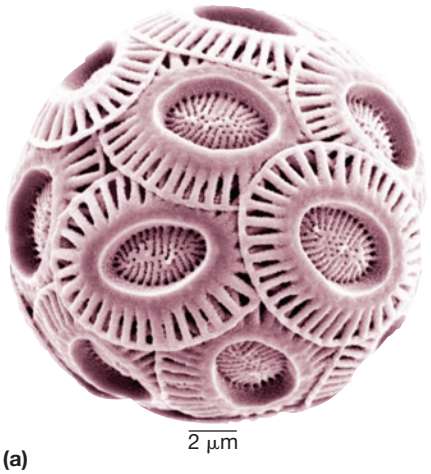
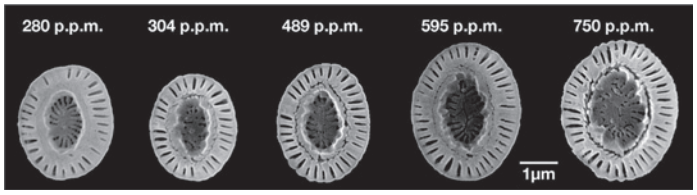
MICRO INQUIRY *Which carbon species, CO_2 or CO_3^{2-}, acidifies seawater?*



(a)



(b)

Figure 30.2 Coccolithophores Respond to Seawater Acidification. (a) *Emiliania huxleyi,* an abundant species in the open ocean. (b) *E. huxleyi* coccoliths increase in size when grown in high partial pressures of CO_2. In addition to an increase in size, the coccolith shape can become distorted above 400 ppm CO_2, the value of atmospheric CO_2 measured in 2014.

effective means of limiting CO_2 emissions are implemented. This is significant because as CO_2 increases, the carbonate equilibrium shifts away from $CaCO_3$, potentially limiting its availability for the formation of shells and skeletons of marine organisms. Because protists known as coccolithophores produce about a third of the marine $CaCO_3$, they have been the focus of investigations seeking to predict the effects of ocean acidification. While responses are species specific, it is clear that these seemingly slight shifts in pH have an impact (**figure 30.2**). Ocean acidification is also having a negative impact on corals. Although it is difficult to predict, some models estimate that when atmospheric CO_2 reaches about 550 ppm, many corals will begin to erode faster rather than grow. If left unchecked, this threshold will be crossed in about 50 years. ◀◀ Haptophyta *(section 25.4); Global climate change (section 28.2)*

Retrieve, Infer, Apply

1. What factors influence oxygen solubility? How is this important in considering aquatic environments?
2. Describe the buffering system that regulates the pH of seawater. What might be the implications of this stable buffering on microbial evolution?
3. How does primary production in lakes and coastal ecosystems differ from that in the open ocean?
4. What features of a thermocline make it similar to hot and cool masses of air?

30.2 Microorganisms in Marine Ecosystems

After reading this section, you should be able to:

- Explain the ecological and economic importance of estuaries and harmful algal blooms
- Diagram carbon and sulfur flux in a Winogradsky column
- Assess the importance of marine microbial primary productivity in the global carbon budget
- Evaluate the interplay between carbon, nitrogen, and iron in the open ocean and how the relative concentrations of these elements influence the productivity of these waters
- Illustrate the microbial loop and evaluate its importance in the open ocean
- Evaluate the importance of members of the SAR11 clade in marine ecosystems
- Describe at least three mechanisms microbes have evolved to adapt to the low nutrient conditions found in the open ocean
- Explain the role of viruses in maintaining and influencing marine microbial populations, as well as their contribution to nutrient cycling
- Convince a layperson that the vast majority of microbes reside below the surface of the Earth
- Explain the distribution of microbial types that inhabit a cross-section sediment

As terrestrial organisms, we must remind ourselves that about 96% of Earth's water is in marine environments. From a microbiological perspective, surface ocean waters have been most intensely studied; only recently have scientists begun to probe the benthos—the deep-sea sediments and the subsurface. Investigations of this kind are revealing many surprises. We begin our discussion of marine ecosystems with estuaries, then consider the microbial communities that inhabit the open ocean and, finally, the dark, cold, high-pressure benthos.

Microorganisms in Coastal Ecosystems Are Adapted to a Changeable Environment

An estuary is a semi-enclosed coastal region where a river meets the sea. Estuaries are defined by tidal mixing between freshwater and saltwater. Most estuaries undergo large-scale tidal flushing; this forces organisms to adapt to changing salt concentrations on a daily basis. Microbes that live under such conditions combat the resulting osmotic stress by adjusting their intracellular osmolarity to limit the difference with that of the surrounding water. Most protists and fungi produce osmotically active carbohydrates for this purpose, whereas bacteria and archaea regulate

internal concentrations of potassium or amino acids such as proline and betaine. Salt is another stressor, and most microbes that inhabit estuaries are halotolerant, which is distinct from halophilic. **Halotolerant** microbes can withstand significant changes in salinity; halophilic microorganisms have an absolute requirement for high salt concentrations. ⏮ *Solutes affect osmosis and water activity (section 7.4)*

Estuaries are unique in many respects. Their calm, nutrient-rich waters serve as nurseries for juvenile forms of many commercially important fish and invertebrates. However, despite their importance to the commercial fishing industry, estuaries are among the most polluted marine environments. Estuaries and the rivers that feed them are the receptacles of toxins discharged during industrial processes as well as agricultural and street runoff. These pollutants include organic materials that can be used as nutrients. If too much organic matter is consistently added, the system is said to be **eutrophic,** and the rate of respiration greatly exceeds that of photosynthesis. Thus the water may become anoxic (chapter opening story). By contrast, if nutrients are introduced in a pulselike fashion, a single photoautotrophic species, either algal or cyanobacterial, grows at the expense of all other organisms in the community. This phenomenon, called a **bloom,** often results from the introduction of nutrients combined with changes in light, temperature, and mixing of water masses. If the microbes produce a toxic product or are in themselves poisonous to other organisms such as shellfish or fish, the term **harmful algal bloom** (**HAB**) is used. Some HABs are called **red tides** because the microbial density is so great that the water becomes red or pink, the color of the algae (**figure 30.3**).

The number of HABs has dramatically increased in the last decade or so. It is predicted that global climate change may trigger more HABs, in part because warmer water forms a more stable thermocline that lasts longer into the autumn. HABs are sometimes responsible for killing large numbers of fish or marine mammals. For instance, off the coast of California, periodic HABs are responsible for sudden, large-scale deaths of sea lions. These blooms are often caused by diatoms in the genus *Pseudonitzschia*. Anchovies consume the diatoms, and a potent neurotoxin, domoic acid, accumulates in the fish. The mammals are poisoned after they ingest large quantities of the fish. ⏮ Stramenopila *(section 25.4)*

In addition to diatoms, HABs are often caused by dinoflagellates. Some bloom-causing dinoflagellates produce potent neurotoxins. Dinoflagellates of the genus *Alexandrium* produce a toxin responsible for paralytic shellfish poisoning (PSP), which affects humans as well as other animals in coastal, temperate North America. The toxin produced by the dinoflagellate *Karenia brevis* killed a number of endangered manatees and bottlenose dolphins in 2002 in a bloom in Florida. Another dinoflagellate, *Pfiesteria piscicida,* has become a problem in the Chesapeake Bay and regions south. This protist produces lethal lesions in fish (**figure 30.4**) and has had a devastating effect on the local fishing industry. Exposure to this microbe may also cause neurological damage to humans. ⏮ Alveolata *(section 25.4)*

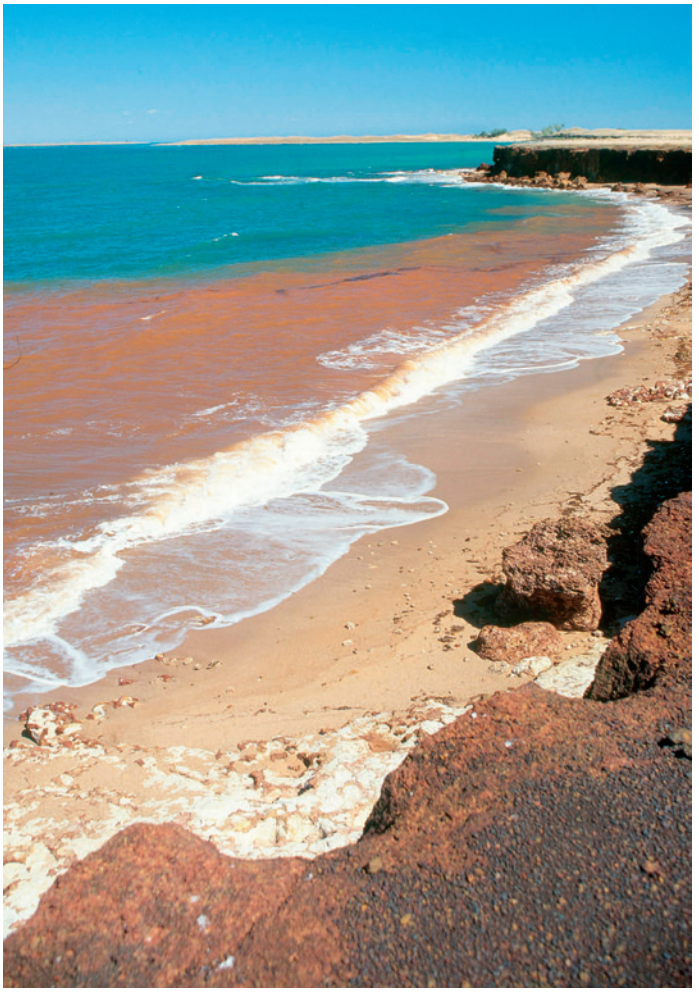


Figure 30.3 Harmful Algal Blooms Are Also Called Red Tides. Blooms often color the water with the pigment of the microbe responsible. In this case, a dinoflagellate has turned the water pink-orange.

Figure 30.4 *Pfiesteria piscicida* Lesions. Lesions on a fish resulting from parasitism by the dinoflagellate *Pfiesteria piscicida.*

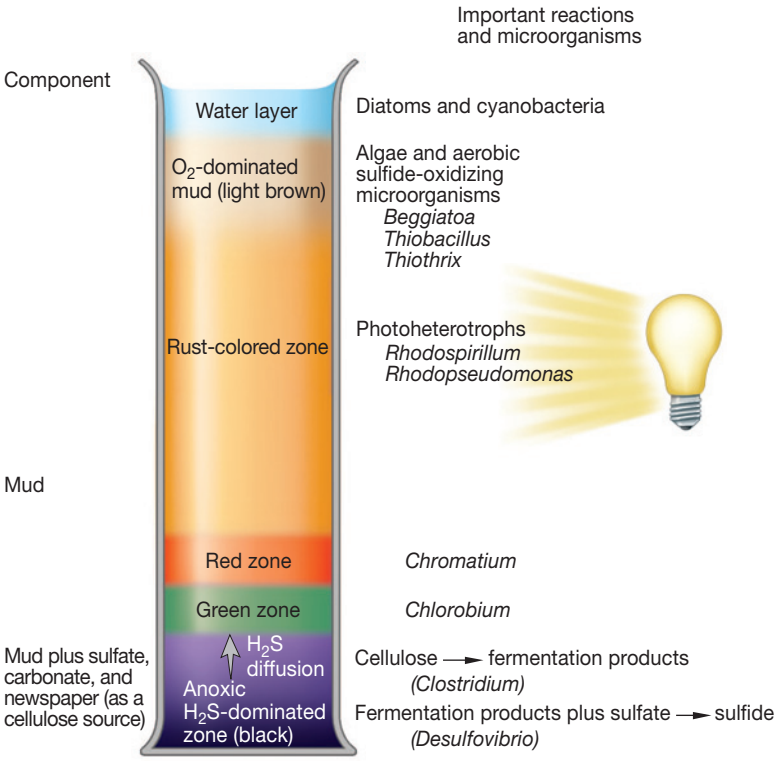

Figure 30.5 The Winogradsky Column. Microorganisms and nutrients interact over a vertical gradient in these microcosms. Fermentation products and sulfide migrate up from the reduced lower zone, and oxygen penetrates from the surface. This creates conditions similar to those in a lake or salt marsh with nutrient-rich sediments. Light simulates the penetration of sunlight into the anoxic lower region, which stimulates photosynthetic microorganism growth.

MICRO INQUIRY *How is sulfur cycled between the anoxygenic photosynthetic microbes belonging to the genera* Chlorobium *and* Chromatium, *and anaerobic heterotrophic* Desulfovibrio spp.?

Salt marshes generally differ from estuaries because their freshwater input is from multiple sources, rather than a single river. The microbial communities within salt marsh sediments are very dynamic. These ecosystems can be modeled in **Winogradsky columns** (**figure 30.5**), named after the pioneering microbial ecologist Sergei Winogradsky (1856–1953).

A Winogradsky column is easily constructed using a glass cylinder into which sediment is placed and then overlaid with saltwater. When the top of the column is sealed, much of the cylinder becomes anoxic. The addition of shredded newspaper introduces a source of organic carbon that is fermented by members of the genus *Clostridium*. With these fermentation products available as electron donors, *Desulfovibrio* spp. and other microbes use sulfate as a terminal electron acceptor to produce hydrogen sulfide (H_2S). The H_2S diffuses upward, creating a stable H_2S gradient where photolithoautotrophs of the genera *Chlorobium* and *Chromatium* develop as visible olive green and purple zones, respectively. These green and purple sulfur bacteria, respectively, use H_2S as an electron source and CO_2, from sodium carbonate, as a carbon source. Above this region, purple nonsulfur bacteria of the genera *Rhodospirillum* and *Rhodopseudomonas* can grow. These photoorganotrophs use organic matter as an electron donor under anoxic conditions and function in a zone where the sulfide level is lower. Both O_2 and H_2S may be present higher in the column, promoting the growth of other microorganisms. These include the chemolithotrophs in the genera *Beggiatoa* and *Thiothrix,* which use reduced sulfur compounds as electron donors and O_2 as an acceptor. In the upper, aerated portion of the column, diatoms and cyanobacteria may be visible. ⏮ *Anaerobic respiration uses the same three steps as aerobic respiration (section 11.7); Phototrophy (section 11.11); Photosynthetic bacteria are diverse (section 21.4); Purple nonsulfur bacteria perform anoxygenic photosynthesis (section 22.1); Class* Gammaproteobacteria *is the largest bacterial class (section 22.3); Class* Clostridia *(section 23.1)*

Retrieve, Infer, Apply

1. Name two groups of protists known to cause HABs in marine ecosystems. What hazards do HABs pose for other marine organisms and humans?
2. Compare the chapter opening figure with figure 30.3 and explain why the water is brown in anoxic zones and may be red during an HAB.
3. Describe the ecosystem that develops within a Winogradsky column. Are any of these organisms chemolithotrophic? What would happen if the column were incubated in the dark for an extended period of time?

Microorganisms in the Open Ocean Are Adapted to Nutrient Limitation

Sometimes called "the invisible rain forest," the illuminated upper 200 to 300 meters of the open ocean, termed the **photic zone,** is home to a diverse collection of microbes. **Phytoplankton** (Greek *phyto,* plant, and *planktos,* wandering) are the source of all organic matter in the open ocean, with the exception of the hydrothermal vent and subsurface chemolithoautotrophic communities (*see figure 32.4*). Roughly half the carbon fixation in the open ocean is performed by cyanobacteria in the genera *Prochlorococcus* and *Synechococcus.* These microbes help constitute the **picoplankton** (planktonic microbes between 0.2 and 2.0 μm in size), which can represent 20 to 80% of the total phytoplankton biomass. Larger unicellular cyanobacteria (*Crocosphera watsonii*) and eukaryotic autotrophs, especially diatoms, contribute the other 50% of fixed carbon. ⏮ *Phylum* Cyanobacteria *(section 21.4);* Stramenopila *(section 25.4)* ⏭ *Sulfide-based mutualisms (section 32.1)*

In contrast to coastal regions, nutrient levels are extremely low in the open ocean, which is unaffected by rivers, streams, and terrestrial runoff. In the open-ocean nitrogen, phosphorus, iron, and even the silica diatoms need to construct their frustules can be limiting. The key to survival in the photic zone is the tight recycling of nutrients, rather than allowing them to sink to the seafloor; this is the essence of the **microbial loop** (**figure 30.6**). Within the microbial loop, heterotrophic microbes consume **dissolved organic matter** (**DOM**) released as exudates by other microbes as well as larger plants and animals. The DOM that

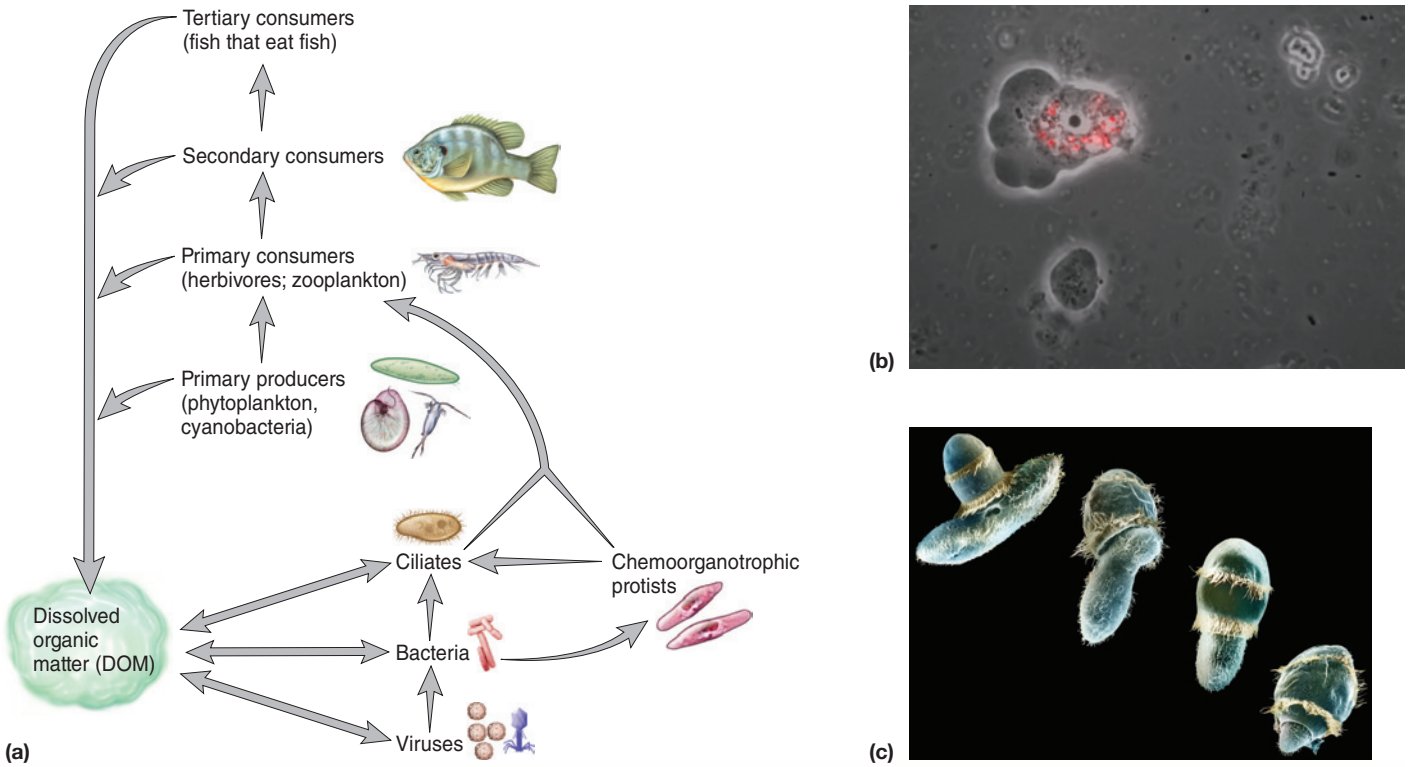

Figure 30.6 The Microbial Loop. (a) Microorganisms play vital roles in ecosystems as primary producers, decomposers, and primary consumers. All organisms contribute to a common pool of dissolved organic matter (DOM) that is consumed by microbes. Viruses contribute DOM by lysing their hosts, and bacterial and archaeal cells are consumed by protists, which also consume other protists. These microbes are then consumed by herbivores that often select food items by size, thereby ingesting both heterotrophic and autotrophic microbes. Thus nutrient cycling is a complex system driven in large part by microbes. (b) Protists consume bacteria; in this case, a naked amoeba is consuming the cyanobacterium *Synechococcus* sp. which fluoresces red. (c) Protists consume protists; here, the ciliate *Didinium* sp. (rounded organism with two rows of cilia) is preying upon another ciliate, *Paramecium* sp.

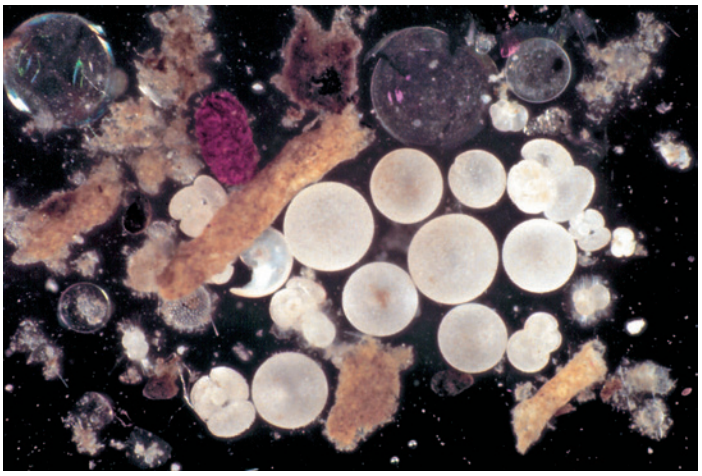
MICRO INQUIRY *How do heterotrophic microbes contribute to the pool of DOM? How does this compare with the manner by which microbial autotrophs contribute to the DOM pool?*

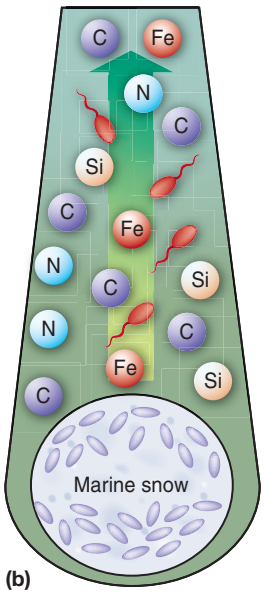
leaks from the photoautotrophic microbes is sometimes called **photosynthate.** Marine viruses, present at concentrations up to 10^8 per milliliter, are also a source of DOM as the lysis of their host cells contributes significantly to the return of nutrients into the microbial loop (p. 658). This generates a common pool of DOM that serves as a nutrient source for all osmotrophic organisms. Heterotrophic protists, including flagellates and ciliates, consume smaller microbes, which may include other protists (figure 30.6*b,c*). Microbial cells, insoluble detritus, and other solid organic material are called **particulate organic matter** (**POM**). Because protists are consumed by zooplankton, both DOM and POM are recycled at a number of trophic levels. The net effect of the microbial loop is the reuse of essential nutrients such as organic carbon, nitrate, and phosphate within the photic zone. Only 5 to 15% this material sinks to the waters below.

The fate of all the carbon fixed by marine phytoplankton has practical importance. Global climate change has focused intense scrutiny on determining how much CO_2 phytoplankton can remove from the atmosphere and sequester in the benthos. In other words, if the microbial loop could be overloaded, organic carbon that started out as atmospheric CO_2 might be pumped to the seafloor. This is sometimes called the "biological carbon pump," and it describes the export of carbon to the seafloor.

To understand how little carbon actually reaches the seafloor, we need to consider the fate of organic matter that escapes the photic zone and falls through the depths as **marine snow** (**figure 30.7*a***). This material gets its name from its appearance, sometimes seen in video images of mid- and deep-ocean water, where drifting flocculent particles resemble snow. Marine snow consists primarily of fecal pellets, diatom frustules, and other materials that are not easily degraded. During its fall to the bottom, marine snow is colonized by microbes so that nutrient recycling and mineralization continue. Bacterial population densities associated with marine snow can reach 10^8 to 10^9 per milliliter, which is orders of magnitudes higher than the surrounding water. These microbes secrete a variety of exoenzymes to break down organic polymers so the resulting monomers can be assimilated. As the marine snow sinks, it leaves a plume of DOM,

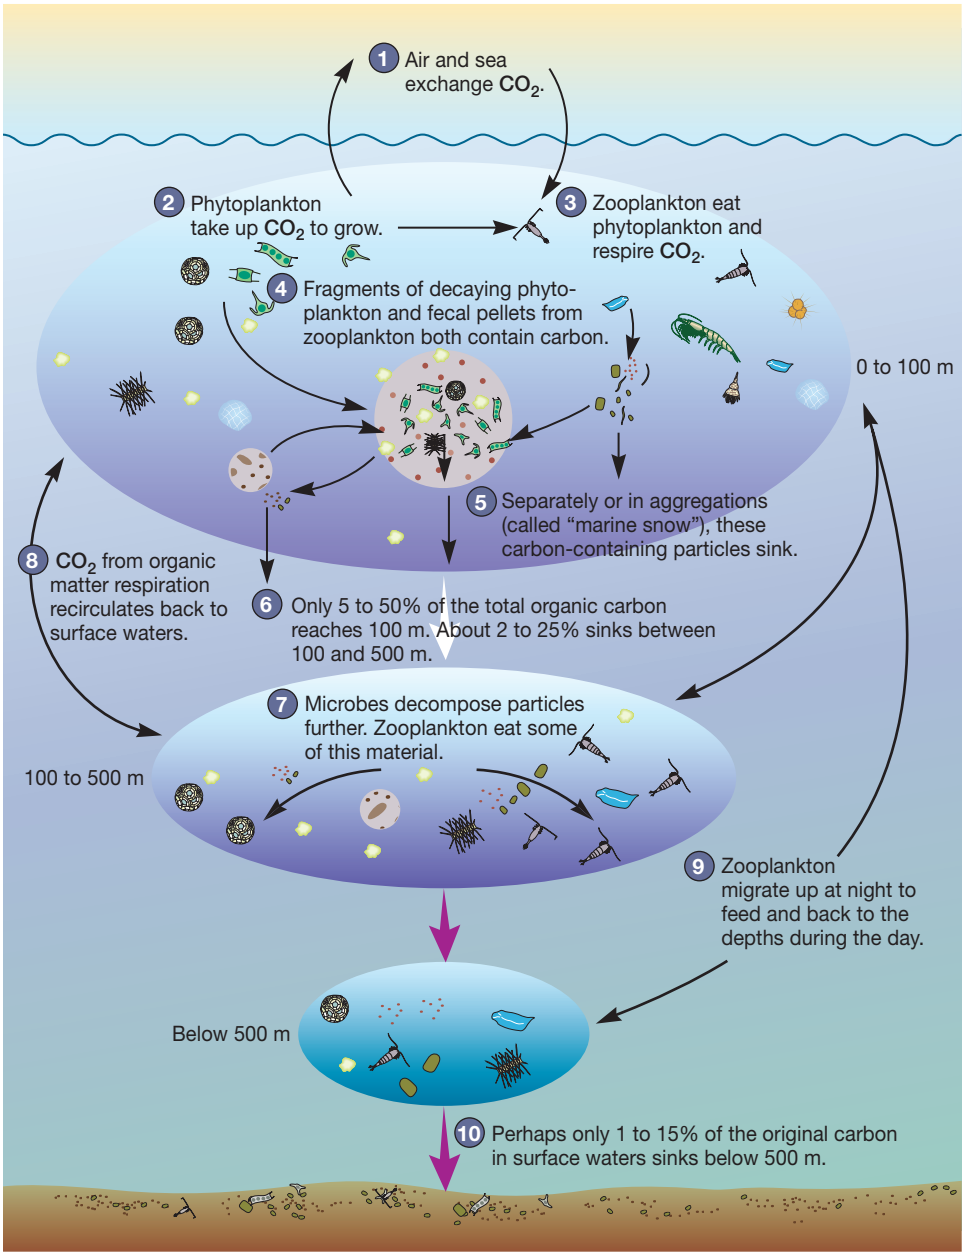


(a)



(b)

Figure 30.7 Marine Snow. The export of organic matter out of the photic zone to deeper water occurs through the sinking of marine snow. (a) Material collected in a sediment trap at 5,367 m on the Sohm Abyssal Plain in the Sargasso Sea. It includes cylindrical fecal pellets, planktonic tests (round white objects), transparent snail-like pteropod shells, radiolarians, and diatoms. (b) The hydrolytic activity of the exoenzymes secreted by the microbes that colonize marine snow generates a plume of nutrients during sinking. This in turn attracts more microbes.



nitrogen, phosphorus, and iron. These nutrients attract chemotactic free-swimming microbes, which help to deplete the nutrient pool even further (figure 30.7*b*). By the time a piece of marine snow reaches the seafloor, less than 1% of photosynthetically derived organic carbon remains unaltered. Once there, only a tiny fraction will be buried in the sediments; most will return to the surface in upwelling regions (**figure 30.8**).

An urgent question is whether or not the oceans can draw down (remove and bury) more CO_2 as atmospheric concentrations continue to increase. Presently it is estimated that about 3 billion tons of carbon per year are buried (sequestered) in deep-ocean sediments. Can increases in atmospheric CO_2 be offset by increasing the rate and volume of carbon sequestration? Could this in turn slow global warming? Such a scenario has been pursued in projects that fertilize

Figure 30.8 Fate of Carbon from the Photic Zone to the Deep Benthos. The vast majority of the carbon fixed by microbial autotrophs at the surface of the open ocean remains in the photic zone. Although a small fraction reaches the seafloor, much of it returns to the surface in regions where deep and surface waters mix (upwelling regions; not shown). The flux of CO_2 in and out of the world's oceans is in equilibrium, but this equilibrium may be upset by the increase in atmospheric CO_2, the hallmark of global warming.

Figure 30.9 **The Filamentous Cyanobacterium *Trichodesmium* sp. Fixes N_2 in the Open Ocean.**

specific regions of the oceans. These regions, known as high-nitrate, low-chlorophyll (HNLC) areas, are limited by iron. A number of experiments have been performed wherein large transects of the southern Pacific have been fertilized with iron to trigger diatom blooms. However, as shown in figure 30.8, the amount of CO_2 sequestered is minimal; the vast majority of the extra carbon that falls from the ocean's surface is consumed (and converted back to CO_2) before it reaches the bottom.

Unlike the HNLC areas, most of the open ocean is limited by nitrogen, not iron. Because there is no terrestrial runoff, the only source of "new" organic nitrogen at sea is biological nitrogen fixation. There appear to be at least four significant sources of N_2 fixation—all of which are cyanobacterial. For many years, it was thought that the filamentous cyanobacterium *Richelia intracellularis* was the only microbe that fixed significant amount of N_2. This microbe lives in association with certain diatoms. However, filamentous cyanobacteria of the genus *Trichodesmium* are now known to be much more important in terms of the amount of N_2 fixed (**figure 30.9**). This microbe drifts on the surface in rafts that cover many square meters in tropical and subtropical oceans. It protects its oxygen-sensitive nitrogenase enzyme by partitioning it to regions of trichomes (filaments) called diazocytes. Because the region of a filament that functions as a diazocyte is not separated from the rest of the trichome by a septum, these structures differ from heterocysts seen on other filamentous cyanobacteria (*see figure 21.13*). Another source of "new" nitrogen is the N_2-fixing, unicellular cyanobacterium *Crocosphera watsonii*. It measures 3 to 8 μm in diameter, making it much bigger than the other unicellular cyanobacteria in the genera *Synechococcus* or *Prochlorococcus. C. watsonii* is found in tropical surface waters.

The last source of "new" nitrogen is an unusual cyanobacterium first reported in 2008. This cyanobacterium fixes N_2 but lacks photosystem II and is photoheterotrophic. Organic carbon is fermented and because it uses only photosystem I no O_2 is produced, so, it can fix N_2 during the day. This microbe has not yet been cultured and is known only as UCYN-A. When observed in natural samples, it is a little less than 1 μm in diameter. It inhabits temperate latitudes, and unlike *Trichodesmium* spp., it is found in coastal waters as well as the open ocean. ⏮ *Nitrogen fixation (section 12.5); Phylum* Cyanobacteria *(section 21.4)*

In addition to nitrogen fixation, other components of the nitrogen cycle occur in the open ocean. Much of this cycling occurs below the photic zone, where oxygen concentrations reach a minimum before increasing with depth. Here two types of microbial-mediated reactions result in the loss of nitrogen as N_2 gas. The first is denitrification—anaerobic respiration using nitrate (NO_3^-) as a terminal electron acceptor and reducing it to N_2. The second is the anammox reaction—the anaerobic oxidation of ammonium (NH_4^+) to N_2 using nitrite (NO_2^-) as the terminal electron acceptor (*see figure 21.16*). These bacteria are members of the interesting phylum *Planctomycetes.* Nitrogen that escapes denitrification or anammox in the oxygen minimum zone and sinks further is mostly NH_3/NH_4^+. However, most of the nitrogen that accumulates at depth is nitrate (NO_3^-). This is because the NH_3/NH_4^+ is oxidized by microbes performing nitrification—the oxidation of NH_3 first to NO_2^- and then to NO_3^-. Most marine nitrification is accomplished by archaea in the phylum *Thaumarchaeota*. These mesophilic archaea oxidize NH_3 to NO_2^- which is then oxidized to NO_3^- by bacteria. The urgency to understand oceanic nitrogen cycling reflects concern about release of the greenhouse gas N_2O (principally by ammonia oxidizing archaea) and increasing levels of atmospheric CO_2. Many question the capacity of the world's oceans to consume more atmospheric CO_2 while maintaining overall ecosystem equilibrium. ⏮ *Phylum* Thaumarchaeota *(section 20.3); Phylum* Planctomycetes *(section 21.5); Nitrogen cycle (section 28.1)*

Given the enormous volume of the ocean, it is probably not surprising that the most abundant monophyletic organisms on Earth are marine α-proteobacteria. Members of the clade called **SAR11** (named after the *Sar*gasso Sea, where they were first discovered) have been detected by their rRNA genes from almost all open-ocean samples taken worldwide. In addition, they have been found at depths of 3,000 m, in coastal waters, and even in some freshwater lakes. Using fluorescence in situ hybridization (FISH; *see figure 29.6*), SAR11 bacteria have been found to constitute 25 to 50% of the total bacteria and archaea in the surface waters in both nearshore and open-ocean samples. Indeed, SAR11 bacteria are estimated to constitute about 25% of all microbial life on the planet. ⏮ *SAR11 clade, the most abundant microorganisms on Earth (section 22.1); Microbial biology relies on cultures (section 29.1)*

The physiology of SAR11 illustrates a recurring metabolic theme that has emerged in the study of marine microorganisms: many have evolved strategies to supplement their energy reserves.

Since the first discovery of rhodopsin-containing γ-proteobacteria in 2000, similar genes have been found in other marine microbes, including α-proteobacteria (i.e., SAR11), β-proteobacteria, bacteroidetes, and new members of the archaeal phylum *Euryarchaeota*. In all cases, the rhodopsin is structurally distinct from the archaerhodopsin found in haloarchaea. None of these microorganisms is autotrophic; it appears that they use the light-driven rhodopsin pump to supplement ATP pools in nutrient-depleted waters. The importance of rhodopsin in marine microorganisms is revealed by metagenomic analysis, which indicates that 13 to 80% of heterotrophic marine bacteria and archaea (depending on sampling location) have the genes needed for proteorhodopsin biosynthesis. ◀◀ *Rhodopsin-based phototrophy (section 11.11); Haloarchaea (section 20.4)*

Another group of marine microbes that appear to be supplementing their energy reserves are aerobic anoxygenic phototrophs (AAnPs). Although these bacteria were discovered several decades ago, for a long time they were considered a physiological curiosity. Bacteria capable of **aerobic anoxygenic phototrophy** are known to possess bacteriochlorophyll *a* (Bchl *a*), but it was a great surprise when it was discovered that this photosynthetic pigment is widely distributed in surface ocean waters. A combination of cultivation and metagenomic techniques demonstrates that some α-proteobacteria (the *Roseobacter* clade), as well as β- and γ-proteobacteria, are capable of this form of phototrophy (*see table 21.2*). It would be incorrect to call these bacteria photosynthetic because they are not autotrophs. Like the rhodopsin-containing microbes, they use light to drive the synthesis of ATP (photophosphorylation) but meet their carbon needs by the assimilation of organic carbon; that is, they are photoheterotrophs. By meeting some of their ATP demands phototrophically, AAnPs and rhodopsin-containing microorganisms can divert more organic carbon to biosynthesis and less to catabolic processes. However, open-ocean bacteria that possess Bchl *a* are much less abundant than those that produce proteorhodopsin. This may reflect the fact that genes for proteorhodopsin have been widely subject to horizontal gene transfer, as only six genes are required for a functional light-driven proton pump. This is in contrast to the roughly 50 genes needed to assemble the anoxygenic light-harvesting complex, reaction center, Bchl *a*, and carotenoids found in AAnPs.

The α-proteobacterium *Silicobacter pomeroyi* appears to be capable of a third interesting metabolic strategy to increase its ATP yield: **lithoheterotrophy** (or chemolithoheterotrophy). Like photoheterotrophy, in which light is used for energy and electrons while organic carbon is consumed, lithoheterotrophy uses inorganic chemicals as a source of energy but requires organic carbon for anabolic purposes. A number of marine carbon monoxide (CO)-oxidizing heterotrophs have been cultured. These bacteria produce CO dehydrogenase, thereby oxidizing CO to CO_2, but unlike other CO-oxidizing bacteria, they do not have the enzymes necessary for the conversion of CO_2 into biomass. As has been shown with *S. pomeroyi,* they seem to use CO as a supplemental electron donor for their electron transport chain. Thus they need not oxidize as much organic carbon to generate NADH for this purpose. Instead, more organic carbon can be used for biosynthesis. This hypothesis is supported by thermodynamic considerations: the oxidation of one molecule of CO should release enough energy to drive the production of one ATP. Measurements of CO lithoheterotrophs show that they make up about 7% of the bacterioplankton in the open ocean and coastal waters sampled.

It is not difficult to hypothesize that these alternatives to "traditional" organotrophy would be beneficial to individual cells in a nutrient-stressed environment. What is more problematic is estimating how much these processes contribute to the carbon budget of marine habitats. Theoretically, the advantage these processes confer must more than offset the energetic cost of carrying the genes required for their expression. But it remains to be seen if these processes actually make these microbes better competitors. Likewise, the impact these metabolic strategies have on carbon flux at the community, ecosystem, and global levels awaits more investigation. It is questions like these that make microbial oceanography such a dynamic and exciting field.

Aquatic Viruses: Mortality at Sea

As mentioned in our discussion of the microbial loop (figure 30.6), viruses are important members of marine and freshwater microbial communities. In fact, **virioplankton** are the most numerous members of marine ecosystems. However, quantifying viruses is tricky: The traditional method of plaque formation requires knowledge of both the virus and its host, and the ability to grow the host in the laboratory. Because so few microbes have been cultured, this prevents the measurement of virus diversity by examining actual virus infection. Instead, virus particles may be visualized directly. There are at least two approaches for this. Electron microscopy is the most rigorous, but fluorescence microscopy is a common and convenient method used to look at viruses in aquatic systems. When seawater is filtered, viruses can be collected on filters with a pore size of 0.02 μm. Viral nucleic acids are stained with a fluorescent dye, such as YO-PRO or SYBR Green for fluorescence microscopy. Although microscopy reveals the presence of virions outside the host cell, it does not prove that they can infect a host cell. Therefore, viruses enumerated in this way are called ***virus*like *p*articles** (**VLPs**). Using this approach, the average VLP density in seawater is between 10^6 to 10^7 per milliliter (although in some cases, it may be closer to 10^8 per milliliter); their numbers decline to roughly 10^6 below about 250 m. Marine viruses are so abundant that VLPs are now recognized as the most abundant microbes on Earth (**figure 30.10**).

Viral diversity is vast, including single- and double-stranded RNA and DNA viruses that infect archaea, bacteria, and protists. Recent advances in metagenomic analysis of viral genomes have been used to explore viral diversity. In one such study, viral communities were sampled from the Arctic Ocean, North Pacific coastal waters, the Gulf of Mexico, and the Sargasso Sea. Of the roughly 1.8 million nucleotides obtained, 90% had no recognizable match on any database. Thus not only is viral genetic diversity immense, it is largely unexplored. ◀◀ *Viruses (chapter 27)*

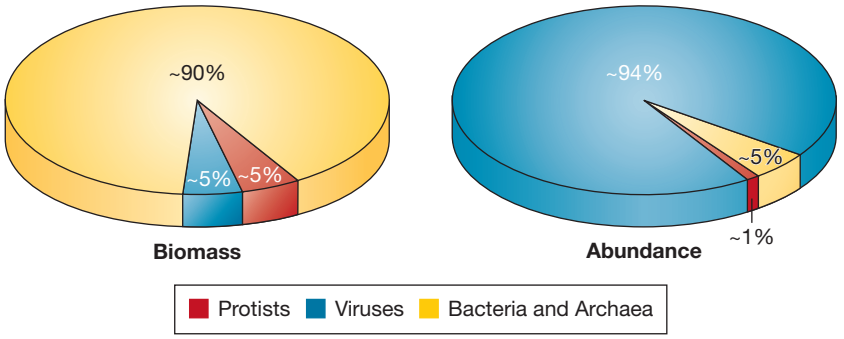


Figure 30.10 Relative Biomass and Abundance of Marine Microbes. (a) The biomass of bacteria and archaea far exceeds that of both protists and viruses. (b) When individuals are counted, however, the vast majority of marine microbes are viruses.

The abundance of marine viruses indicates that they must be major agents of mortality in the sea. Indeed, viruses are thought to kill on average about 20% of the marine microbial biomass daily. However, measurement of virus-induced microbial mortality shows that it is highly variable. Viral abundance frequently corresponds to the microbial host that is most active in the community. Models predict that as one microbial species (or strain) becomes numerically dominant, it soon will be targeted by lytic viruses and thus its population will decline. This permits another microbial species (or strain) to flourish, which then becomes subject to intense viral lysis, and so on. This "kill the winner" model has garnered much attention, but more experimental evidence is needed before it is widely accepted. Perhaps most compelling is the fate of blooms of the coccolithophore *Emiliania huxleyi*. Such blooms are so intense they can be imaged from space, yet their collapse is thought to be (at least in part) the result of viral lysis (**figure 30.11**). Although this phenomenon is interesting, in most cases, viral lysis does not result in the complete collapse of a host population. This may be due partly to strains of the host species that are resistant to virus infection, as has been shown with members of the abundant cyanobacterial genus *Synechococcus*. Computer modeling and model experiments indicate that viruses contribute to nutrient cycling by accelerating the rate at which their microbial hosts are converted to POM and DOM, thereby feeding other microorganisms without first making them available for protists and other bacteriovores. This "short-circuits" the microbial loop (**figure 30.12**).

As might be predicted, viruses are important vectors for horizontal gene transfer in marine ecosystems. In fact, it has been calculated that in the oceans, phage-mediated gene transfer occurs at an astounding rate of 20 billion times per second. The importance of phage-mediated horizontal gene transfer is demonstrated by cyanophages that infect species of *Synechococcus* and *Prochlorococcus*. These phages carry the structural genes for photosynthetic reaction center proteins. By shuttling these genes between strains of cyanobacteria, these phages may play a critical role in the evolution of these important primary producers.

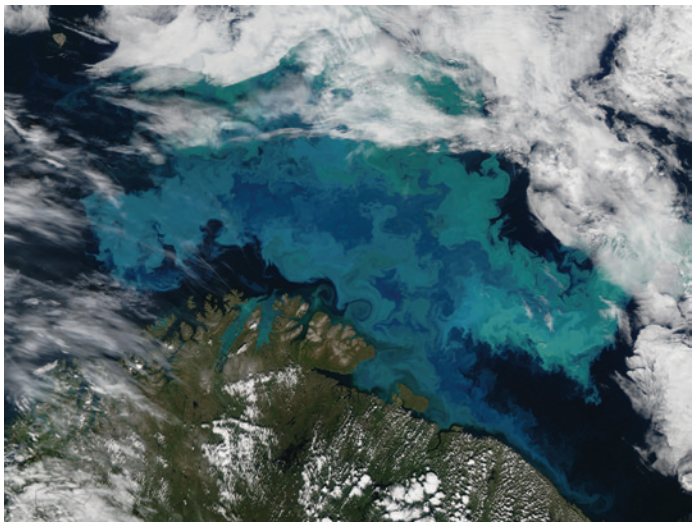

Figure 30.11 Viral Lysis and the Termination of a Massive Plankton Bloom. This satellite image shows the demise of a 500 km-long bloom (light blue region) of the coccolithophore *Emiliania huxleyi*. While the exhaustion of available nutrients also contributes to the death of such an enormous bloom, research has demonstrated that viruses specific to this protist are principle agents in the bloom's demise. The green land mass is Ireland.

Microbial Communities in Benthic Marine Sediments Are Enormous and Mysterious

Sixty-seven percent of the Earth's surface lies under the sea, which means that of all the world's microbial ecosystems, we know the least about the largest. However, the combination of deep-ocean drilling projects and the exploration of geologically active sites, such as submarine volcanoes and hydrothermal vents, has revealed that the study of ocean sediments, or benthos, can be rewarding and surprising. Marine sediments range from the very shallow to the deepest trenches, from dimly illuminated to completely dark, and from the newest sediment on Earth to material that is millions of years old. The temperature and age of marine sediments depend on their proximity to geologically active areas. Hydrothermal vent communities with large and diverse invertebrates, some of which depend on endosymbiotic chemolithotrophic bacteria, have been intensely investigated since their exciting discovery in the late 1970s. These microbes are discussed in chapter 32. Because the vast majority of Earth's crust lies at great depth far from geothermally active regions, most benthic marine microbes live under high pressure, without light, and at temperatures between 1°C and 4°C.

Deep-ocean sediments were once thought to be devoid of all life and thus not worth the considerable effort it takes to study them. But sediment samples from water depths up to 8,200 m (at its deepest, the ocean is about 11,000 m) reveal the presence of a vast "piezosphere" (Greek, *piezein,* to squeeze or press). The piezosphere describes the biome at depths with pressures exceeding 100 atm (pressure increases about 1 atm per 10 m depth). Microbes that grow at such great pressures are termed **piezophilic** and their density is 10 to 10,000 greater per unit volume than in productive surface waters. Reasons for this difference are complicated but include energy

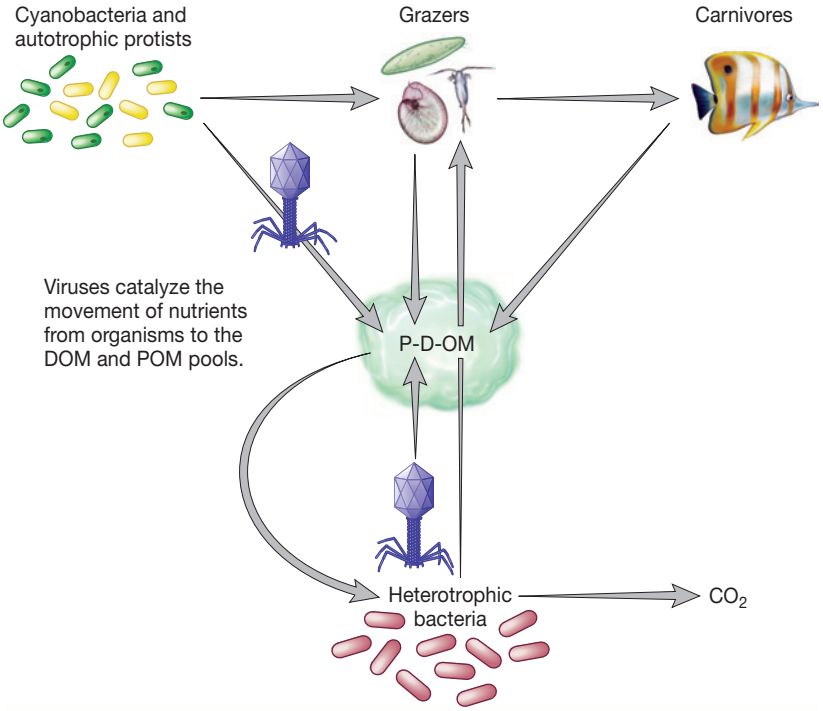

Figure 30.12 The Role of Viruses in the Microbial Loop. Viral lysis of autotrophic and heterotrophic microbes accelerates the rate at which these microbes are converted to particulate and dissolved organic matter (P-D-OM). This is thought to increase net community respiration and decrease the efficiency of nutrient transfer to higher trophic levels.

MICRO INQUIRY *When might viruses choose lysogeny rather than lysis and how would this affect carbon flow (also see figure 30.6)?*

availability and limited grazing pressure. This result is especially surprising because the majority of the ocean floor receives only about 1 gram of organic carbon per square meter per year.

It is now accepted that the biosphere below the Earth's crust represents the "hidden majority" of all microbial biomass. Estimates range from half to five-sixths of the Earth's total microbial biomass and up to one-third of Earth's total living biomass. As might be predicted, most of these microbes are not amenable to laboratory culture. In fact, these microbes "breathe" about a million times slower than surface microorganisms, making their metabolism so slow that doubling times are measured in hundreds, and sometimes thousands, of years. Subsurface microbes truly stretch the limits of what we have come to define as life.

Global surveys show that the deep subsurface biosphere within relatively nutrient-rich continental margin sediments varies from that in the organic-poor distant abyss. Seawater is rich in sulfate, which is used as an electron acceptor in anaerobic respiration. In the continental margin, sulfate in sediments is depleted within 100 m depth, at which point methanogenesis becomes dominant. However, in the abyss, sulfate penetrates much more deeply, and distinct zonation between sulfate-reducing bacteria and methanogenic archaea is absent. Despite biochemical evidence for the presence of sulfate reduction and methanogenesis, SSU rRNA sequence analysis of DNA has been surprising in the number of genes that lack homology to known sulfate reducers and methanogens. Furthermore, the sediment surface and subsurface appear to be teeming with viruses; it is estimated that each year viral lysis in the benthos releases up to 630 million tons of carbon that had been sequestered by marine snow and other falling particulates. These exciting findings suggest that a significant fraction of Earth's biomass is amazingly active yet largely uncharacterized.

Although thermophilic and hyperthermophilic bacteria and archaea are found at hydrothermal vent sites, most deep-sea microbes are psychrophilic. The majority recovered so far are Gram-negative, facultative anaerobic bacteria. Common genera include γ-proteobacteria in the genera *Shewanella, Photobacterium, Colwellia, Moritella,* and *Psychromonas.* Interestingly, it appears that the subterranean depth limit of microbial growth is not governed by pressure; rather, it is determined by temperature. It seems unlikely that the maximum temperature at which life can be sustained has been identified. ⏮ *Environmental factors affect microbial growth (section 7.4)*

Exploration of deep-sea subsurface microbiology has turned our understanding of bacterial energetics literally upside down. As discussed in chapters 11 and 28, it is generally understood that anaerobic respiration occurs such that there is preferential use of available terminal electron acceptors (*see figure 28.1*). Acceptors that yield the most energy (more negative ΔG) from the oxidation of NADH or a reduced inorganic compounds (e.g., H_2, H_2S) will be used before those that produce a less negative ΔG. Thus following oxygen depletion, nitrate will be reduced, then manganese, iron, sulfate, and, finally, carbon dioxide. This is demonstrated in sediment cores up to 420 m deep collected off the coast of Peru (**figure 30.13**). However, when these signature chemical compounds were measured at greater depth, the profile was reversed. This suggests the presence of unknown sources of these electron acceptors at subsurface depths of more than 420 m. In addition, contrary to our long-held notion of thermodynamic limits, methane formation (methanogenesis) and iron and manganese reduction co-occur in sediments with high sulfate concentrations. Although the identity of the microbes that make up these communities awaits further study, it is clear that with densities of 10^8 cells per gram of sediment at the seafloor surface and 10^4 cells per gram in deep subsurface sediments, these communities are important. ⏮ *Redox reactions (section 10.3); Anaerobic respiration uses the same three steps as aerobic respiration (section 11.7); Chemolithotrophy (section 11.10)*

Another outcome of deep-ocean sediment exploration has been the discovery of microbial communities on continental margins fueled by the release of hydrocarbons at depths between 200 and 3,500 m. Depending on the surface topology and the rate at which hydrocarbons are emitted, they are called pockmarks, gas chimneys, mud volcanoes, brine ponds, and oil and asphalt seeps. A variety of microbes can use hydrocarbons as a sole carbon source, oxidizing them with oxygen or sulfate as the electron acceptor. In addition, methane-oxidizing archaea grow in consortia with sulfate-reducing bacteria of the *Desulfococcus* and *Desulfobulbus* groups, as discussed in chapter 20. Some regions are the

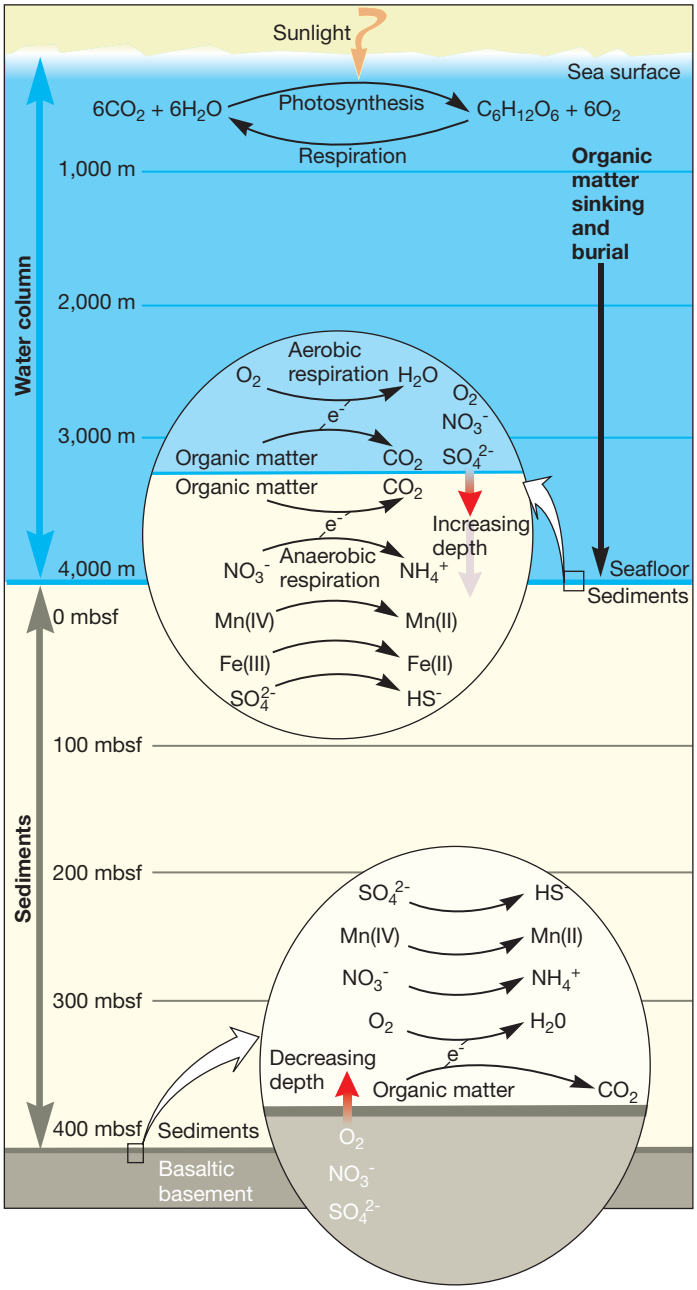

Figure 30.13 Microbial Activity in Deep-Ocean Sediments. At the surface of the seafloor, reduction of oxidized substrates that serve as electron acceptors in anaerobic respiration follows a predictable stratification based on thermodynamic considerations. This sequence reverses in very deep subsurface sediments, suggesting a source of electron acceptors from deep within Earth's crust. Meters below seafloor, mbsf.

sites of microbial mats, which can sometimes cover several hundreds of meters. These mats are dominated by the giant, vacuolated sulfur-oxidizing bacteria in the genera *Beggiatoa* and *Thiomargarita (see figures 22.23 and 22.24).* ◀◀ *Class* Gammaproteobacteria *is the largest bacterial class (section 22.3)*

Perhaps the most industrially important of these hydrocarbon-fueled communities are those found at **methane hydrates.** Methane hydrates are lattice-like ice structures in which methane is trapped. The methane is produced by both geothermal activity and methanogenic archaea. The lack of associated methane-oxidizing microbes has enabled this pool of natural gas to accumulate in latticelike cages of crystalline water 500 m or more below the sediment surface in many regions of the world's oceans. This discovery is significant because there may be up to 10^{13} metric tons of methane hydrate worldwide. Thus 80,000 times the world's current known natural gas reserve awaits the development of the technology to access it. ◀◀ *Phylum* Euryarchaeota *(section 20.4)*

30.3 Microorganisms in Freshwater Ecosystems

After reading this section, you should be able to:

- Appreciate the scarcity of freshwater on Earth
- Contrast and compare the microbial communities found in lotic systems with those in lentic systems
- Describe the differences between the microbial communities found in a deep, stratified lake with those of a shallow lake that lacks stratification
- Describe how seasonal changes influence lake microbial communities and how these changes can lead to blooms

While the vast majority of water on Earth is in marine environments, freshwater is crucial to our terrestrial existence. As shown in **figure 30.14**, of the 3.9% of Earth's water that is not saline, only a tiny fraction represents the familiar streams, rivers, and wetlands

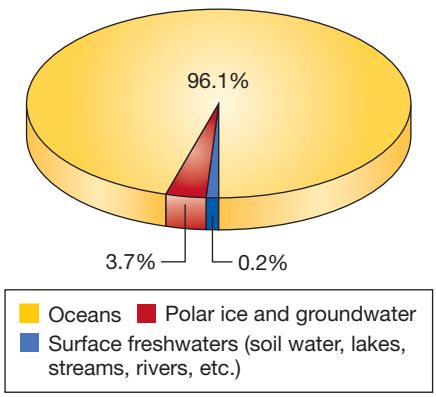

Figure 30.14 Relative Distribution of Freshwater on Earth.

that we associate with the term freshwater. We begin our discussion with the largest fraction of freshwater—that which is frozen at the Earth's polar regions. We then move to streams, rivers, and lakes.

Glaciers and Permanently Frozen Lakes Support Active Microbial Communities

Much of the ice on Earth has remained frozen for millions of years. Indeed, it is important to note that a majority of the Earth's surface never exceeds a temperature of 5°C. This includes polar regions, the deep ocean, and high-altitude terrestrial locations throughout the world. Surprisingly, microbes within glaciers are not dormant. Rather, evidence that active microbial communities exist in these environments has been growing over the last decade. In fact, this is an exciting time in glacial microbiology; determining the diversity in these systems and assessing the role of these microorganisms in biogeochemical cycling can involve novel and creative techniques. In addition, since the discovery of ice on Mars and on Jupiter's moon Europa, astrobiologists have become very interested in ice-dwelling psychrophilic microbes. ⏮ *Temperature (section 7.4).*

The biology of lakes associated with glaciers has gained importance as it has been recognized that these ecosystems function as sentinels of climate change. Glacial lakes are constrained by low temperature and reduced solar radiation, and in the Antarctic, lakes are separated from macrofauna as well. Here phytoplankton, bacteria, and protists form simple food webs almost completely devoid of multicellular organisms (**figure 30.15**). Microbial growth rates are slow, so it not surprising that primary productivity within these lakes must be supplemented by the deposition of organic carbon from the surrounding environment. Indeed, phototrophic flagellated and ciliated protists are also capable of consuming bacteria and dissolved organic carbon. These mixotrophs are not the only consumers of bacteria; most of the viruses are bacteriophages. Viral lysis of bacteria in Antarctic lakes is almost 10 times that found in similar temperate and tropical lakes.

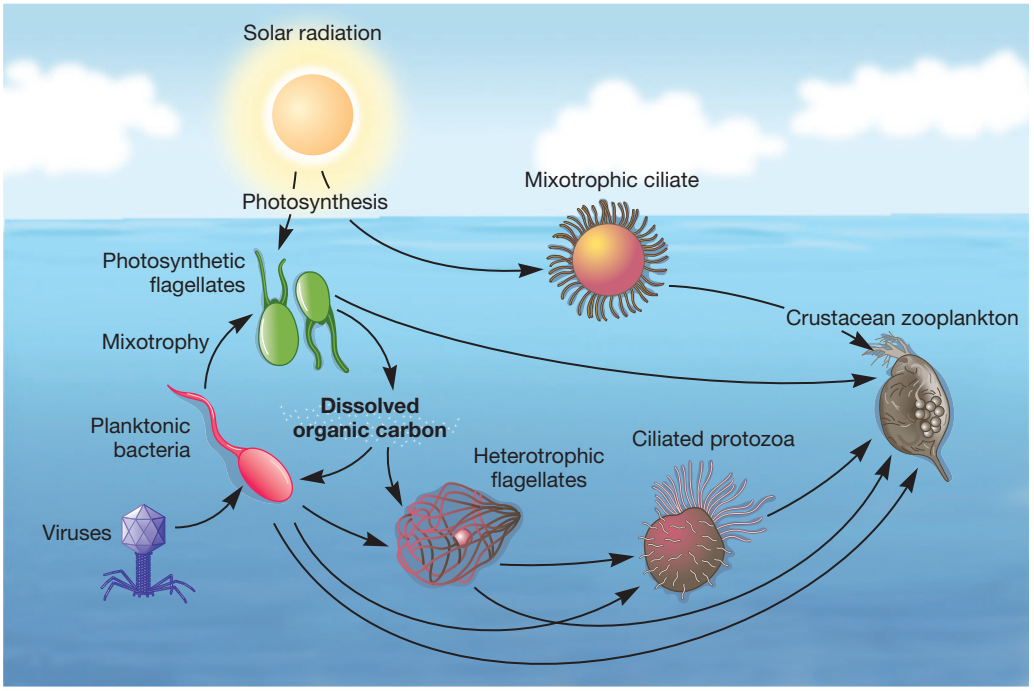

Figure 30.15 Nutrient Cycling in Antarctic Lakes Is Performed Entirely by Microbes. Antarctic glacial lakes lack multicellular organisms, so all nutrient cycling is between various types of microbes, including bacteriophages. The surrounding environment provides some organic carbon.

MICRO INQUIRY *List three major differences between this microbial loop and that found in the open ocean (figure 30.6).*

Microbial Communities in Streams and Rivers Differ

Streams and rivers are much more dynamic than glacial lakes. Some of the physical and biological factors that help regulate the microbial communities of these freshwater systems are listed in **table 30.1**. Lakes, rivers, and streams can be broadly

Table 30.1 Physical and Biological Factors Influencing Microbial Communities in Freshwater Habitats

Habitat	Major Microbial Community	Major Physical Characteristic	Major Biological Constraints
Lake	Plankton	Stratification, wind-generated turbulence	Nutrient competition, grazing, parasitism
Floodplain	Plankton, biofilms attached to plants	Periodic desiccation	Competition between algae and macrophytes
Rivers and streams	Benthic microbes	Flow-generated turbulence	Colonization competition, biofilm grazing
Estuary—mudflats	Biofilms	Desiccation, high light, salt exposure	Competition and grazing at mud surface
Estuary—outflow	Plankton	Mixing with saltwater, turbidity	Grazing in water column

classified as either **lotic** systems with free-running waters (streams, most rivers, canals) or **lentic** systems with free-standing waters (e.g., ponds; lakes; marshes; very broad, slow-moving rivers). In large, lentic rivers and lakes, phytoplankton thrive and are responsible for most of the fixed carbon. The biologically available carbon that is produced within the system is called **autochthonous.** By contrast, the constant flow of water in streams and all but the largest rivers prevents the development of significant planktonic communities. In addition, phytoplankton growth can be further limited by the amount of available light due to overhanging foliage, turbidity, and rapid mixing of the water. In most streams and rivers, the source of nutrients therefore comes from the surrounding land. Such nutrients are called **allochthonous.** This distinction is important, as lentic systems often have a net autotrophic metabolism, whereas lotic systems are generally heterotrophic.

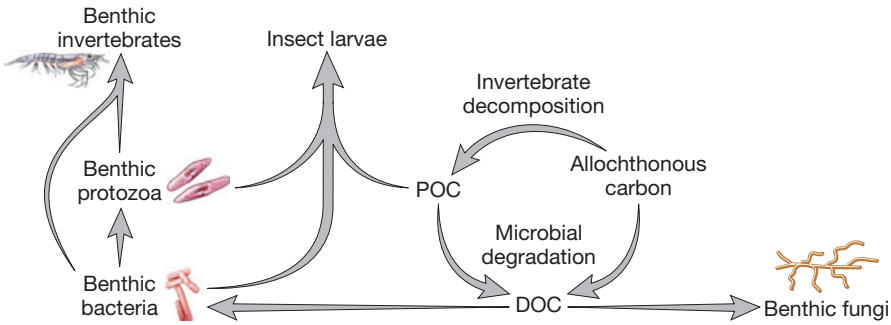

Figure 30.16 A Benthic Microbial Loop in Lotic Systems. In contrast to the microbial loop in planktonic systems (figure 30.6), the benthos of a lotic system, such as a fast-moving river or stream, features small eukaryotes such as invertebrates and insect larvae. These organisms play an important part in nutrient cycling. At the same time, macrofauna such as fish and other top carnivores may be absent or play relatively minor roles.

The allochthonous carbon that enters rivers and streams includes both dissolved and particulate organic carbon (DOC and POC, respectively). The amount of carbon that enters freshwater systems depends on surrounding vegetation, proximity to human activity, and local geology. In addition, hydrological factors such as how long water stays in the soil before entering the river or stream also influence the nature of the organic carbon. Thus DOC ranges from material that can be readily assimilated to refractory carbon that only a few microbial groups can slowly degrade. Much of the particulate organic carbon includes large items such as leaf litter, which provide substrates for fungi and bacteria to colonize. Initially, the activity of these microbes releases a pulse of DOC; this is followed by the slow leaching of nutrients that may not be as easy to assimilate.

Most rivers and streams have healthy benthic communities of attached microbes that form biofilms consumed by invertebrates and other grazing organisms. In shallow rivers and streams, some biofilms are dominated by diatoms and other photosynthetic protists, which contribute to the total primary production of the system. Biofilms that consist primarily of heterotrophic microbes are important sources of degradation and mineralization. The role of benthic microbes in rivers and streams can be generally characterized by the microbial loop shown in **figure 30.16**.

As in any microbial community, when river and stream chemoorganotrophic microorganisms metabolize the available organic material, they recycle nutrients within the ecosystem. Autotrophic microorganisms require minerals released from organic matter. This leads to the production of O_2 during daylight hours, when the rates of photosynthesis and respiration are in dynamic equilibrium. When the amount of organic matter added to streams and rivers does not upset this balance, so that heterotrophy and autotrophy are roughly equal, productive streams and rivers are maintained. However, as seen with ocean dead zones, when the supply of organic matter supports a vast heterotrophic population whose respiration rate outpaces oxygenic photosynthesis, the water may become anoxic. This can occur in streams and rivers adjacent to urban and agricultural areas. The release of inadequately treated municipal wastes and other materials from a specific location along a river or stream represents point source pollution. Such additions of organic matter can produce distinct and predictable changes in the microbial community and oxygen concentration, creating an oxygen sag curve in which oxygen is depleted just downstream of the pollution source (**figure 30.17**). Runoff from agriculturally active fields and feedlots is an example of nonpoint source pollution. This can also cause disequilibrium in the microbial community, leading to algal or cyanobacterial blooms.

2. What is an oxygen sag curve? What changes in a river cause this effect?
3. What are point and nonpoint source pollution? Can you think of examples in your community?

Microorganisms in Lakes Can Cause Seasonal Blooms

Lakes differ from rivers and streams because they are lentic systems, thus dominated by planktonic microbes and invertebrates. The topology and hydrology of lakes are key factors in the development of these communities. Lake hydrology incorporates all aspects of water flow: the water in the lake itself, plus its inflow and outflow. Because much of the water in a lake comes from the surrounding land, the geology and use of the land that feeds the lake largely determine the chemistry of the inflow water. For instance, mountain lakes are fed water from relatively infertile land, resulting in oligotrophic conditions within the lake. This explains why mountain lakes tend to be so clear: microbial growth is limited to those species that tolerate low nutrient levels. Such microbes tend to have long generation times. On the other hand, low-lying lakes generally catch water from fertile, cultivated soils and so are nutrient rich. This supports a high level of planktonic growth, and the lakes may appear turbid. The picoplankton often include freshwater species of *Synechococcus,* whereas filamentous cyanobacteria

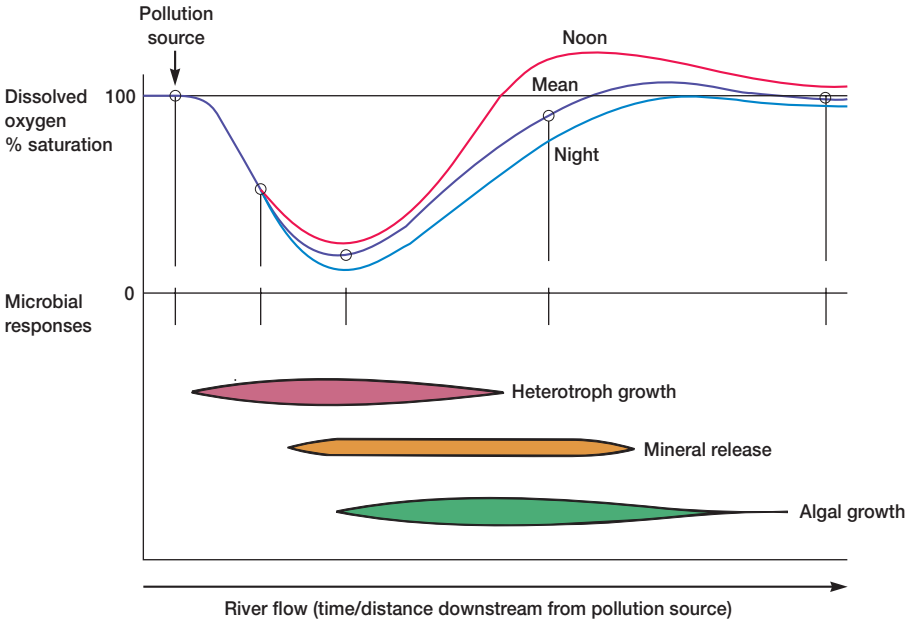

Figure 30.17 The Dissolved Oxygen Sag Curve. Microorganisms can create gradients over distance and time when nutrients are added to rivers. An excellent example is the dissolved oxygen sag curve, caused when organic wastes are added to a clean river system. During the later stages of self-purification, the phototrophic community will again become dominant, resulting in diurnal changes in river oxygen levels.

such as those in the genera *Anabaena* and *Microcystis* constitute the macroplankton (microbes larger than 200 μm).

Deep lakes can be divided into two main regions: the **littoral zone,** or shoreline, and the central, **pelagic zone** (these terms also apply to marine systems). As shown in **figure 30.18*a***, the littoral region is also defined by the depth of the photic zone. The two zones have distinct microbial communities. In the littoral zone, allochthonous DOC introduces organic substrates and nutrients such as phosphate and nitrate. Because the water is shallow, light penetrates throughout the water column, enabling the development of larger plants. Biofilms frequently form on these plants and in the sediments.

The microbial community within the pelagic zone is partly determined by the depth of the lake. Light penetrates the entire water column in shallow lakes (less than about 10 m), so benthic autotrophs, including diatoms and cyanobacteria, may be the principle primary producers (figure 30.18*b*). In deeper lakes, the central, pelagic region can become thermally stratified. This is the case in temperate regions (**figure 30.19**). In the summer, the upper layer, called the **epilimnion,** becomes warmed and oxygen is released into the atmosphere. The thermocline spans a region called the **metalimnion;** this region acts as a barrier to mixing of upper and lower water masses. The lower, colder, dark region, known as the **hypolimnion,** can become anoxic because oxygenic photosynthesis is confined to the epilimnion. Because these two water masses do not mix (or mix very little), the upper layer supports a rich diversity of primary producers and consumers, which can deplete nutrients. Just the opposite is true for the hypolimnion, where dark, anoxic, cold conditions limit growth. Nutrients accumulate and the microbial community primarily consists of benthic heterotrophs. When autumn weather cools the surface and storms physically mix the two layers, a short-lived bloom can occur as nutrients from the bottom of the lake are mixed into the photic zone. Much longer blooms may occur in the spring, when thermal stratification occurs but nutrients in the epilimnion have not yet been depleted by microbial growth.

Tropical lakes lack significant temperature changes during the year but have seasonal differences in rainfall. Although many aspects of tropical lakes are similar to those of a summer temperate lake, there are several key differences. The warmer, year-round temperatures support higher productivity, and plankton blooms may occur at any time during the year. Cyanobacteria capable of nitrogen fixation may dominate, reflecting the low N:P ratios frequently found in tropical lakes. Nutrient cycling in temperate lakes is largely driven by physical mixing, whereas biological processes are more important in tropical lakes. In this regard, the microbial loop shown in figure 30.6 can be applied to the epilimnion of larger tropical lakes that receive few allochthonous nutrients.

Lakes vary in nutrient status. Some are oligotrophic and others are eutrophic. Nutrient-poor lakes remain oxic throughout the year, and seasonal temperature shifts usually do not result in distinct oxygen stratification. In contrast, eutrophic lakes usually have bottom sediments that are rich in organic matter. In oligotrophic lakes, cyanobacteria capable of nitrogen fixation may bloom. Members of several genera, notably *Anabaena, Nostoc,* and *Cylindrospermum,* can fix nitrogen under oxic conditions. Those in the genus *Oscillatoria* use hydrogen sulfide as an electron donor for photosynthesis, enabling nitrogen fixation under anoxic conditions. If both nitrogen and phosphorus are present, cyanobacteria compete with algae. Cyanobacteria function more efficiently in alkaline waters (pH 8.5 to 9.5) and higher temperatures (30 to 35°C). By using CO_2 at rapid rates, cyanobacteria also increase the pH, making the environment less suitable for protists. Cyanobacteria have additional competitive advantages. Many produce siderophores to bind iron, making this important trace nutrient less available for protists. Some cyanobacteria also resist predation because they produce toxins. In addition, some synthesize odor-producing compounds that affect the quality of drinking water. These problems become magnified when cyanobacteria or protists (algae) produce massive blooms in strongly eutrophied lakes.

1. What terms can be used to describe the different parts of a lake?
2. What are some important effects of eutrophication on lakes?
3. Why do cyanobacteria often dominate waters that have been polluted by the addition of phosphorus?

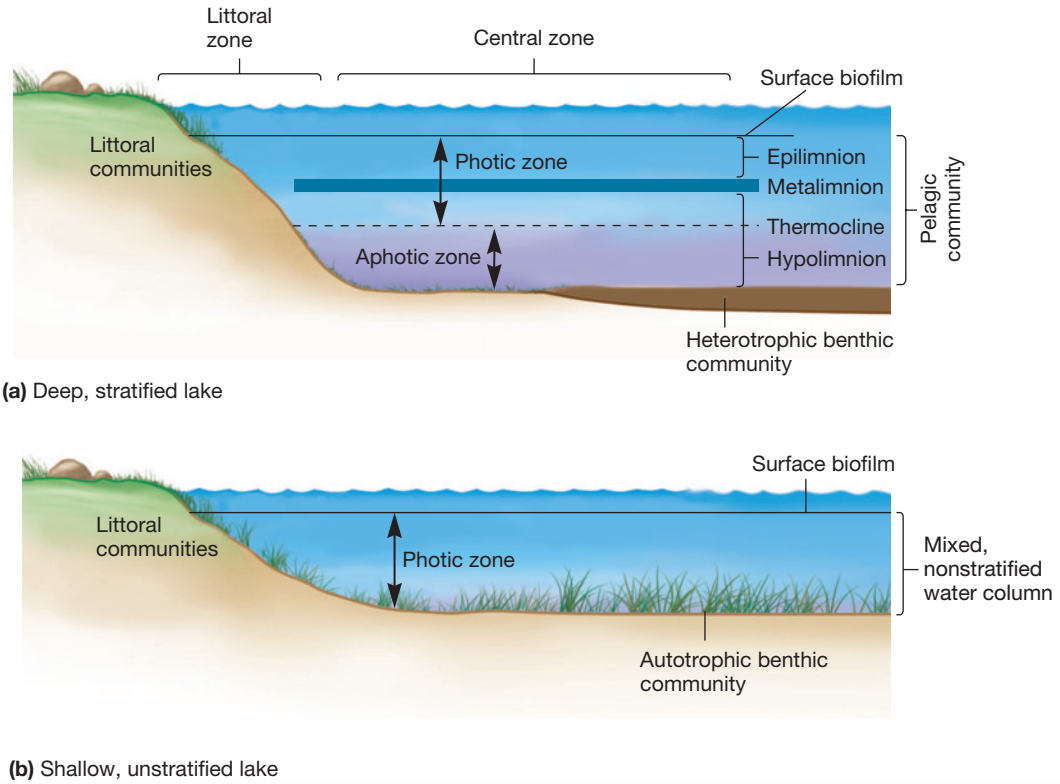

Figure 30.18 The Depth of a Lake Is a Key Factor in Shaping the Microbial Community. (a) Deep lakes have autotroph-dominated littoral and epilimnion microbial communities. Waters below the thermocline and photic zone form the hypolimnion, which can become oxygen depleted. Here a heterotrophic benthic community thrives. (b) Shallow lakes have little mixing, and the photic zone reaches the lake bottom. Thus autotrophs dominate the water column and benthic regions throughout the lake.

MICRO INQUIRY *How does the contribution of benthic autotrophs differ in deep lakes compared to that in shallow lakes? How does this affect the relative contribution of phytoplankton in these two aquatic systems?*

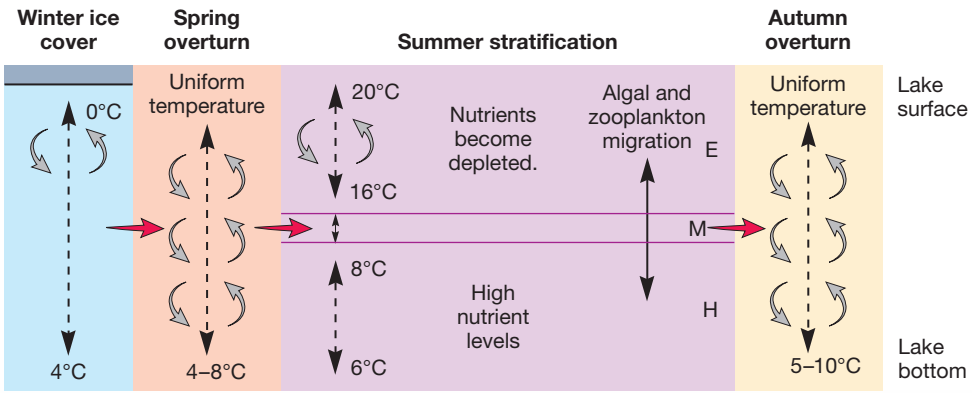

Figure 30.19 Seasonal Changes in a Temperate Lake Are Associated with Blooms. In the spring, the water begins to warm, and lack of thermal stratification ensures ample nutrients for microbes that can grow in the relatively warmer surface waters. During the summer as the surface waters warm, thermal stratification separates the cool, deep, nutrient-rich waters from the warm, illuminated waters. Because microbial growth is favored in the warmer surface water, this water becomes depleted of nutrients. During the autumn, waters cool and storms mix the layers, bringing the bottom nutrients to the surface. This pulse of nutrients can support a bloom of microbes or algae. Water turbulence is indicated by arrows; E, epilimnion; M, metalimnion; H, hypolimnion.

MICRO INQUIRY *Why does water turbulence play only a minor role in mixing the water column in the summer?*

Key Concepts

30.1 Water Is the Largest Microbial Habitat

- Most water on the Earth is marine (97%). The majority of this is cold (2 to 5°C) and at high pressure. Freshwater is a minor but important part of Earth's biosphere.
- The carbonate equilibrium system keeps the oceans buffered at pH 7.6 to 8.2; however, ocean acidification threatens the health of marine ecosystems (**figure 30.1**).
- The penetration of light into surface waters determines the depth of the photic zone. Warming the surface waters can lead to the development of a thermocline.

30.2 Microorganisms in Marine Ecosystems

- Tidal mixing in estuaries causes daily swings in osmolarity. Thus microbes within estuaries have evolved mechanisms to cope with rapid changes in salinity.
- Coastal regions such as estuaries and salt marshes can be the sites of harmful algal blooms (**figure 30.3**).
- Autotrophic microbes in the photic zone within the open ocean account for about one-half of all the carbon fixation on Earth.
- The microbial loop describes the transfer of nutrients between trophic levels while taking into account the multiple contributions of microbes to recycling nutrients. Nutrients are recycled so efficiently, very little organic carbon is buried in the seabed (**figures 30.6–30.8**).
- The carbon and nitrogen budgets of the open ocean are intensely studied because of their implications for the future of climate change.
- Bacteria in the α-proteobacterial clade SAR11 are the most abundant organisms on Earth and demonstrate unique adaptations to life in the oligotrophic open ocean.
- Viruses are present at high concentrations in many waters and occur at ten-fold higher levels than bacteria. In marine systems, they play a major role in nutrient turnover (**figures 30.10–30.12**).
- Sediments deep beneath the ocean's surface are home to perhaps one-half of the world's bacterial and archaeal biomass.
- Methane hydrates, the result of psychrophilic archaeal methanogenesis under extreme atmospheric pressure, may contain more natural gas than is currently found in known reserves.

30.3 Microorganisms in Freshwater Ecosystems

- Glaciers and permanently frozen lakes are sites of active microbial communities. Antarctic lakes lack multicellular organisms and have truncated food webs (**figure 30.15**).
- Nutrient sources for streams and rivers may be autochthonous or allochthonous. Often allochthonous inputs include urban, industrial, and agricultural runoff.
- The depth of a lake determines the microbial communities it will support. Deep lakes have a planktonic, autotrophic community in the epilimnion, and shallow lakes support large autotrophic communities (**figure 30.18**).
- Seasonal mixing of temperate lakes can introduce conditions that support microbial blooms in the spring and fall (**figure 30.19**).

Compare, Hypothesize, Invent

1. The unicellular cyanobacterium *Prochlorococcus* sp. is the most abundant photosynthetic microbe in tropical and subtropical oceans. At least two ecotypes exist: one is adapted to high light and the other to lower light intensities. How does the presence of these two ecotypes contribute to their physiological success and their numerical success? How would you determine the amount of fixed carbon they contribute to these open-ocean ecosystems?
2. How might it be possible to cleanse an aging eutrophic lake? Consider chemical, biological, and physical approaches as you formulate your plan.
3. It is well known that bacterivory (the consumption of bacteria) supports the growth of marine protists that lack plastids. However, measurements of bacterivory among plastid-containing planktonic algae are surprising in showing that small (<5 μm) algae carry out between about 40 to 95% of the bacterivory in the photic zone of the North Atlantic. Discuss how this level of mixotrophy impacts the concept of the microbial loop (figure 30.6).

   Read the original paper: Zubkov, M. V., and Tarran, G. A. 2008. High bacterivory by the smallest phytoplankton in the North Atlantic Ocean. *Nature,* 455:224.
4. Picoplanktonic cyanobacteria belonging to the genera *Synechococcus* and *Prochlorococcus* are estimated to account for up to 25% of primary productivity in certain regions of the open ocean. This makes them profoundly important in local nutrient cycling as well as in the global carbon budget. A group of international scientists developed a model to predict the fate of these microbes as global temperatures continue to rise. After determining that temperature and light are the two most important environmental factors influencing the currently observed variability in cyanobacterial abundance, they project a worldwide 14% and 29% increase in *Synechococcus* and *Prochlorococcus* abundance, respectively. What biological factors might affect the population of these cyanobacteria? How might such a large increase in primary production affect the export of carbon out of the photic zone (refer to figures 30.7 and 30.8)?

   Read the original paper: Flombaum, P. et al., 2013. Present and future global distributions of the marine cyanobacteria *Prochlorococcus* and *Synechococcus*. *Proc. Nat. Acad. Sci., USA*. 110:9824.

Microorganisms in Terrestrial Ecosystems

The plant pathogenic fungus Puccinia graminis *grows within the tissues of wheat plants, using plant nutrients and producing rusty streaks of red spores that erupt at the stem and leaf surface, where spores can be dispersed. Fungi are the most important group of plant pathogens.*

A Short History of Rust

Aristotle wrote about them. The Romans had a ceremony to prevent them. Over 2 million Indians starved in the 1940s because of them. They are responsible for the loss of more than a million metric tons of wheat in the United States every year. Norman Borlaug won a Nobel Peace Prize fighting them. What are they? Fungal plant pathogens: the cause of more than 70% of all major crop diseases.

The worst offenders among fungal plant pathogens are the "rusts," which are basidiomycetes (*see section 26.6*). In North America, probably the most important rust is *Puccinia graminis* subsp. *tritici*, the causative agent of wheat stem rust. Other important rusts include barley stem rust, soybean rust, cedar-apple rust, and poplar leaf rust. The introduction of fungi from Europe triggered chestnut blight (*Cryphonectria parasitica*), Dutch elm disease (*Ophiostoma ulmi*), and white pine blister rust (*Cronartium ribicola*). With over 6,000 different rust species known to cause plant diseases, it would seem the only approach to saving millions of dollars of valuable agricultural products would be to spray heavily with a fungicide and hope for the best.

Norman Borlaug knew that expensive fungicides were not an option for inhabitants of developing countries. Shortly after earning his Ph.D. in plant pathology at the University of Minnesota, he moved to Mexico to breed new, disease-resistant wheat strains. He later turned his attention to the Indian subcontinent, where he helped develop hardy strains of rice. In 1970 the Nobel committee noted that "More than any other single person of this age, he has helped provide bread for a hungry world." It is estimated that each day at least half the global population consumes grain that arose through Borlaug's plant breeding efforts. Borlaug was an active scientist until his death at age 91 in 2009.

Most microbes that associate with plants, whether that association is good, bad, or neutral, live in soil. Soil is a hugely underappreciated resource. It is a vast reservoir of nutrients, wastes, energy, and even pharmaceutical products. Although much is known about the geology and chemistry of soil, our understanding of the microbial communities that drive the development and continued health of soils is far from complete. However, the introduction of new, innovative culture techniques combined with culture-independent approaches has made the study of terrestrial microbiology an exciting and dynamic field.

Readiness Check:

Based on what you learned previously, you should be able to:

- ✔ List environmental factors that influence microbial growth (section 7.4)
- ✔ Compare and contrast the growth and physiology of obligate aerobes, facultative anaerobes, and strict anaerobes (section 7.4)
- ✔ Evaluate the importance of intercellular molecular signaling to microbial growth in nature (section 7.5)
- ✔ Diagram, in general terms, the standard reduction potentials of electron donors as compared to electron acceptors and relate this to standard free energy change (section 10.3)
- ✔ Recall the basic enzymology of nitrogenase (section 12.5)
- ✔ Explain why SSU rRNA is used as a taxonomic marker (section 19.3)
- ✔ Describe members of the *Glomeromycota* (section 26.4)
- ✔ Identify microorganisms responsible for nitrogen fixation (sections 22.1 and 24.1)
- ✔ Describe how stable isotope analysis is used to reveal microbial community dynamics (section 29.3)
- ✔ Explain how the oxidation-reduction (redox) state of an environment impacts the types of microbial metabolic processes that might be found there (section 28.1)
- ✔ Explain the global impact that microbes have on carbon and nitrogen cycling (section 28.1)

31.1 Soils Are an Important Microbial Habitat

After reading this section, you should be able to:

- Differentiate between a mineral and an organic soil, and describe the role of microbes in generating soil organic matter
- Explain why lignin degradation is confined to only a few types of microbes
- Predict how a specific carbon to nitrogen ratio will influence the microbial community within a given soil

The level of microbial diversity in soil exceeds that of any other habitat on Earth, with estimates of 10,000 to 50,000 species at densities of 10^7 to 10^{10} cells per gram of soil. The soil environment

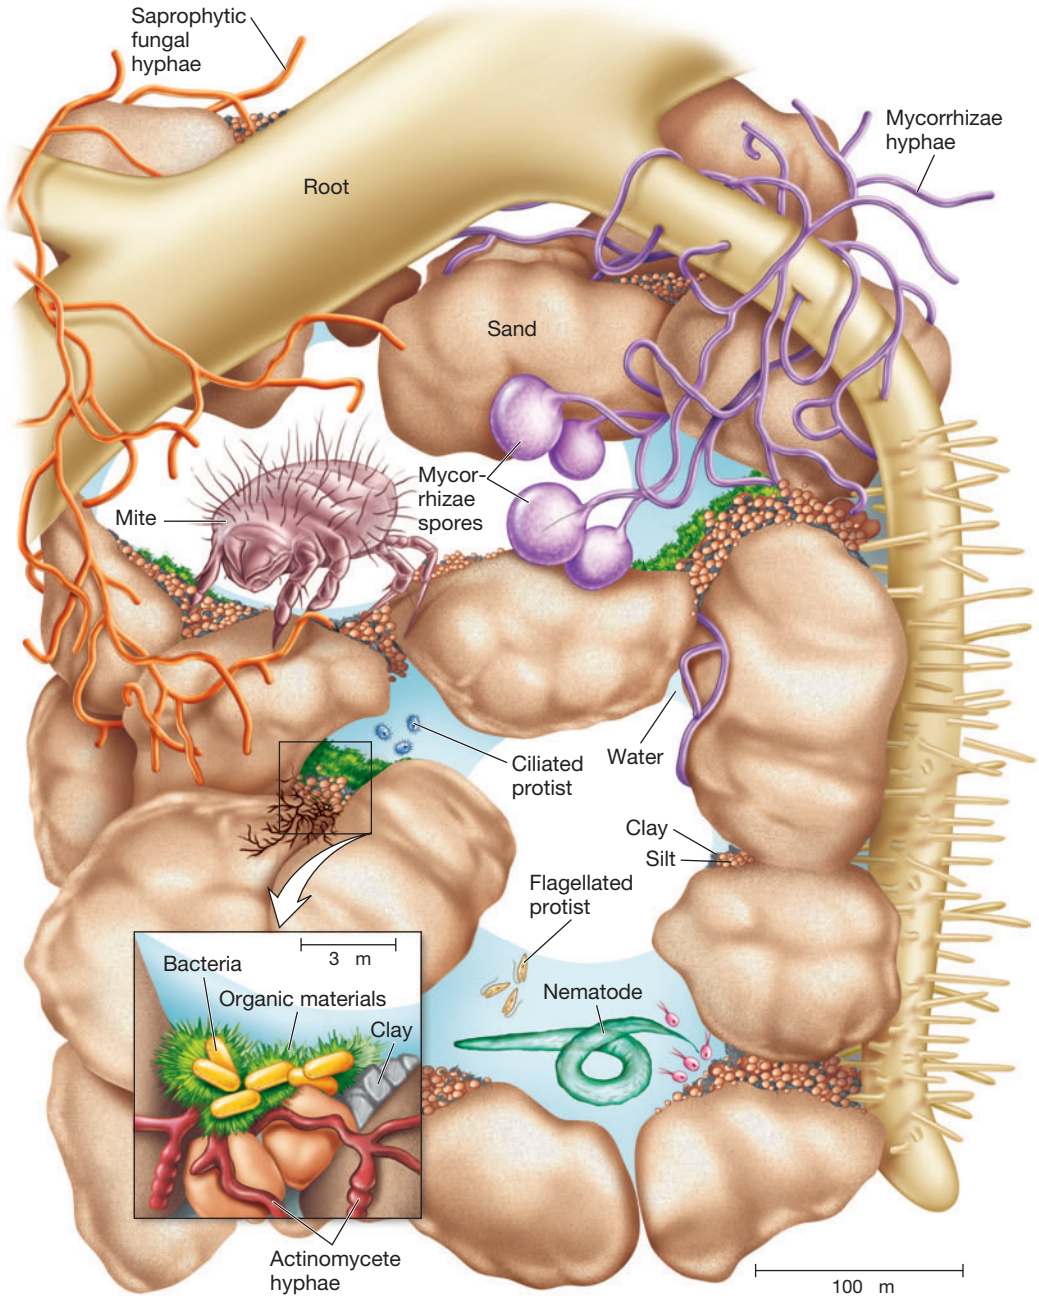

Figure 31.1 The Soil Habitat.
A typical soil habitat contains a mixture of clay, silt, and sand along with soil organic matter. Roots, animals (e.g., nematodes and mites), and chemoorganotrophic bacteria consume oxygen, which is rapidly replaced by diffusion within the soil pores where the microbes live. Two types of fungi are present: mycorrhizal fungi, which derive their organic carbon from their symbiotic partners, plant roots; and saprophytic fungi, which contribute to the degradation of organic material. In addition to heterotrophs, chemolithotrophic microorganisms are important in elemental cycling within the soil environment.

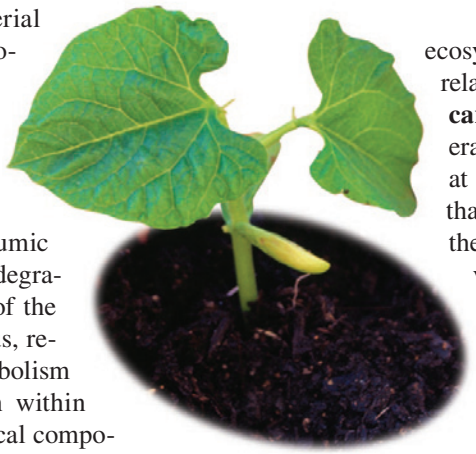
MICRO INQUIRY *How are filamentous microbes especially well suited to the soil ecosystem?*

supports active microbial growth that contributes to global elemental cycling and makes nutrients available to plants. Simply put, without soil microbes, there would be no plants, which would eliminate herbivores, and so on up the food chain.

Soil microbial communities are supported by complex physical and chemical parameters, which provide a vast array of microhabitats. These include soil particles and the pore space between them, which is critical for the movement of water and gases (**figure 31.1**). Total pore space, and thus gas diffusion, is determined by the texture of the soil. For instance, sandy soils have larger pore spaces than do clay soils, so sandy soils tend to drain more quickly. Pores are also critical because they provide the optimum environment for microbial growth. Here microbes are within thin water films on particle surfaces where oxygen is present at high levels and can be easily replenished by diffusion.

Soil environments can change rapidly. For instance, rainfall or irrigation may quickly change a well-aerated soil to one with isolated pockets of water, generating miniaquatic habitats. If flooding continues, a waterlogged soil can be created that is more like lake sediment. If oxygen consumption exceeds that of oxygen diffusion, waterlogged soils can become anoxic. Shifts in water content and gas fluxes also affect the concentrations of CO_2 and other gases. These changes are accentuated in the smaller pores, where many bacteria are found. The roots of plants growing in aerated soils also consume oxygen and release CO_2, influencing the concentrations of these gases in the root environment.

Soils can be divided into two general categories: A **mineral soil** contains less than 20% organic carbon, whereas an **organic soil** possesses at least this amount. By this definition, the vast majority of Earth's soils are mineral. The importance of organic matter within soils cannot be overstated. **Soil organic matter** (**SOM**) helps to retain nutrients, maintain soil structure, and hold water for plant use. SOM is subject to gains and losses, depending on changes in environmental conditions and agricultural practices. Plowing and other disturbances expose SOM to more oxygen, leading to extensive microbiological degradation of organic matter. Irrigation causes periodic wetting and drying, which can also lead to increased degradation of SOM, especially at higher temperatures.



Microbial degradation of plant material results in the release of CO_2 and the incorporation of plant carbon into microbial biomass. However, a small fraction of the decomposed plant material remains in the soil as SOM. When considering this material, it is convenient to divide SOM into humic and nonhumic fractions. Nonhumic SOM is free from significant biochemical degradation. It can represent up to about 20% of the soil organic matter. Humic SOM, or humus, results when the products of microbial metabolism have undergone chemical transformation within the soil. Although it has no defined chemical composition, humus can be described as a complex blend of phenolic compounds, polysaccharides, and proteins. The recalcitrant nature of SOM to degradation is evident by ^{14}C dating: the average age of most SOM ranges from 150 to 1,500 years.

Microbial degradation of plant material and the development of SOM can be thought of as a three-step process. First, easily degraded compounds such as soluble carbohydrates and proteins are broken down by a variety of heterotrophic microorganisms. About half the carbon is respired as CO_2, and the remainder is rapidly incorporated into new biomass. During the second stage, complex carbohydrates, such as the plant structural polysaccharide cellulose, are degraded. Cellulose represents a vast store of carbon, as it is the most abundant organic compound on Earth. Brown rot fungi and filamentous bacteria in the genera *Coniophora* and *Streptomyces,* respectively, and nonfilamentous bacteria such as *Cytophaga* and *Bacillus* spp. produce extracellular cellulase enzymes that break down cellulose into two and three glucose units called cellobiose and cellotriose, respectively. These smaller compounds are readily degraded and assimilated as glucose monomers. Finally, very resistant material, in particular lignin, is attacked.

Lignin is an important structural component of woody plants. While its exact structure differs among plant species, the common building block is the phenylpropene unit. This consists of a hydroxylated benzene ring and a three-carbon linear side chain (**figure 31.2**). A single lignin molecule can consist of up to 600 cross-linked phenylpropene units. It is therefore not surprising that degradation of lignin is much slower than that of cellulose. Basidiomycete fungi commonly termed white rot fungi (e.g., *Phanerochaete* and *Phlebia* spp.) and actinobacteria (e.g., *Streptomyces* spp.) are capable of extracellular lignin degradation. These filamentous microbes produce extracellular phenoloxidase enzymes needed for aerobic lignin degradation. Lignin decomposition is also limited by the physical nature of the material. For example, healthy woody plants are saturated with sap, which limits oxygen diffusion. In addition, high ethylene and CO_2 levels and the presence of phenolic and terpenoid compounds retard the growth of lignin-degrading microbes. It follows that no more than 10% of the carbon found in lignin is recycled into new microbial biomass. Lignin can be degraded anaerobically, but this process is very slow, so lignin accumulates in wet, poorly oxygenated soils, such as peat bogs.

Nitrogen is another important element in soil ecosystems. Nitrogen in soil is often considered in relation to the soil carbon content as the organic **carbon to nitrogen ratio** (**C/N ratio**). As a general rule, decomposition is thought to be maximal at a C/N ratio of 30 (i.e., 30 times more carbon than nitrogen). A ratio of less than 30 can result in the loss of soluble nitrogen from the system. Conversely ratios above 30 may cause the microbial community to be nitrogen limited. In fact, many soils are nitrogen limited. This is why each year tons of nitrogen fertilizer are added to agricultural soils. Most fertilizers include ammonium ion because it will bind to the negatively charged clays in a soil until used as a nutrient by the plants. However, when ammonium is in excess, nitrifying microorganisms in a soil can oxidize the ammonium ion to nitrite and nitrate, and these anions can be leached from the plant environment and pollute surface waters and groundwater. ⏮ *Nitrifying bacteria oxidize ammonium or nitrite to gain energy and electrons (section 22.1); Nitrogen cycle (section 28.1); Global climate change (section 28.2)*

Phosphorus is also commonly in short supply in soils, so it is also added to fertilizers. The binding of anionic phosphate molecules to soils depends on the cation exchange capacity and soil pH. As the soil's phosphorus sorption capacity is reached, the excess, together with phosphorus released by soil erosion, moves to lakes, streams, and estuaries, where it can stimulate the growth of freshwater organisms, particularly nitrogen-fixing cyanobacteria, resulting in eutrophication. ⏮ *Microorganisms in lakes can cause seasonal blooms (section 30.3)*

3. Describe the three phases of plant degradation and SOM formation.
4. What microbes commonly degrade cellulose and lignin? Why is their filamentous morphology advantageous?
5. Which of the following soils would a farmer be most likely to fertilize: A soil with a C:N ratio of 23, 28, or 37?
6. Why is most nitrogen fertilizer added as ammonium ion?

31.2 Diverse Microorganisms Inhabit Soil

After reading this section, you should be able to:

- Estimate the relative microbial populations in several soil types
- List the microbial genera that are easily cultured from soil
- Describe the different ecological niches occupied by microbes in soil and how microbes have evolved to take advantage of the niches
- Compare the soil microbial loop with an aquatic microbial loop

An average gram of forest soil contains about 4×10^7 bacteria and archaea, while a gram of grassland or cultivated soil may

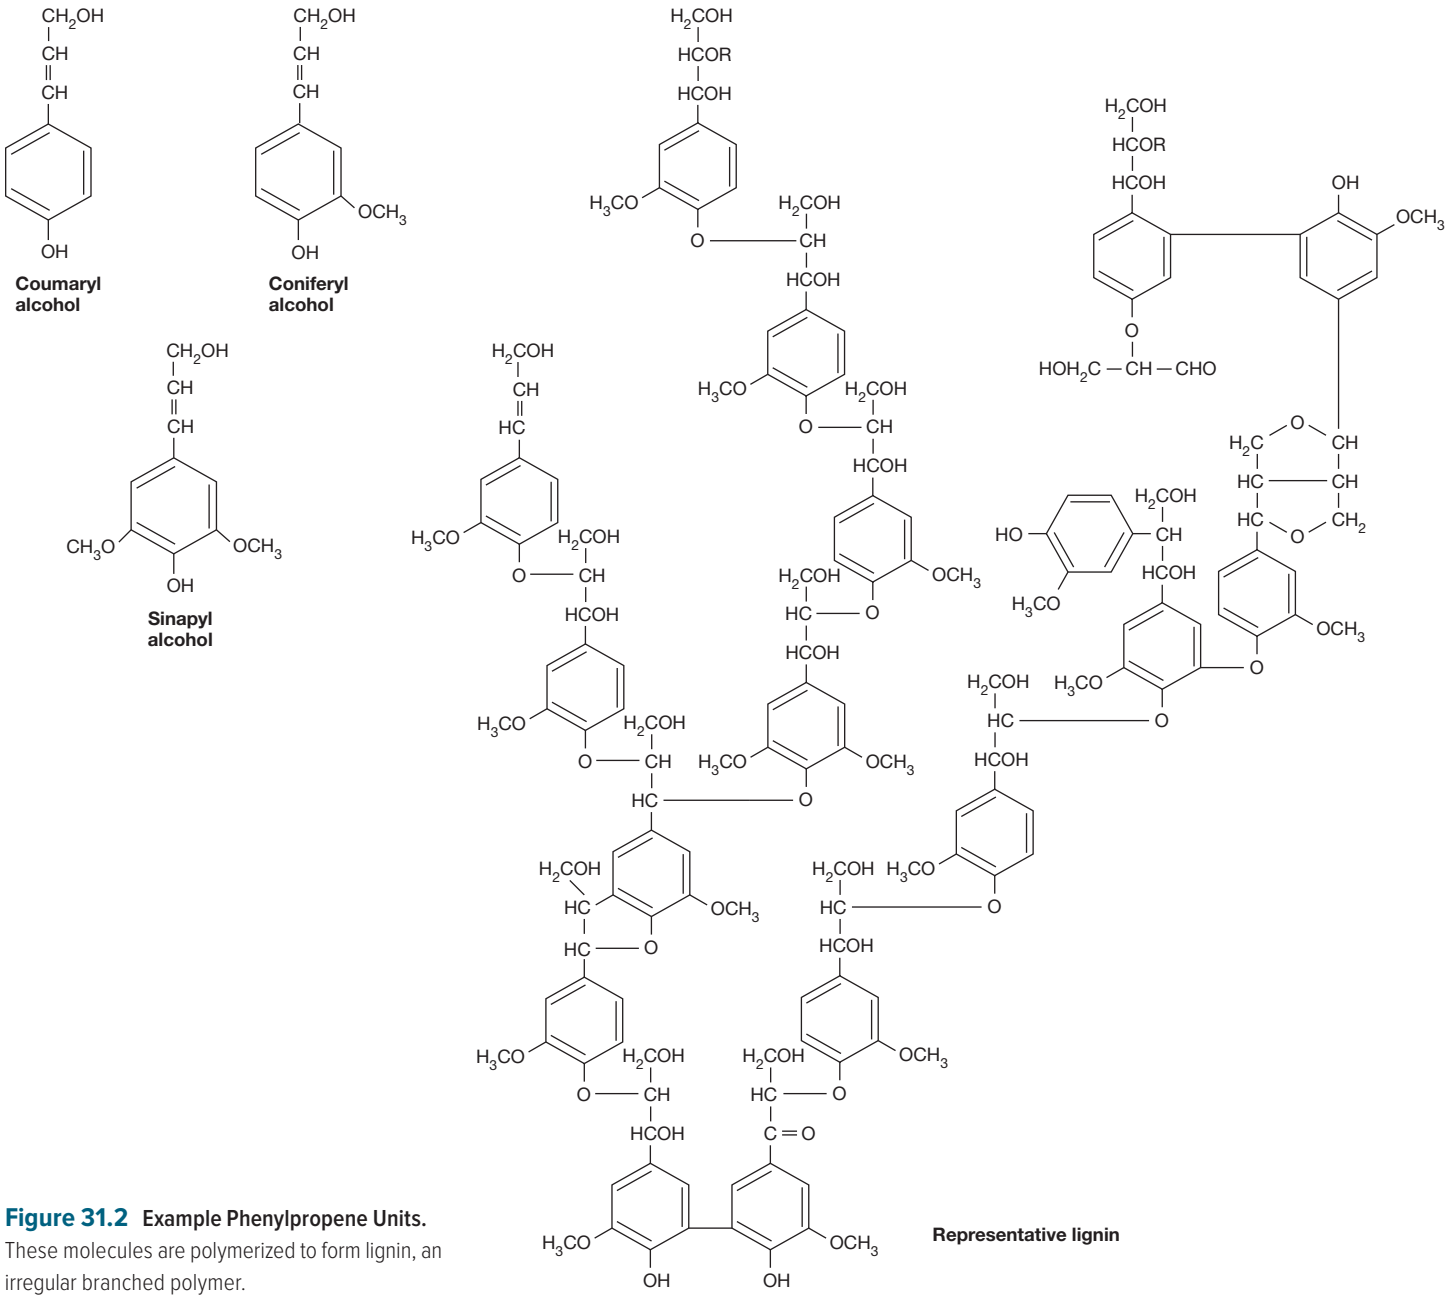

Figure 31.2 **Example Phenylpropene Units.**
These molecules are polymerized to form lignin, an irregular branched polymer.

possess 2×10^9 cells. It is difficult to determine how many different taxa are represented, but estimates based on DNA reassociation range from 2,000 to 18,000 distinct genomes per gram of soil. These numbers suggest that the microbial diversity in just 1 gram of soil may exceed the combined number of known archaeal and bacterial species—just over 16,000. ◀◀ *Genetic methods are used to assess microbial diversity (section 29.2)*

Small subunit rRNA gene surveys from different soils show some major trends. Although most rRNA gene sequences could be assigned to well-studied bacterial phyla, the majority (79 to 89%) could not be placed in any existing genera. Overall, bacteria belonging to at least 32 different phyla have been identified, with over 90% of soil bacterial 16S rRNA assigned to the nine phyla displayed in **figure 31.3**. Interestingly, this includes *Acidobacteria* and *Verrucomicrobia,* phyla about which little is known. Other important phyla not shown in figure 31.3 include *Chlamydiae, Chlorobi, Cyanobacteria, Deinococcus-Thermus,* and *Nitrospirae*. Coryneforms, nocardioforms, and streptomycetes are easily cultured and therefore well-characterized members of the soil community (**table 31.1**). These actinobacteria play a major role in the degradation of hydrocarbons, older plant materials, and soil humus. In addition, some members of these groups actively degrade pesticides. Filamentous bacteria, primarily of the genus *Streptomyces,* produce an odor-causing compound called geosmin, which gives soils their characteristic earthy odor. ◀◀ Actinobacteria: *High G + C Gram-positive bacteria (chapter 24)*

Of course, bacteria are not the only microbes present in soils. Among archaea, ammonia-oxidizing members of the phylum *Thaumarchaeota* usually prevail, and may constitute up to 10% of the microorganisms identified by SSU rRNA sequencing.

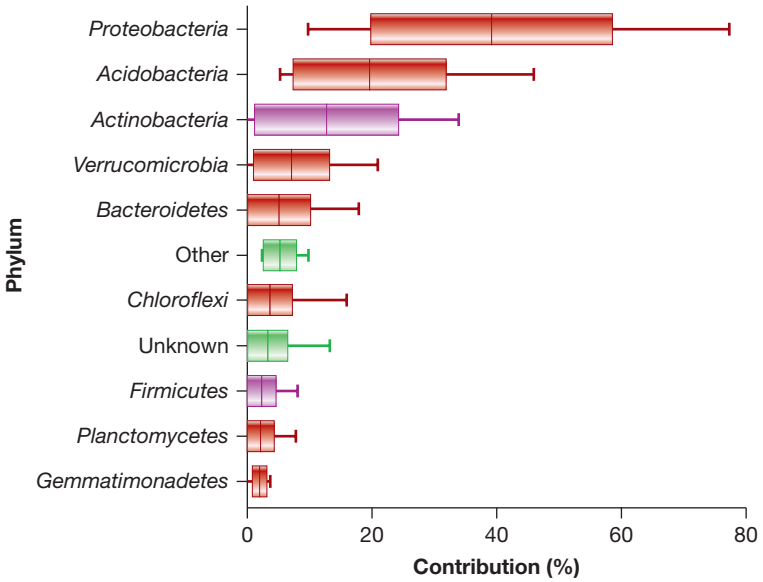

Figure 31.3 Bacterial Phyla Identified from 16S rRNA and 16S rRNA Genes Extracted from Soil. Data from 21 soil metagenomic libraries were analyzed to assess soil bacterial diversity. The horizontal line in the middle of each block represents the mean. The block represents one standard deviation around the mean. The vertical lines extending above and below indicate the maximum and minimum values for each phylum. Gram-negative phyla are shown in red, Gram-positive in violet, unknown and other phyla found in very small numbers in green.

The number of archaea appears to be related to the C/N ratio, with larger archaeal populations occurring in soils with higher concentrations of nitrogen. The relative contribution of bacterial and archaeal nitrification in soils is an active area of research *(see figure 22.15).* ◀◀ *Nitrogen cycle (section 28.1)*

Fungi are also very important members of the soil microbial community. Fungi that grow in the so-called bulk soil—soil not close to plant roots—are saprophytic, helping to degrade complex plant molecules. Fungi can extend up to several hundred meters of hyphae per gram of soil. Although we tend to think of soil fungi as the mushrooms sprouting on our lawns, the vast majority of fungal biomass is below ground. There filaments bridge open areas between soil particles or aggregates and are exposed to high levels of oxygen. These fungi tend to darken and form oxygen-impermeable structures called sclerotia and hyphal cords. This is particularly important for basidiomycetes, which form these structures as an oxygen-sealing mechanism. Within these structures, the filamentous fungi move nutrients and water over great distances, including across air spaces, a unique part of their functional strategy. Fungal biomass can be enormous; an individual clone of the fungus *Armillaria bulbosa,* which lives associated with tree roots in hardwood forests, covers about 30 acres in the Upper Peninsula of Michigan, USA. It is estimated to weigh a minimum of 100 tons (an adult blue whale weighs about 150 tons) and to be at least 1,500 years old. Thus some fungal mycelia are among the largest and most ancient living organisms on Earth. ◀◀ Basidiomycota *includes mushrooms and plant pathogens (section 26.6)*

The flux of nutrients through soil differs from the microbial loop that operates in aquatic ecosystems. In nearly all terrestrial ecosystems, plants, rather than microbes, account for most primary production. Soil microbes rapidly recycle the organic material derived from plants and animals, including the many nematodes and insects, which function to reduce the size of solid organic matter. In turn, microbes themselves are preyed upon by viruses, other bacteria (e.g., species within the genera *Lysobacter* and *Myxococcus*), and soil protists, whose numbers can reach 100,000 per gram of soil. This makes microbial organic matter available to other trophic levels. Another difference between aquatic and terrestrial nutrient flux reflects the physical and biological properties of soil. Degradative enzymes released by microbes, plants, insects, and other animals do not rapidly diffuse away. Instead, they represent a significant contribution to the biological activity in soil ecosystems by contributing to the many hydrolytic degradation reactions needed for the assimilation and recycling of nutrients.

Table 31.1 Easily Cultured Gram-Positive Bacteria in Soils

Bacterial Group	Representative Genera	Comments and Characteristics
Coryneforms	*Arthrobacter*	Rod-coccus cycle
	Cellulomonas	Important in degradation of cellulose
	Corynebacterium	Club-shaped cells
Mycobacteria	*Mycobacterium*	Acid-fast
Nocardioforms	*Nocardia*	Rudimentary branching
Streptomycetes	*Streptomyces*	Aerobic filamentous bacteria
Bacilli	*Thermoactinomyces*	Higher temperature growth

3. Compare and contrast the general flux of nutrients in terrestrial and aquatic ecosystems.

31.3 Microbe-Plant Interactions Can Be Positive, Negative, or Neutral

After reading this section, you should be able to:

- Describe mechanisms by which plants and microbes communicate
- Differentiate between the phyllosphere, rhizosphere, and rhizoplane environments and the microbes that dwell there
- Explain the importance of mycorrhizae to the growth of vascular plants
- Contrast and compare the ectomycorrhizal life cycle and that of arbuscular fungi

- Diagram the steps that result in the formation of rhizobium nodules on leguminous plants
- Compare the process of stem nodulation with root nodulation
- Discuss other microbes, in addition to rhizobia, that fix nitrogen
- Explain how *Agrobacterium tumefaciens* cause tumors in plants
- List at least five plant pathogens other than *Agrobacterium tumefaciens* and the diseases they cause
- Identify a plant disease that is likely to be found near your home or school

The evolution of aquatic plants into terrestrial organisms roughly 470 million years ago was made possible by cooperation with soil microbes, and many of these microbe-plant interactions remain. Some are commensalistic—no harm is done to the plant, but the microbe gains some advantage. Many others are beneficial to both the microorganism and the plant (e.g., they are mutualistic). Finally, other microbes are plant pathogens and parasitize their plant hosts. In all cases, the microbe and the plant have established the capacity to communicate. The microbe detects and responds to plant-produced chemical signaling molecules. This generally triggers the release of microbial compounds that are in turn recognized by the plant, thereby beginning a two-way "conversation" that employs a molecular lexicon. Once a microbe-plant relationship is initiated, microbes and plants continue to monitor the physiology of their partner and adjust their own activities accordingly. The nature of the signaling molecules and the mechanisms by which both plants and microbes respond have stimulated exciting multidisciplinary research in soil microbiology, ecology, molecular biology, genetics, and biochemistry. ⏮ *Cell–cell communication within microbial populations (section 7.5)* ⏭ *Many types of microbial interactions exist (section 32.1)*

Microbes that interact with plants can be broadly divided into two classes: microbes that live on the surface of plants, called **epiphytes,** and those that colonize internal plant tissues, called **endophytes.** We can further classify microbes into those that live in the aboveground, or aerial, surfaces of plants separately and those that inhabit below-ground plant tissues. We begin our discussion of microbe-plant interactions by introducing the microbial communities associated with aerial regions of plants. We then turn our attention to two important microbe-root symbioses—mycorrhizal fungi and nitrogen-fixing rhizobia. Finally, we consider several important microbial plant pathogens.

Phyllosphere Microorganisms Are Stress Resistant

The environment of the aerial portion of a plant (e.g., stems and leaves), called the **phyllosphere,** undergoes frequent and rapid changes in humidity, ultraviolet (UV) light exposure, and temperature. This causes fluctuations in the leaching of organic material (primarily simple sugars) that supports a diverse assortment of microbes, including bacteria, filamentous fungi, yeasts, and photosynthetic and heterotrophic protists. Bacterial densities are estimated to be 10^6 to 10^7 cells per cm^2 of plant tissue. Bacteria include the γ-proteobacteria *Pseudomonas syringae, Erwinia* spp., and *Pantoea* spp. In addition, methylotrophic α-proteobacteria such as *Methylobacterium* spp. are supported by the release of methanol by pectin methylesterase enzymes. Members of another abundant bacterial genus, *Sphingomonas,* produce pigments that function like sunscreen so they can survive the high levels of UV irradiation striking plant surfaces. The phyllosphere microbial community contributes to global carbon and nitrogen cycling, the removal of airborne pollutants, and the decomposition of leaf litter.

A metagenomic survey of the bacterial diversity of the phyllosphere of the Atlantic Forest in Brazil reveals some intriguing findings. This forest is thought to be the oldest on Earth, with over 20,000 vascular plant species. SSU rRNA analysis of bacteria in the phyllosphere of three plant species shows amazing species richness—from 95 to 671 bacterial species, and all but 3% are members of undescribed species. The diversity is further extended by the observation that each plant species has an almost unique phyllosphere bacterial community. Extrapolation of these results to the entire forest indicates that there are millions of new bacterial species yet to be discovered.

The Rhizoplane and Rhizosphere Support Complex Microbial Communities

Plant roots receive between 30 and 60% of the net photosynthesized carbon. Of this, an estimated 40 to 90% enters the soil as a wide variety of materials, including alcohols, ethylene, sugars, amino and organic acids, vitamins, nucleotides, polysaccharides, and enzymes. The plant root surface, termed the **rhizoplane,** provides an exceptional environment for microorganisms, as these gaseous, soluble, and particulate materials move from plant to soil.

The **rhizosphere** is the region surrounding a plant root rich in plant exudates more easily degraded than lignin and cellulose. This in turn supports bacterial and fungal populations, which can be as much as 100 times greater than surrounding bulk soil that lacks these nutrients. Microbes in these dense rhizosphere communities must compete with one another, and they do so by the secretion of antimicrobial agents, lytic enzymes, and even hydrogen cyanide. Other microbes counteract these inhibitors by efflux pumps, detoxification enzymes, and secretion of molecules that alter competitor gene expression. Importantly, rhizosphere and rhizoplane microorganisms provide nutrients for other organisms, including plants and other microbes, thereby playing critical roles in organic matter synthesis and degradation.

A wide range of microbes in the rhizoplane and rhizosphere promote plant growth, orchestrated by their ability to communicate with plants using chemical signals. Bacteria and fungi enhance plant growth by producing a variety of compounds. These include molecules that regulate plant growth called phytohormones (e.g., auxin and gibberellin) and compounds that stimulate host plant production of phytohormones. The production of volatile organic compounds including acetoin, and phenazines—a diverse class of heterocyclic compounds—stimulates plant responses to stress. In addition, some bacteria secrete compounds that suppress the growth of plant fungal pathogens. The use of these compounds in agriculture is an active area of research.

Associative nitrogen fixation is a critical process performed by nitrogen-fixing microorganisms in the rhizoplane as well as in

the rhizosphere. It is carried out by members of a number of genera, including *Azotobacter, Azospirillum,* and *Acetobacter.* These bacteria enhance the growth of agriculturally important crops such as wheat, potato, and barley. Interestingly, some evidence suggests that their major contribution may not be nitrogen fixation but the production of growth-promoting hormones that increase root hair development, thereby enhancing plant nutrient uptake.

Mycorrhizae Facilitate the Growth of Most Plants

Mycorrhizae (Greek, "fungus root") are mutualistic relationships that develop between about 80% of all land plants and a limited number of filamentous fungal species. Mycorrhizae are so abundant that up to 100 meters of mycorrhizal filaments can commonly be found in a gram of soil. Unlike most fungi, **mycorrhizal fungi** are not saprophytic; that is, they do not obtain organic carbon from the degradation of organic material. Instead, they use photosynthetically derived carbohydrate from their host. In return, they provide a number of services for their plant hosts. In moist environments, they increase the availability of nutrients, especially phosphorus. In arid environments, where nutrients do not limit plant growth to the same degree, mycorrhizae aid in water uptake, increasing transpiration rates in comparison with nonmycorrhizal plants. ▶▶| *Mutualism (section 32.1)*

Mycorrhizae can be broadly classified as **endomycorrhizae**—those with fungi that enter root cells, or as **ectomycorrhizae**—those that remain extracellular, forming a sheath of interconnecting filaments (hyphae) around roots. Although six types of mycorrhizae are detailed in **table 31.2** and **figure 31.4**, we focus primarily on the two most important types: ectomycorrhizae and arbuscular mycorrhizae. |◀◀ Glomeromycota *are mycorrhizal symbionts (section 26.4)*

Ectomycorrhizae (ECM) are formed by both ascomycete and basidiomycete fungi. ECM colonize almost all trees in cooler climates. Their importance arises from their ability to transfer essential nutrients, especially phosphorus and nitrogen, to the

Table 31.2 Mycorrhizal Associations

Mycorrhizal Classification	Fungi Involved	Plants Colonized	Fungal Structural Features	Fungal Function
Ectomycorrhizae	Basidiomycetes, including those with large fruiting bodies (e.g., toadstools); some ascomycetes	~90% of trees and woody plants in temperate regions; fungal-plant colonization is often species specific	Hartig net, mantle or sheath; rhizomorphs; root hair development is usually limited	Nutrient (N and P) uptake and transfer
Arbuscular	Glomeromycetes, in particular six genera of glomeromycetes	Wild and crop plants, tropical trees; fungal-plant colonization is not highly specific	Arbuscules: hyphae-filled invaginations of cortical root cell	Nutrient (N and P) uptake and transfer; facilitate soil aggregation; promote seed production; reduce pest and nematode infection; increase drought and disease resistance
Ericaceous	Ascomycetes Basidiomycetes	Low evergreen shrubs, heathers	Some intracellular, some extracellular	Mineralization of organic matter
Orchidaceous	Basidiomycetes	Orchids	Hyphal coils called pelotons within host tissue	Some orchids are non-photosynthetic and others produce chlorophyll when mature; these organisms are almost completely dependent on mycorrhizae for organic carbon and nutrients.
Ectendomycorrhizae	Ascomycetes	Conifers	Hartig net with some intracellular hyphae	Nutrient uptake and mineralization of organic matter
Monotropoid mycorrhizae	Ascomycetes Basidiomycetes	Flowering plants that lack chlorophyll (*Monotropaceae;* e.g., Indian pipe)	Hartig net one cell deep in the root cortex	Nutrient uptake and transfer

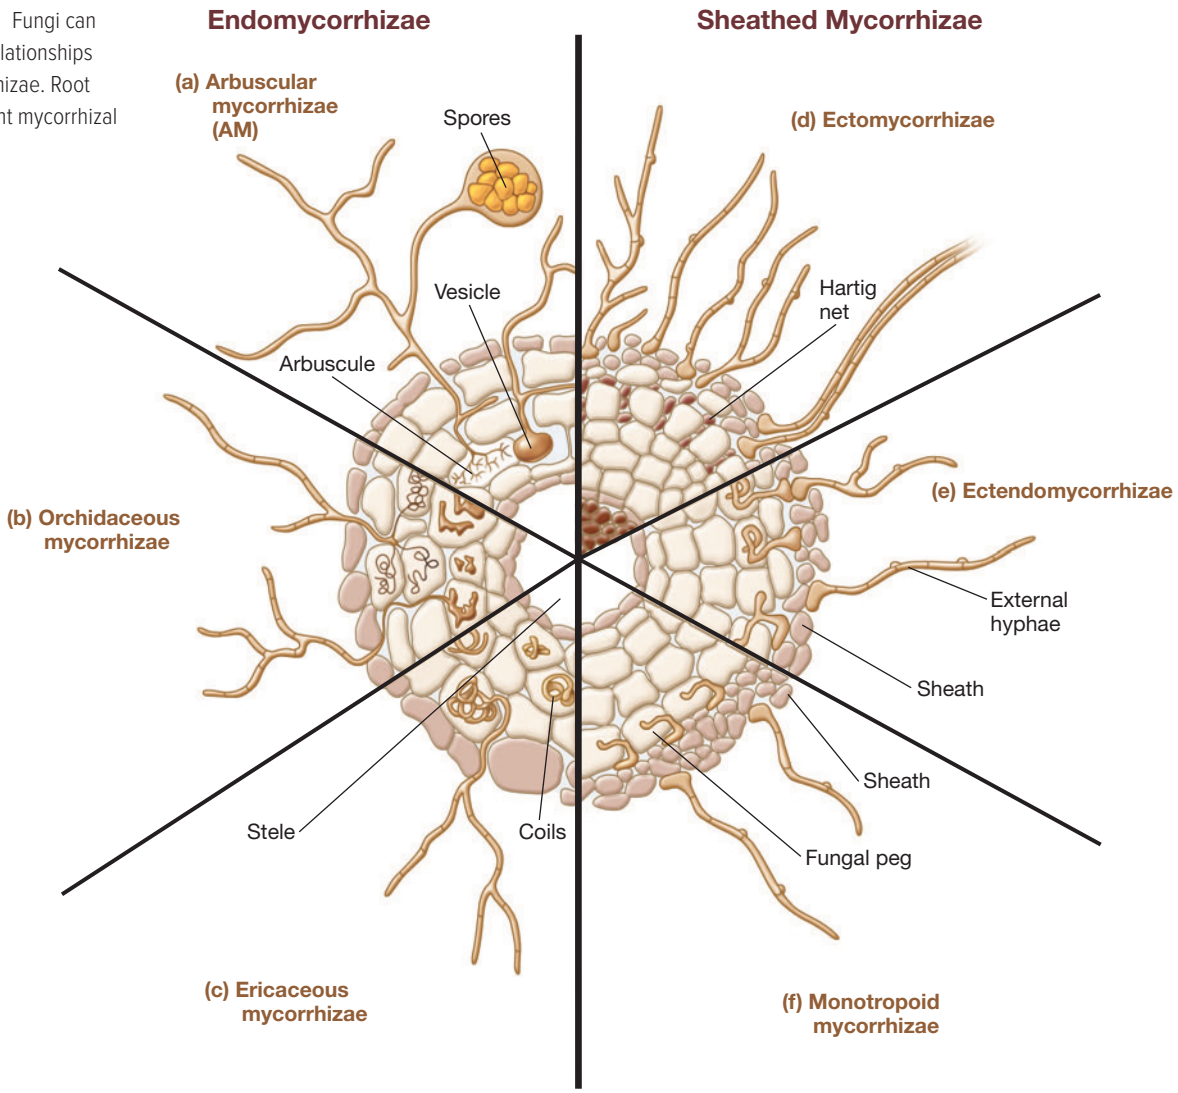

Figure 31.4 Mycorrhizae. Fungi can establish mutually beneficial relationships with plant roots, called mycorrhizae. Root cross sections illustrate different mycorrhizal relationships.

root. The development of ECM starts with the growth of a fungal mycelium around the root. As the mycelium thickens, it forms a sheath or mantle so that the entire root may be covered by the fungal mycelium (**figure 31.5**). Most ECM produce signaling molecules that limit the growth of root hairs; thus ECM-colonized roots often appear blunt and covered in fungi. From the root surface, the fungi extend hyphae into the soil; these filaments may aggregate to form **rhizomorphs**—dense mats of hyphae that are often visible to the naked eye. Hyphae on the inner side of the sheath penetrate between (but not within) the cortical root cells, forming a characteristic meshwork of hyphae called the **Hartig net** (figure 31.4*d*). Soil nutrients taken up by rhizomorphs must first pass through the hyphal sheath and then into the Hartig net filaments, which form numerous contacts with root cells. This results in efficient, two-way transfer of soil nutrients to the plant and carbohydrates to the fungus. This relationship has evolved to the point that some plants synthesize sugars such as mannitol and trehalose that they cannot use but are consumed by their fungal symbionts.

Arbuscular mycorrhizae (**AM**) are the most common type of mycorrhizae and make up about half the fungal biomass in most soils. They are found in association with many tropical plants and, importantly, with most crop plants. AM fungi belong to the taxon *Glomeromycota* and can be cultured only with roots of their plant hosts. These microbes enter root cells between the

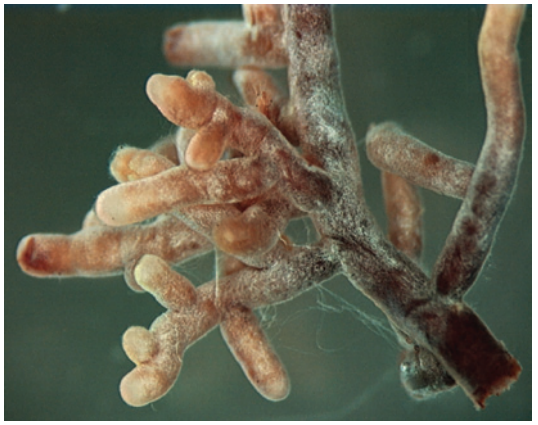

Figure 31.5 Ectomycorrhizae as Found on Roots of a Pine Tree. Typical irregular branching of the white, smooth mycorrhizae is evident.

plant cell wall and invaginations in the plasma membrane (figure 31.4*a*). So, although AM are endomycorrhizae, they do not breach the root cell membrane. Instead, treelike hyphal networks called **arbuscules** develop within the folds of the plasma membrane. Individual arbuscules are transient; they last at most 2 weeks. Spores released by nearby root-associated fungi germinate and colonize roots. This requires a number of specific steps, as shown in **figure 31.6**. AM can be vigorous colonizers: a 5 cm segment of root can support the growth of as many as eight species, and hyphae from a single germinated spore can simultaneously colonize multiple roots from unrelated plant species, forming a complex underground highway for nutrient transport.

The AM symbiosis is ancient, having appeared over 400 million years ago. Like the α-proteobacteria belonging to the rhizobium family (discussed next), AM establish symbioses with legumes (among other plants). The secretion of so-called "**Nod factors**" by rhizobia has been well established (p. 677), and analogous "**Myc factors**" have been purified from AM fungi (**figure 31.7**). Both Nod and Myc factors are lipochitooligosaccharides that prompt legume roots to accept the symbiont. Myc factors have a simpler structure than Nod factors. Given that the rhizobium-legume symbiosis is believed to have arisen only about 60 million years ago, it is likely that this signaling mechanism was adopted by rhizobia, who then further modified it.

AM are believed to provide a number of services to their plant hosts, including protection from disease, drought, nematodes, and other pests. Their capacity to transfer phosphorus to roots has been well documented. AM also provide nitrogen for their plant partners. Interestingly, AM assimilate NO_3^- and NH_4^+ through the glutamine synthetase–glutamate synthase (GOGAT) pathway (*see figure 12.13*), and therefore incorporate nitrogen into glutamine, which they then convert to arginine. But rather than transferring arginine to host cells, intracellular fungal hyphae degrade the amino acids, transferring only the NH_4^+ (**figure 31.8**). Thus while the fungus provides its host with much needed ammonium, it retains the carbon skeleton required for nitrogen uptake. In contrast, little is known about how mycorrhizal fungi take up carbon from their hosts. However, recent studies have revealed

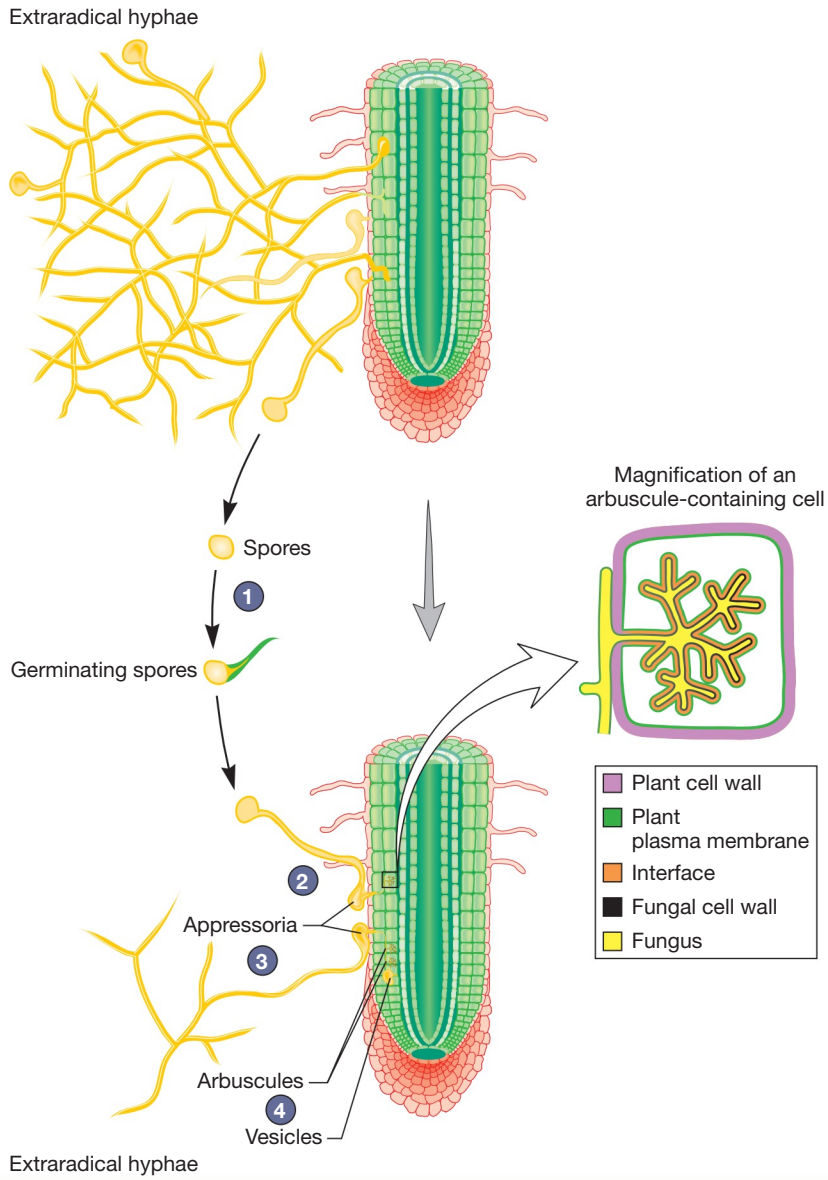

Figure 31.6 The Process of Root Colonization by Arbuscular Mycorrhizal Fungi.

MICRO INQUIRY *Which hyphae are growing saprotrophically in this diagram? How does the proportion of the organism growing saprotrophically change during host colonization?*

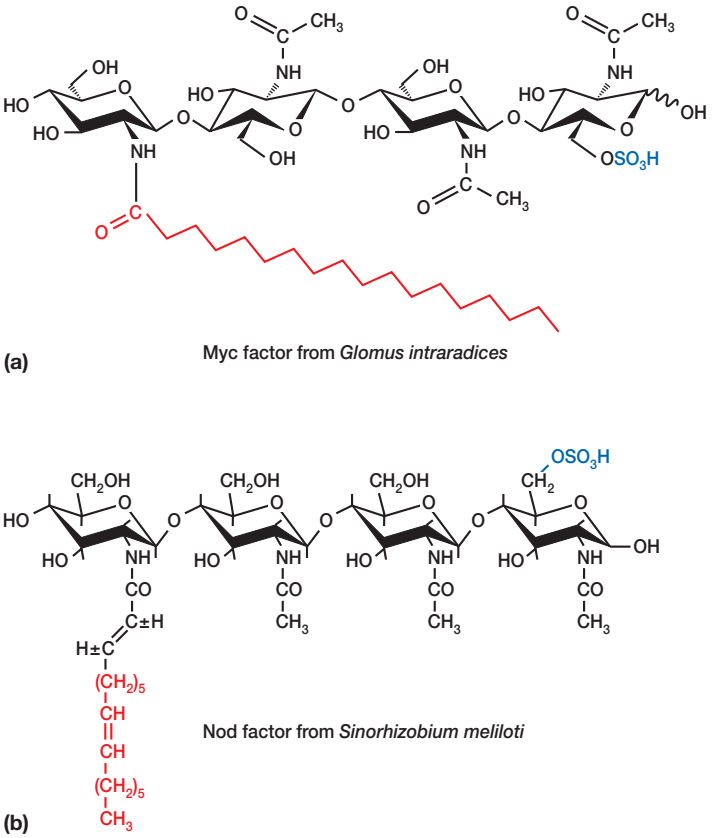

Figure 31.7 Myc and Nod Factors. Both arbuscular mycorrhizae and rhizobia form symbioses with legumes. In both cases, the symbiosis is initiated when the microbe secretes a lipochitooligosaccharide. (a) Myc factors, produced by fungi, have a simpler structure than (b) Nod factors of bacteria. The precise structure of individual Myc and Nod factors depends on the microbial species, but all consist of four to five units of β–1,4 linked *N*-acetyl-*D*-glucosamine bearing a species-specific acyl chain (red) at the nonreducing terminal residue. All Nod factors have a sulfate attached to the reducing end (blue), while not all Myc factors are sulfonated.

that the plants can detect, discriminate, and reward the best fungal partners with more carbohydrates. In return, the fungi transfer more nutrients to the plants that "feed" them best. This tight plant-microbe coupling probably accounts for the evolutionary stability of this partnership. ◀◀ *Inorganic nitrogen assimilation (section 12.5)*

In addition to these two most abundant mycorrhizal types, the orchidaceous mycorrhizae are of particular interest (figure 31.4*b*). Orchids are unusual plants because many never produce chlorophyll, while others only do so after they have matured past the seedling stage. Therefore all orchids have an absolute dependence on their endomycorrhizal partners for at least part of their lives. Indeed, orchid seeds will not germinate unless first colonized by a basidiomycete orchid mycorrhiza. Because orchids cannot produce photosynthetically derived organic carbon (or produce very little), orchid mycorrhizal fungi are saprophytic. They must degrade organic matter to obtain carbon, which the orchids then also consume. In this case, the orchid functions as a parasite.

The nature of some mycorrhizae-host relationships is currently being reevaluated. It is now known that in addition to orchids, some green plants such as serrated wintergreen (*Orthilia secunda*) also parasitize their mycorrhizal partners. Likewise, the nuisance plant spotted knapweed (*Centaurea maculosa*) in the United States may obtain up to 15% of its organic carbon from mycorrhizal fungi. Finally, mycorrhizae may limit plant species diversity in some ecosystems, as the growth of certain seedlings is promoted by mycorrhizae that will only associate with a particular plant species.

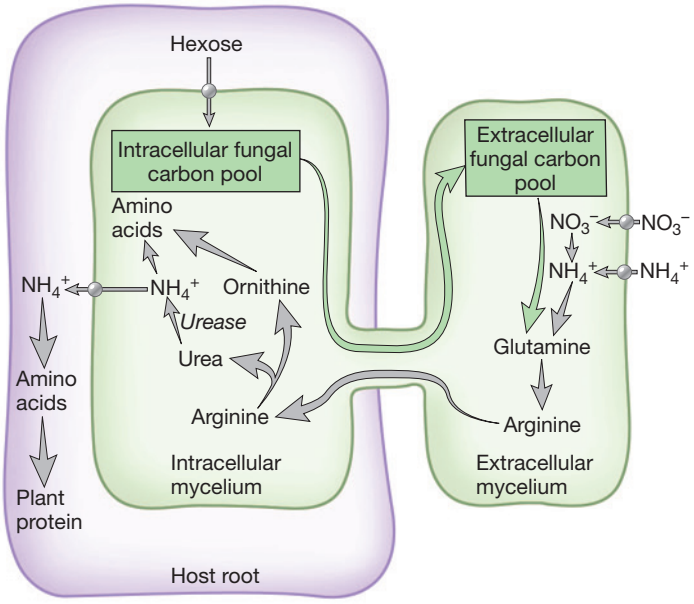

Figure 31.8 Nitrogen and Carbon Exchange Between Arbuscular Mycorrhizal Fungi and Host Plant. Nitrate and ammonium are taken up by the fungal mycelium that is outside the host plant cell (extracellular mycelium) and converted to arginine. This amino acid is transferred to the mycelium within the host plant cell and broken down so that only the ammonium enters the plant.

Just as bacteria associate with plant roots, they also interact with mycorrhizal fungi. As the external hyphal network radiates out into the soil, a mycorrhizosphere is formed due to the flow of carbon from the plant into the mycorrhizal hyphal network and then into the surrounding soil. These bacteria are called mycorrhization helper bacteria because they may play a role in the development of mycorrhizal relationships involving ectomycorrhizal fungi; they include species of *Pseudomonas, Bacillus*, and *Burkholderia*. Bacterial symbionts have also been found in the cytoplasm of AM fungi. These organisms appear to form a distinct lineage of β-proteobacteria, most closely related to *Burkholderia, Pandoraea*, and *Ralstonia*. Their role within the fungi remains unclear.

4. Describe the uptake and transfer of ammonium by arbuscular mycorrhizae to the plant host. Why is only the ammonium is transferred?
5. Propose two potential functions for mycorrhization helper bacteria.

Nitrogen-Fixing Bacteria Are Vital to Agriculture

The conversion of gaseous nitrogen (N_2) to ammonia (NH_3) often occurs as part of a symbiotic relationship between bacteria and

plants. These symbioses produce more than 100 million metric tons of fixed nitrogen annually and are a vital part of the global nitrogen cycle, and without them life on Earth could not have evolved. Currently, symbiotic nitrogen fixation accounts for more than half of the nitrogen used in agriculture (the remainder is applied as fertilizer). The provision of fixed nitrogen enables the growth of host plants in soils that would otherwise be nitrogen limiting. At the same time, it reduces loss of nitrogen by denitrification and leaching. It follows that nitrogen fixation, particularly that by members of the genus *Rhizobium* and related α-proteobacteria in association with their leguminous host plants, has been the subject of intense investigation. ◀◀ *Nitrogen cycle (section 28.1)*

Rhizobia Are Symbionts of Leguminous Plants

Several α-proteobacterial genera contain species that are able to form nitrogen-fixing nodules with legumes. These include *Allorhizobium, Azorhizobium, Bradyrhizobium, Mesorhizobium, Sinorhizobium,* and *Rhizobium.* Collectively these bacteria are often called **rhizobia.** The phylogenetic diversity of rhizobia has been extended by the discovery that the β-proteobacteria *Burkholderia caribensis* and *Cupriavidus* (formerly *Ralstonia*) *taiwanensis* also form nitrogen-fixing nodules on legumes. Here we discuss the general process of nodulation, including some molecular details that have been revealed largely through studies of bacteria in the genus *Rhizobium* ◀◀ *Class* Alphaproteobacteria *includes many oligotrophs (section 22.1); Class* Betaproteobacteria *includes chemoheterotrophs and chemolithotrophs (section 22.2)*

Rhizobia live freely in the soil. In nitrogen-sufficient soils, plants secrete ethylene-mediated compounds that inhibit nodulation. But even in nitrogen-starved soils, when rhizobia approach the plant root, they are assumed to be invaders. The plant responds with an oxidative burst, producing a mixture of compounds that can contain superoxide radicals, hydrogen peroxide, and N_2O. This oxidative burst is critical in determining the fate of the infection process. Rhizobia that become effective colonizers mount antioxidant defenses. Only rhizobia with sufficient antioxidant abilities are able to proceed to the next step in the infection process.

Infection is initiated by the exchange of signaling molecules between the plant and rhizobia in the rhizosphere. Plant roots release flavonoid inducer molecules (2-phenyl-1,4-benzopyrone derivatives) that stimulate rhizobial colonization of the root surfaces (**figure 31.9*a***). Flavonoids bind the bacterial protein NodD, which can then function as a transcriptional regulator. NodD activates transcription of *nod* genes, which encode the biosynthetic enzymes needed for the production of Nod factor signaling compounds (figure 31.9*b*). Conversely flavonoids from nonhost plants inhibit the production of Nod factors. Upon receipt of the Nod factor signal, gene expression in the outer (epidermal) cells of the roots is altered, resulting in oscillations in the levels of intracellular calcium. This "calcium spiking" triggers the root hairs to curl, resembling a shepherd's crook, thereby entrapping bacteria (figure 31.9*c,d*). Nod factors trigger root cortex cells to initiate cell division, and these cells will eventually form the nodule primordium that accepts the invading rhizobium.

In addition to Nod factors, the bacteria now produce an exopolysaccharide that induces changes in the plant cell wall, and the plant plasma membrane invaginates. This leads to the development of a bacteria-filled, tubelike structure called the **infection thread** (figure 31.9*e,f*). Plant cell division drives the growth of the infection thread. When bacteria penetrate the base of a root hair cell, they stimulate growth of the infection thread through additional plant cell walls and membranes. This is dependent on the plant hormone cytokinin in concert with Nod factor stimulation of plant cell mitosis. Finally, the infection thread filled with bacteria reaches the inner plant cortex, where each bacterial cell is endocytosed by a plant cell in a discrete, unwalled membrane compartment that arises from the infection thread. This unit, consisting of an individual bacterium and the surrounding endocytic membrane, is called the **symbiosome** (figure 31.9*g*). It is here that each bacterial cell differentiates into the nitrogen-fixing form called a **bacteroid.** Depending on the plant species, bacteroids may be terminally differentiated: they can neither divide nor revert back to the nondifferentiated state. Terminal differentiation is controlled by the production of nodule-specific cysteine-rich (NCR) peptide signals by the plant host; interestingly, these signals are similar in structure to antimicrobial peptides produced by humans called defensins. ▶▶ *Antimicrobial peptides and proteins (section 33.3)*

The low levels of oxygen within the symbiosome triggers a regulatory cascade that controls nitrogen fixation and the switch to microaerobic respiration needed to provide ATP and reducing equivalents to the nitrogenase enzyme. These regulatory proteins include an oxygen-sensing, two-component signal transduction system (FixL and FixJ) and an alternative sigma factor, σ^N. Overall, most metabolic processes within bacteroids diminish with the exception of nitrogen fixation and respiration, which are upregulated. The assembly of many symbiosomes gives rise to the **root nodule** (figure 31.9*h,i*). ◀◀ *Nitrogen fixation (section 12.5); Bacteria combine several regulatory processes to control complex cellular processes (section 14.5)*

The reduction of atmospheric N_2 to ammonia by the differentiated bacteroids depends on the production of a protein called **leghemoglobin.** Recall that the nitrogenase enzyme is disabled by oxygen. To help protect the nitrogenase, leghemoglobin binds oxygen and helps maintain microaerobic conditions within the mature nodule. Leghemoglobin is similar in structure to the hemoglobin found in animals; however, it has a higher affinity for oxygen. Interestingly, the protein moiety is encoded by plant genes, whereas the heme group is a bacterial product.

The transfer of ammonia from the rhizobium to the host plant involves a complex cycling of amino acids. The plant provides certain amino acids to the bacteroids so that they do not need to assimilate ammonia. In return, the bacteroids shuttle amino acids (which bear the newly fixed nitrogen) back to the plant. This creates an interdependent relationship, providing selective pressure for the evolution of mutualism. The bacteria also receive carbon and energy in the form of dicarboxylic acids from their host legume.

The molecular mechanisms by which both the legume host and the rhizobial symbionts establish productive nitrogen-fixing bacteroids within nodules is an intense area of research. A major

goal of biotechnology is to enable nitrogen fixation within cereal plants such as rice, wheat, and corn. Three approaches are being pursued: (1) modifying rhizobia to form productive nodules on these nonleguminous plants; (2) creating strains of non-nodulating nitrogen-fixing bacteria that will colonize cereal plants; and (3) introducing nitrogen-fixation genes into plants that are not rhizobium hosts. Although progress has been made using each approach, nitrogen fixation on these important crops has yet to be realized, and the use of human-made fertilizer, with all its environmental problems, continues. ◀◀ *Global climate change (section 28.2)*

Stem-Nodulating Rhizobia

A few leguminous plants support rhizobia that nodulate stems, rather than roots. Nodules form at the base of roots branching out of the stem just above the soil surface. These plants are generally found in waterlogged soils and riverbanks. Nodulation of the

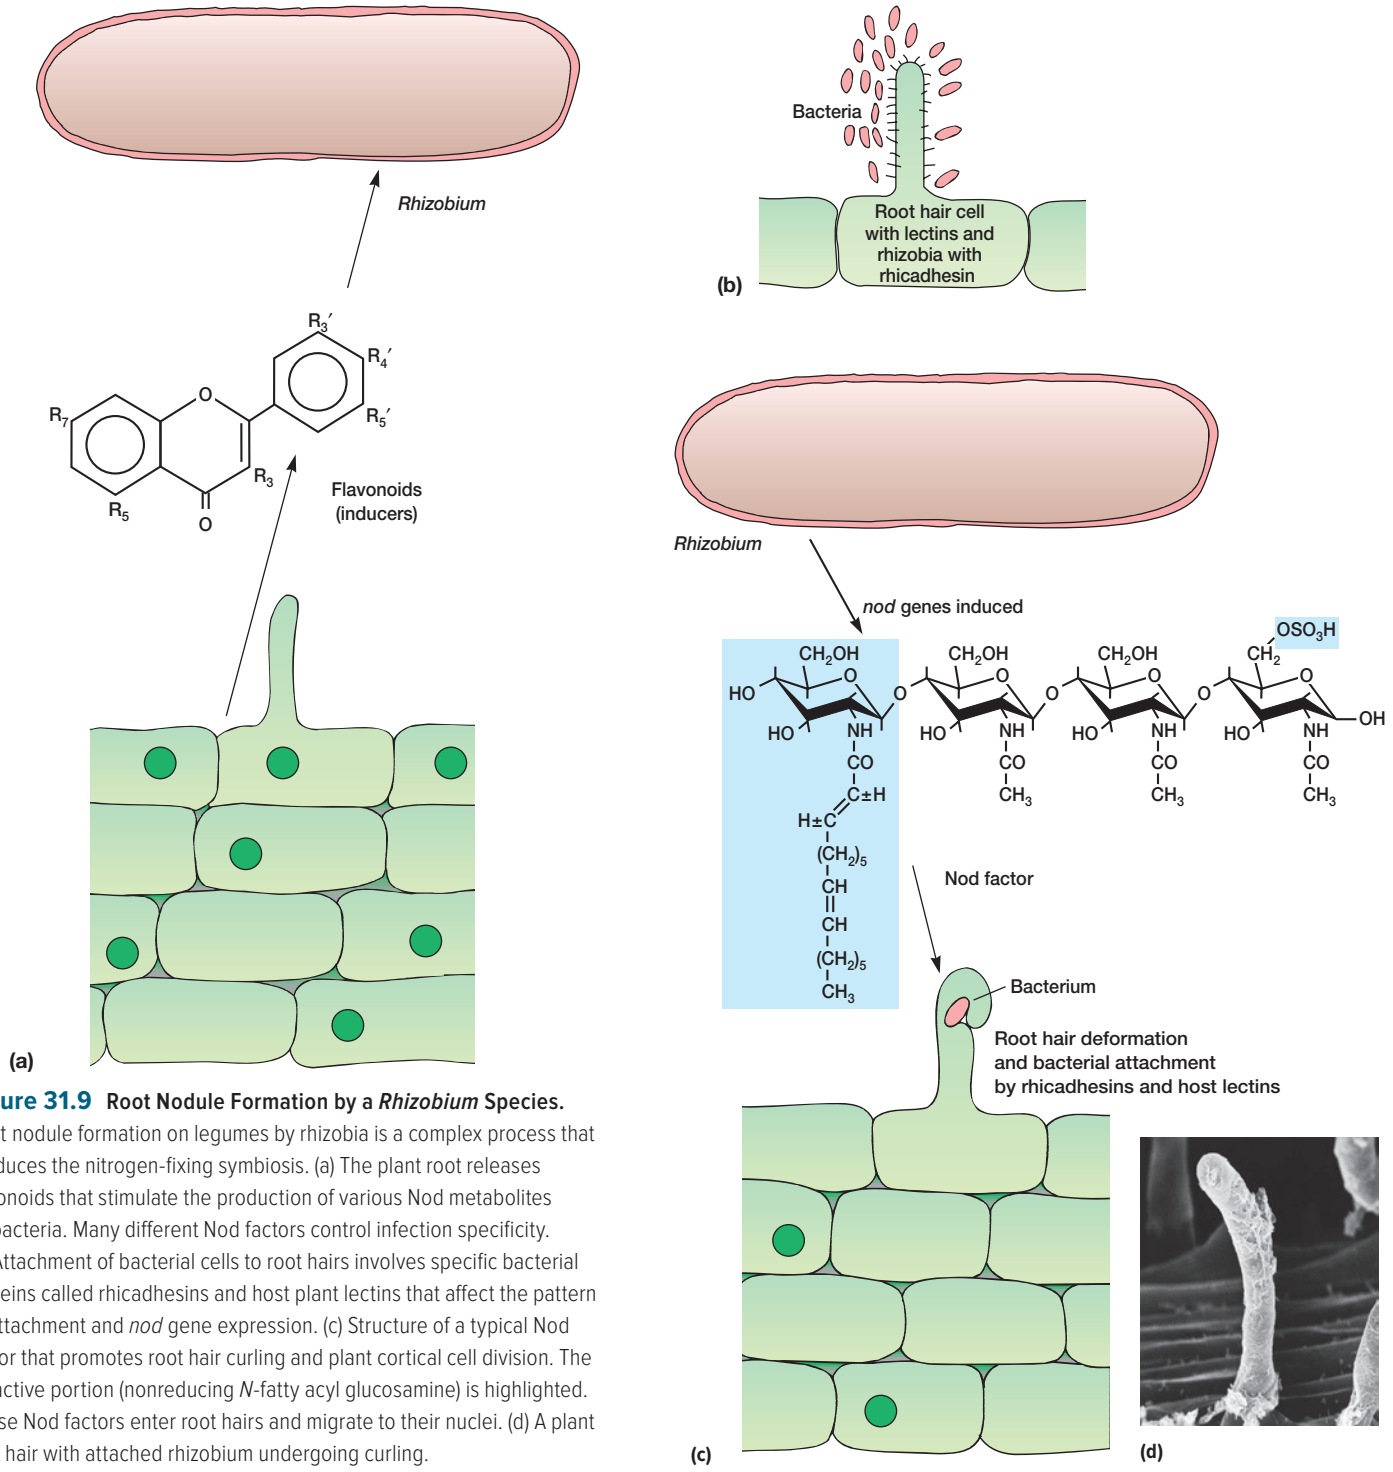

Figure 31.9 Root Nodule Formation by a *Rhizobium* Species. Root nodule formation on legumes by rhizobia is a complex process that produces the nitrogen-fixing symbiosis. (a) The plant root releases flavonoids that stimulate the production of various Nod metabolites by bacteria. Many different Nod factors control infection specificity. (b) Attachment of bacterial cells to root hairs involves specific bacterial proteins called rhicadhesins and host plant lectins that affect the pattern of attachment and *nod* gene expression. (c) Structure of a typical Nod factor that promotes root hair curling and plant cortical cell division. The bioactive portion (nonreducing *N*-fatty acyl glucosamine) is highlighted. These Nod factors enter root hairs and migrate to their nuclei. (d) A plant root hair with attached rhizobium undergoing curling.

vetch *Aeschynomene sensitiva* by a photoheterotrophic strain of *Bradyrhizobium* has been studied in some detail. *Bradyrhizobium* strain BTAi synthesizes its light-harvesting apparatus only under aerobic day–night cycles of illumination, and optimal nodulation and nitrogen fixation occur only if the microbe is phototrophic. It is thought that light-driven cyclic electron transfer generates a proton gradient used for either ATP synthesis or substrate transfer.

The process of stem nodulation differs from that of root nodulation. Stem nodulation starts with the entry of bacteria through ruptures in stem epidermal cells that occur during emergence of the root tip. Unlike root nodulation, the infection of *Bradyrhizobium* strain BTAi does not involve the production of Nod factors or plant calcium spikes (**figure 31.10**). Nonetheless, as with root nodulation, bacteria within stem nodules are protected from the external environment and can obtain plant-derived energy substrates.

Frankia form Actinorhizae

Another example of symbiotic nitrogen fixation occurs between actinobacteria of the genus *Frankia* and eight nonleguminous host plant families. These bacterial associations with plant roots are called **actinorhizae** or actinorhizal relationships (**figure 31.11**). *Frankia* spp. are important particularly in trees and shrubs. The nodules of some plants (*Alnus, Ceanothus* spp.) can be as large as baseballs. The nodules of *Casuarina* spp. (Australian pine) approach soccer ball size.

Depending on the host plant, the infection process proceeds either by root hair infection or by direct penetration of the matrix between root cells. When infecting through root hairs, the bacteria induce plant cell division, leading to the development of a prenodule. *Frankia* cells then enter the cortex of the root and form a nodule that resembles a lateral root. When infection is independent of root hair invasion, the bacteria are encapsulated in a shell made of pectin that then extends through the plant intercellular spaces. Although *Frankia* nodules vary in morphology, they all bear the general appearance of lateral root clusters that grow by repeated branching of the tips. Some nodules are found just below the surface of the soil, whereas others—particularly those forming on plants that grow in dry, rocky soil—develop very deep below the surface. ◀◀ *Order* Frankiales *(section 24.1)*

Agrobacterium Is a Model Plant Pathogen

Clearly some microbe-plant interactions are beneficial for both partners. However, others involve microbial pathogens that harm or even kill their host. *Agrobacterium tumefaciens* is an α-proteobacterium that has been studied intensely for several decades. Initially research focused on how this microbe causes crown gall disease, which results in the formation of tumorlike growths in a wide variety of plants (**figure 31.12**). Within the last 20 years or so, however, *A. tumefaciens* has become one of biotechnology's most important tools. The molecular genetics by which this pathogen infects its host are the basis for plant genetic engineering. ⏮ *Class* Alphaproteobacteria *includes many oligotrophs (section 22.1)* ⏭ *Agricultural biotechnology relies on a plant pathogen (section 42.5)*

The genes for plant infection and virulence are encoded on an *A. tumefaciens* plasmid called the **Ti** (**tumor-inducing**) **plasmid.** These genes include 21 *vir* genes (*vir* stands for virulence), found in six separate operons. Two of these genes, *virD1* and *virD2,* encode proteins that excise a specific region of the Ti plasmid, called **T DNA.** After excision, the T DNA fragment is integrated into the host plant's genome. Once incorporated into a plant cell's genome, T DNA directs the overproduction of phytohormones that cause unregulated growth and reproduction of plant cells, thereby generating a tumor or gall in the plant.

The *vir* genes are not expressed when *A. tumefaciens* is living saprophytically in the soil. Instead, they are induced by the presence of plant phenolics and monosaccharides in an acidic (pH 5.2–5.7) and cool (below 30°C) environment (**figure 31.13*a***). The microbe infects its host through a wound. Upon reception of the plant signal, a two-component signal transduction system is activated: VirA is a sensor kinase that, in the presence of a phenolic

The T DNA is moved into the plant cell, where it integrates into the plant DNA. T DNA induces the production of plant hormones that cause the plant cells to divide, producing the tumor. (b) The tumor cells produce opines that can serve as a carbon source for the infecting *A. tumefaciens*. Ultimately a crown gall is formed on the stem of the wounded plant above the soil surface.

MICRO INQUIRY *How does the production of opines by the plant accelerate and amplify the* A. tumefaciens *infection process?*

signal, phosphorylates the response regulator VirG. Activated VirG then induces transcription of the other *vir* genes. This enables the bacterial cell to become adequately positioned relative to the plant cell, at which point the *virB* operon expresses the apparatus that will transfer the T DNA. This transfer is similar to bacterial conjugation and involves a type IV secretion system. After VirD1 and VirD2 excise the T DNA from the Ti plasmid, the T DNA, with the VirD2 protein attached to the 5′ end, is delivered to the plant cell cytoplasm. The protein VirE2 is also transferred, and together with VirD2, the T DNA is shepherded to the plant cell nucleus, where it is integrated into the host's genome.

Once it is part of the host cell genome, the T DNA has two specific functions. First, it directs the host cell to overproduce phytohormones that cause tumor formation. Second, it stimulates the plant to produce special amino acid and sugar derivatives called opines (figure 31.13*b*). Opines are not metabolized by the plant, but *A. tumefaciens* is attracted to opines; chemotaxis of bacteria from the surrounding soil population will further advance the infection because the bacterium can use opines as sources of carbon, energy, nitrogen, and, in some cases, phosphorus. ◀◀ *Bacteria combine several regulatory processes to control complex cellular processes (section 14.5); Bacterial conjugation requires cell-cell contact (section 16.6)*

Microbial Plant Pathogens Are Diverse

In terms of both diversity and economic costs, fungi are the most important plant pathogens, causing about 70% of plant disease (**table 31.3**; also see chapter-opening story). Fungal plant pathogens can be classified by their relationship with their plant hosts: they consume either living or dead plant material. **Biotrophic fungi** assimilate living plant material, and as such this term can also be applied to mutualistic mycorrhizae. Parasitic biotrophic fungi include powdery mildew and rust fungi; these microorganisms have evolved a special feeding apparatus called the haustorium to take up nutrients. Haustoria develop by the expansion of

fungal hyphae that penetrate plant host cells. By contrast, **necrotrophic fungi** kill their host plant cells by releasing toxins or enzymes prior to consuming plant nutrients. Necrotrophic fungi infect (and kill) a broader range of hosts. *Sclerotinia sclerotiorum* (white mold fungus) and *Botrytis cinerea* (grey mold fungus) are two notorious necrotrophic fungi that each parasitize over 200 different plant species and are responsible for the loss of millions of pounds of produce both pre- and post-harvest annually.

Many bacteria are also plant pathogens (table 31.3). Like *A. tumefaciens,* some plant pathogenic bacteria infect through a wound in the plant. Others, like the soft-rot bacteria *Erwinia chrysanthemi* and *E. carotovora,* digest plant tissue by secreting enzymes that degrade pectin, cellulose, and proteins. Another group of important bacterial plant pathogens includes the walless bacterial phytoplasms that infect vegetable and fruit crops such as sweet potatoes, corn, and citrus.

As discussed in chapters 25 and 27, protists, viruses, and viroids can also be devastating plant pathogens. Examples include the öomycete *Phytophthora infestans,* which was responsible for the Irish potato famine (and continues to extract an economic burden), and tobacco mosaic virus (TMV), the first virus to be characterized. A virus of particular interest in terms of plant-pathogen interactions is a hypovirus (family *Hypoviridae*) that infects the fungus *Cryphonectria parasitica,* the cause of chestnut blight. Based on studies carried out in Europe, workers in the United States noted that if they infected the fungus with this hypovirus,

the rate and occurrence of blight were decreased. Infection of trees with the less lethal virus strains is the basis of biological control efforts for chestnut blight. The goal is to vaccinate trees against the indigenous lethal strains of *Cryphonectria*.

1. What is the difference between the Ti plasmid and T DNA?
2. What functions do the members of the two-component system play in infection of a plant by *A. tumefaciens?* What are the roles of phenolics and opines in this infection process?
3. What are the two general ways by which plant pathogens gain entry into the host plant tissue? What are the advantages and disadvantages of each mechanism?
4. How are plant pathologists attempting to control chestnut blight?

31.4 The Subsurface Biosphere Is Vast

After reading this section, you should be able to:

- Relate the metabolic processes that occur in the subsurface biosphere to the free energy released during the use of each successive compound as a terminal electron acceptor
- Describe the distribution of subsurface methane production
- Explain at least one new discovery that has come from exploring the "deep hot biosphere"

For many years, it was thought that life could exist only in the thin veneer of Earth's surface and that any microbes recovered from sediments hundreds of meters deep were contaminants obtained during sampling. This view was drastically altered in the 1980s when the U.S. Department of Energy started looking for novel ways to store toxic waste. The agency began funding studies that applied modern technologies to sample the deep subsurface biosphere. Subsequent reports of microbes at great depth gained credibility, and international teams of geologists and microbiologists have since recovered microbes from thousands of meters below Earth's surface. The application of culture-independent techniques to quantify the density, diversity, and activity of microbes has revealed that subsurface microbes constitute about one-third of Earth's living biomass. This realization has made deep subsurface microbiology an exciting and active field.

Microbial processes take place in different subsurface regions, including (1) the shallow subsurface where water flowing from the surface moves below the plant root zone; (2) regions where organic matter, originally from the Earth's surface, has been transformed by chemical and biological processes to yield coal (from land plants), kerogens (from marine and freshwater microorganisms), and oil and gas; (3) zones where methane is being synthesized as a result of microbial activity; and (4) the energy-starved deep biosphere.

In the shallow subsurface, surface waters often move through aquifers—porous geological structures below the plant root zone. In a pristine system with an oxic surface zone, the electron acceptors used in catabolism are distributed from the most oxidized and energetically favorable (oxygen) near the surface to the least favorable (in which CO_2 is used in methanogenesis) in lower zones (*see figures 28.1 and 30.13*).

In subsurface regions where organic matter from the Earth's surface has been buried and processed by thermal and biological processes, kerogens and coals break down to yield gas and oil. After their generation, these mobile products, predominantly hydrocarbons, move upward into the more porous geological structures where microorganisms are active. Chemical signature molecules from plant and microbial biomass are present in these petroleum hydrocarbons.

Microorganisms also appear to be growing in intermediate-depth, oil-bearing structures. Active bacterial and archaeal assemblages are present in high-temperature (60 to 90°C) oil reservoirs, including members of such genera as *Thermotoga, Thermoanaerobacter,* and *Thermococcus.* The archaeal species are dominated by methanogens.

The "deep hot biosphere" is a term suggested by Thomas Gold to describe the largest and most mysterious biosphere on Earth: bacteria and archaea that live kilometers beneath the Earth's crust. The lack of apparent substrates to support growth and the calculated generation times in centuries to even 1,000 years seem alien to our understanding of microbial life. Anaerobic chemolithoautotrophy, independent of photosynthetically derived compounds, fuels these microbes; abiotically produced H_2 is believed to the most important energy and electron source. An interesting example of such bacterial activity was discovered in 2.8 km-deep, high-pressure water within a crustal fracture in a South African gold mine. Surprisingly, at least 99% of the microbes belong to a single firmicute species, as determined by 16S rRNA analysis. DNA collected from this unusual habitat was assembled into a complete genome to reveal a novel bacterium provisionally called *Candidatus* Desulforudis audaxviator. It appears to be a motile, spore-forming, sulfate-reducing chemoautotroph that is moderately thermophilic. This microbe most likely infiltrated the fracture zone 3 million to 25 million years ago, and its growth has apparently been sustained by hydrogen as electron donor and sulfate as terminal electron acceptor. ⏮ *Class* Clostridia *(section 23.1)*

The discovery of deep subsurface microbes has a variety of implications. For example, the presence of primary production in the absence of sunlight suggests that autotrophy might also be possible in the subsurface sediments of Mars. Exploring this possibility, along with investigating the level of metabolic activity among Earth's deep subsurface microbes, remains the next challenge. ⏮ *Microbial communities in benthic marine sediments are enormous and mysterious (section 30.2)*

Retrieve, Infer, Apply

1. Compare and contrast the metabolism (specifically, electron donors and acceptors) of microbes in the shallow subsurface with that of microbes in the very deep subsurface.
2. What happens in terms of microbiological processes when organic matter leaches from the surface into the subsurface?
3. What microbial genera have been observed in oil field materials?

Key Concepts

31.1 Soils Are an Important Microbial Habitat

- Soil is a complex mixture of clay, sand, silt, organic matter, and water. This provides many micro-environments that can support a diverse microbial community (**figure 31.1**).
- Soil organic matter (SOM) helps retain nutrients and water, and maintain soil structure. It can be divided into humic and nonhumic material.

31.2 Diverse Microorganisms Inhabit Soil

- Soils support the highest levels of microbial diversity measured.
- Archaea are not as abundant as bacteria in soils; ammonia-oxidizing archaea contribute to nitrification in soils.
- Saprophytic and mycorrhizal fungi constitute about half the soil microbial biomass in most soils.

31.3 Microbe-Plant Interactions Can Be Positive, Negative, or Neutral

- The phyllosphere includes all parts of a plant that are aboveground. These structures offer a unique but changeable environment for microbial growth.
- The rhizosphere is the region around plant roots into which plant exudates are released. The rhizoplane is the plant root surface. A variety of microbes growing in these regions promote plant growth.
- Mycorrhizal relationships (plant-fungal associations) are varied and complex. Six basic types are observed, including endomycorrhizal and sheathed/ectomycorrhizal types. The hyphal network of the mycobiont can lead to the formation of a mycorrhizosphere (**figures 31.4–31.8; table 31.2**).
- The rhizobium-legume symbiosis is one of the best-studied examples of plant-microorganism interactions. Rhizobia form nodules on the roots of host plants in which specialized bacterial cells (bacteroids) fix nitrogen (**figure 31.9**).
- The interaction between rhizobia and host plants is mediated by complex chemicals that serve as communication signals (**figures 31.7–31.10**).
- *Actinobacteria* in the genus *Frankia* form nitrogen-fixing symbioses with some trees and shrubs.
- *Agrobacterium tumefaciens* establishes a complex communication system with plant hosts into which they transfer a fragment of DNA. Genes on this DNA encode proteins that promote bacterial growth and result in the formation of plant tumors or galls (**figures 31.12** and **31.13**).

31.4 The Subsurface Biosphere Is Vast

- The subsurface includes at least four zones: the shallow subsurface; the zone where gas, oil, and coal have accumulated; intermediate depths where oil and methane are found; and the very deep, hot subsurface.
- Microbial activity in the deep subsurface suggests extraordinarily slow growth fueled by substrates of geological, rather than photosynthetic, origin. These compounds support anaerobic chemolithoautotrophy.

Compare, Hypothesize, Invent

1. Why might vascular plants have developed relationships with so many types of microorganisms? These molecular-level interactions show many similarities when microbe-plant and microbe-human interactions are considered. What does this suggest concerning possible common evolutionary relationships?
2. How might you maintain organisms from the deep hot subsurface under their in situ conditions when trying to culture them? Compare this problem with that of working with microorganisms from deep marine environments.
3. Soil bacteria such as *Streptomyces* spp. produce the bulk of known antibiotics. It has been suggested that in nature antibiotics serve as signaling molecules, allowing members of the same species or strain to communicate. If this is the case, what might these molecular signals be "saying" and how would such a message be transmitted?
4. The Nod factor signals produced by the root nodulating bacterium *Sinorhizobium meliloti* are essential for biofilm formation as well as N_2 fixation. In what ways are nodulation and biofilm formation similar, and why do you think this microbe evolved to use the same signal for the development of both?
5. In 2008 the annotated genome sequence of the ectomycorrhizal basidiomycete *Laccaria bicolor* was published. Surprisingly, *L. bicolor* produces a large number of small, secreted proteins (SSPs), some of which are only expressed in hyphae that colonize the host root. Another interesting finding was the presence of genes encoding enzymes for the degradation of cell wall polysaccharide only found in organisms other than plants. Formulate a hypothesis regarding the role of the SSPs during host colonization, and discuss the metabolic significance of the types of cell walls *L. bicolor* is able to degrade.

   Read the original paper: Martin, F. 2008. The genome of *Laccaria bicolor* provides insights into mycorrhizal symbiosis. *Nature* 452:88.
6. Although the role of viruses and bacteriophages in marine and freshwater systems has been studied for a number of years, little is known about viruses in soils. Using stable isotope probing (see *page 646*), Li and colleagues showed that carbon in rice plants was incorporated into the capsid of a soil bacteriophage. What does this imply about the trophic transfer of carbon in this soil? Suggest two other experimental approaches that might increase our understanding of viruses in soil ecosystems.

   Read the original paper: Li, Y. et al., 2013. Identification of the major capsid gene (*g23*) of T4-type bacteriophages that assimilate substrates from root cap cells under aerobic and anaerobic soil conditions using a DNA-SIP approach. *Soil Biol. Biochem*. 63:97.

Microbial Interactions

There has been an alarming increase in the number of patients developing Clostridium difficile *infections. This bacterium is normally held in check by other gut microflora, but when antibiotic therapy eliminates these helpful bacteria, antibiotic-resistant* C. difficile *can flourish, causing colitis that can be life-threatening. A small but growing number of physicians are turning to fecal transplants as a last-resort treatment option.*

Embrace Your Gut Flora, for You Know Not What They Do

Samantha D. was desperate. Over the course of 8 months, she had been battling diarrhea so severe she had lost 60 pounds, was confined to a wheelchair, and was wearing adult diapers. For a period of 6 months, Vanessa R. ran high fevers and had diarrhea every 15 minutes on her worst days. Her better days were spent sleeping. Both these women suffered from *Clostridium difficile* infection. Both were eventually cured by a treatment once considered crazy: fecal transplants.

First, the microbe: *C. difficile* (C. diff for short) is a Gram-positive, endospore-forming firmicute (see sections 23.1 and 39.6) that resides in low numbers in the human gut. It is normally outcompeted by nonpathogenic bacteria. Many C. diff infections arise in people undergoing antibiotic therapy. This leads to the inhibition of normal gut microflora, enabling the overgrowth of C. diff and its release of a suite of toxins triggering disabling diarrhea accompanied by sloughing of the gut epithelium. It is most commonly seen in hospitalized patients, but community-acquired C. diff infections are on the rise.

Next the cure: Antibiotic therapy frequently fails because C. diff has acquired resistance to multiple antimicrobials and antibiotic treatment continues to suppress the growth of gut microorganisms needed to outcompete this virulent pathogen. A growing number of physicians are now treating patients with recurrent C. diff infections with fecal microbiome transplants. The patient's fecal donor is often a healthy family member whose stool is first tested to be sure it is free of pathogenic viruses, bacteria, and protozoa. The stool is then mixed with sterile saline and infused into the patient from one end (via a nasogastric tube) or the other (via a colonoscope). About 85 to 90% of patients report a complete cure within 48 hours to a week.

How did such a treatment start? It probably began with farmers who long ago realized that cattle with intestinal illnesses could be cured by ingesting the rumen fluid of another, healthy animal. Current human treatment started in the 1980s, when Australian gastroenterologist Thomas Borody was caring for a patient who had returned from vacation with incurable colitis caused by an unknown pathogen. After exhausting every conventional treatment, he began looking for alternative therapies. He found one in a 1958 edition of the journal *Surgery,* where he read a report of four patients who were cured by fecal transplants. So Dr. Borody asked the patient's brother to donate his stool, and within days after infusion, the patient's colitis was gone, never to return. But it wasn't until the number of antibiotic-resistant C. diff infections climbed in the 2000s that a handful of doctors around the globe began to treat patients with fecal transplants. Efforts are now under way to encapsulate the fecal microbiota as a more acceptable and standardized treatment.

Apart from the gross factor, what is the message? For a very long time, gut microorganisms have been termed commensals—organisms that live within another without injuring or benefiting the host. Clearly, the severity of C. diff infections and its cure by fecal transplant argue that this term should no longer be considered accurate.

Microbes rarely live alone. They have evolved in specific ways with other organisms, including microbes, plants, and animals. In this chapter, we define types of microbial interactions and present illustrative examples. We then apply these interactions to examine perhaps the most intimate, yet still relatively unexplored, microbial habitat: the human body.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ List environmental factors that influence microbial growth (section 7.4)
- ✔ Compare and contrast the growth and physiology of obligate aerobes, facultative anaerobes, and strict anaerobes (section 7.4)
- ✔ Explain the general morphology of protists and the structure and function of hydrogenosomes (sections 5.6 and 25.2)
- ✔ Summarize the mechanisms of horizontal gene transfer (section 16.4)
- ✔ Diagram, in general terms, the standard reduction potentials of electron donors as compared to electron acceptors and relate this to standard free energy change (section 10.3)
- ✔ Describe the difference between heterotrophy and autotrophy (section 11.1)
- ✔ Compare anaerobic and aerobic respiration (section 11.2)

- ✔ Define chemolithotrophy and identify an example electron donor and acceptor (section 11.10)
- ✔ Compare and contrast oxygenic and anoxygenic phototrophy (section 11.11)
- ✔ Summarize the fate of pyruvate in fermentation (section 11.8)
- ✔ Explain carbon and nitrogen fixation (sections 12.3 and 12.5)
- ✔ Identify substrates used in methanogenesis (section 20.4)
- ✔ Relate genome reduction to obligate intracellular lifestyles (section 18.7)
- ✔ Describe the principles and application of metagenomics (sections 18.3 and 29.3)

32.1 Many Types of Microbial Interactions Exist

After reading this section, you should be able to:

- Compare and contrast different types of microbial interactions, including mutualism, cooperation, commensalism, predation, parasitism, amensalism, and competition
- Provide at least one specific example of each of these types of interactions

You need look no further than in a mirror to grasp the importance of microbial-host interactions. Your body possesses about three times as many bacterial cells than it does somatic cells (and that doesn't include the fungi, bacteriophages, and protists you host). Indeed, the vast majority of microbes live in complex communities that include organisms from other domains of life. The stable association of one organism with another is called **symbiosis,** regardless of whether the association is beneficial for both partners, as in mutualism, cooperation, and commensalism, or has a negative impact, described as predation, parasitism, amensalism, and competition (**figure 32.1**).

For many years bacterial symbioses were viewed as the relationship between one bacterial species and one host species. However, the wide application of metagenomics, single-cell sequencing, next-generation sequencing, and new approaches to culturing microbes have revealed that microbial symbioses can range from a single species of microorganism and its host to hosts with thousands of different kinds of microbes. In fact, there have been so many discoveries of new, and never imagined, symbiotic relationships that the vocabulary of microbial interactions is changing. For example, while the smaller organism in a symbiotic relationship has always been called the **symbiont** and the larger organism the host, these organisms are now sometimes regarded as partners. What was once considered a microbe-host relationship is now sometimes called a holobiont or a superorganism to reflect the critical nature of the interaction.

All symbionts must undergo the process of host colonization, reproduction, and persistence within the host, as well as transmission to a new host. Because microbial symbioses are the result of thousands, if not millions, of years of coevolution, these processes have been optimized. However, their specifics differ and make each symbiotic relationship seem like a clever feat of natural history. For example, host specificity can range from very narrow to very broad. Symbionts may be transmitted horizontally from host to host or vertically during reproduction, or each host may have to acquire the symbiont from the environment. Symbioses can range from those that are very stable (e.g., aphids and their bacterial mutualists, as discussed next), to interactions that are temporary, depending on the life cycle of the host or other variables. Symbionts can live within the host as an **endosymbiont,** or on the surface of the host as an **ectosymbiont.** Finally, symbionts alter not only the health of their hosts, but their behavior, evolution, and reproductive success as well (**Microbial Diversity & Ecology 32.1**)

◀◀ *Metagenomics provides access to uncultured microbes (section 18.3); Microbial biology relies on cultures (section 29.1)*

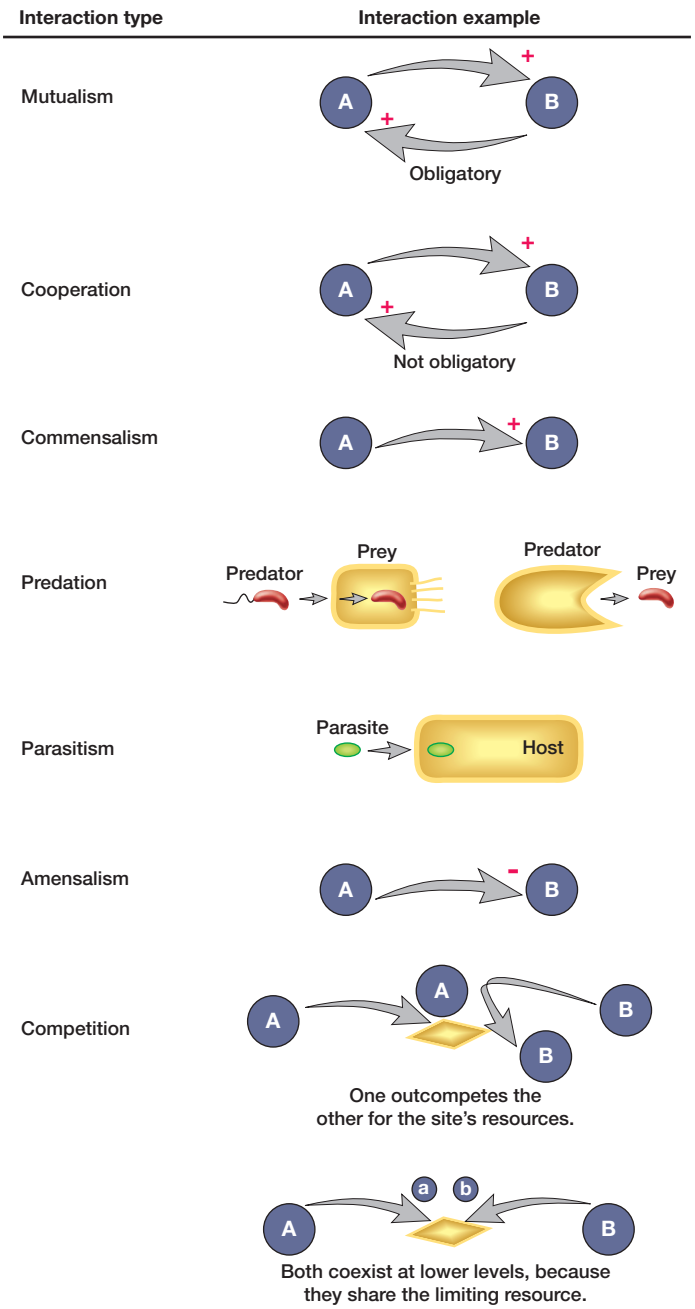

Figure 32.1 Microbial Interactions. Basic characteristics of symbiotic interactions that can occur between different organisms.

MICROBIAL DIVERSITY & ECOLOGY

32.1 *Wolbachia pipientis:* The World's Most Infectious Microbe?

Most people have never heard of the bacterium *Wolbachia pipientis,* but this rickettsia infects more organisms than any other microbe. It is known to infect a variety of crustaceans, spiders, mites, millipedes, and parasitic worms, and may infect more than a million insect species worldwide. To what does *W. pipientis* owe its extraordinary success? Quite simply, this endosymbiont is a master at manipulating its hosts' reproductive biology. In some cases, it can even change the sex of its host.

W. pipientis inhabits the cytoplasm of its host and is transferred from one generation to the next through the eggs of infected females. To survive, *Wolbachia* must ensure the fertilization and viability of infected eggs while decreasing the likelihood that uninfected eggs survive. The mechanism by which this is accomplished depends on the host. In wasps and mosquitoes, *W. pipientis* causes "cytoplasmic incompatibility," which simply means that mating will be abnormal if the only the male is infected. For instance, when infected sperm of the wasp *Nasonia vitripennis* fertilizes uninfected eggs, chromosomes from the *W. pipientis*–laden sperm prematurely try to align with the egg's chromosomes. These eggs then divide as if never fertilized. However, chromosomes behave normally when an infected female mates with an uninfected male. This yields a normal sex distribution, and all progeny are infected with the rickettsia.

In other infected insects, *W. pipientis* may simply kill all the male offspring and induce parthenogenesis of infected females; that is, the mothers simply clone themselves. This limits genetic diversity but allows 100% transmission of rickettsia to the next generation. In still other hosts, the microbe allows the birth of males but then modifies their hormones so that the males become feminized and produce eggs.

The ability of this microbe to manipulate the reproduction of its hosts may play a role in insect speciation. Two genetically similar North American wasp species (*Nasonia giraulti* and *N. longicornis*) each carry a different strain of *W. pipientis.* Predictably, when the two species mate with each other, there are no viable offspring. But when the wasps are first treated with an antibiotic to cure them of their bacterial infections, viable, fertile offspring are produced. It thus appears that *W. pipientis* infection, not genetic differences, forms the reproductive wall that drives speciation. The role of *Wolbachia* bacteria in generating genetic diversity among its hosts is further illustrated by the discovery of horizontal gene transfer (HGT) from the bacterium to its host's genome. This has been confirmed in several insect and nematode species that harbor *W. pipientis* symbionts. In fact, the fruit fly *Drosophila ananassae* contains the entire *W. pipientis* genome within its own.

W. pipientis infection has been implicated in several human diseases, including river blindness, which has a worldwide incidence of about 18 million people. The causative agent, *Onchocerca volvulus,* is a filarial nematode transmitted by black flies in Africa and Latin America. When a fly bites a person, the nematode establishes its home in small nodules beneath the skin, where it can survive for up to 14 years. During that time, it releases millions of larvae, many of which migrate to the eye. Eventually the host mounts an inflammatory response that results in progressive vision loss (**box figure**). It is now recognized that this inflammatory response is principally directed at the bacteria infecting the nematodes, not the worms themselves. Nematode reproduction stops in patients treated with an antibiotic that kills the endosymbiont. While inflammatory damage cannot be reversed, disease progression is halted. Antibacterial treatment is now combined with antiparasitic medications in the treatment of this disabling condition.

Our understanding of the distribution of *W. pipientis* and the mechanistically clever ways it has evolved to ensure its survival will continue to grow. The microbe may ultimately become a valuable tool in investigating the complexities of speciation, as well as the key to eliminating a devastating disease.

Sources: St. Andre, A., et al. 2002. The role of endosymbiotic Wolbachia *bacteria in the pathogenesis of river blindness.* Science *295:1892–95; Zimmer, C. 2001.* Wolbachia*: A tale of sex and survival.* Science *292:1093–95.*

River blindness. This is the second-leading cause of blindness worldwide. Evidence suggests that it is not the nematode but its endosymbiont, *Wolbachia pipientis*, that causes the severe inflammatory response that leaves many, like the woman shown here, blind.

Mutualism: Obligate Positive Interactions Between Host and Microbe

Mutualism (Latin *mutuus,* borrowed or reciprocal) defines the relationship in which some reciprocal benefit accrues to both partners. This is an obligatory relationship in which the **mutualist** and the host are dependent on each other. In many cases, the individual organisms will not survive when separated. Several examples of mutualism are presented next.

Microorganism-Insect Mutualisms

Mutualistic associations are common between microbes and insects partly because insects often consume plant sap or animal fluids lacking essential vitamins and amino acids. These are provided by bacterial symbionts in exchange for a secure habitat and ample nutrients. Aphids and their γ-proteobacterium *Buchnera aphidicola* partner are a model system for the study of mutualistic symbioses. A mature aphid contains literally millions of these bacteria within specialized cells called bacteriocytes. Strains of *B. aphidicola* provide their hosts with ten essential amino acids absent in sap. If the insect is treated with antibiotics, it dies. Likewise, *B. aphidicola* is an obligate mutualistic symbiont. The inability of either partner to grow without the other indicates that the two organisms underwent **coevolution;** that is, they have evolved together. In fact, the pea aphid (*Acyrthosiphon pisum*) and its *B. aphidicola* symbionts share the genes for the biosynthesis of several amino acids such that certain steps occur only in one organism.

It is estimated that the *B. aphidicola*–aphid endosymbiosis was established about 150 million years ago. The genomes of different endosymbiotic *B. aphidicola* strains reveal that about 75% of the ancestral *B. aphidicola* genome has been eliminated. It follows that these genomes are very small: in most cases, only about 0.52 Mb each. Over 90% of the genes are common among these bacterial strains, and the genomes show no evidence of gene duplication, translocation, inversion, or horizontal transfer. This implies that although the initial acquisition of the endosymbiont by ancestral aphids enabled their use of an otherwise deficient food source (sap), the bacteria have not continued to expand the ecological niche of their insect host through the acquisition of new traits that might be advantageous elsewhere. ◀◀ *Comparative genomics (section 18.7)*

Termites are another terrific model system for the study of endosymbiosis. Some termites harbor protist, bacterial, and archaeal endosymbionts and eat only wood. The main structural polysaccharides of wood are cellulose (an unbranched glucose polymer) and hemicellulose (a smaller, branched glucose polymer), which combine with lignin *(see figure 31.2)* to form lignocellulose. A diet of wood poses two problems for the termite: how to degrade polysaccharides that may possess as many as 15,000 glucose monomers and where to get organic nitrogen needed for nucleotide and protein synthesis. Although these termites produce a cellulolytic enzyme, only their mutualistic protists can complete lignocellulose degradation. Nitrogen-fixing bacteria that live in the termite gut solve the problem of obtaining organic nitrogen. ◀◀ *Nitrogen fixation (section 12.5)*

Most termite-associated protists are members of the *Excavata* supergroup and as such are quite ancient, possessing hydrogenosomes rather than mitochondria. These protists ferment cellulose to acetate, CO_2, and H_2. Acetate is the termite's preferred carbon source, and termites rely on bacterial symbionts to convert the CO_2 and H_2 released by the protists to acetate by the reductive acetyl-CoA pathway (*see figure 20.3*). In addition, termites harbor methanogenic archaea that use these substrates to form CH_4, which is excreted. ◀◀ *Mitochondria related organelles and chloroplasts are involved in energy conservation* (section 5.6); *Supergroup* Excavata *(section 25.2)*

Some termite protists also harbor endosymbionts (i.e., endosymbionts of endosymbionts). For instance, the protist *Trichonympha* sp. relies on a bacterial endosymbiont in the new genus *Elusimicrobium* to convert glutamine to other amino acids and nitrogenous compounds (**figure 32.2**). In exchange, the protist supplies *Elusimicrobium* sp. with glucose 6-phosphate, which can directly enter glycolysis. In addition, motility is often provided by spirochetes that cover the protist surface. Motility is essential to prevent protist expulsion by the termite gut and to acquire food.

Zooxanthellae

Many marine invertebrates (sponges, jellyfish, sea anemones, corals, ciliated protists) harbor endosymbiotic dinoflagellates called zooxanthellae within their tissues. Because the degree of host dependency on the dinoflagellate is variable, only one well-known example is presented here. ◀◀ *Alveolata* (*section 25.4*)

The hermatypic (reef-building) corals satisfy most of their energy requirements using their zooxanthellae, which include members of the dinoflagellate genus *Symbiodinium* (**figure 32.3*a***). These protists line the coral gastrodermal tissue at densities between 5×10^5 and 5×10^6 cells per square centimeter of coral animal. *Symbiodinium* cells give up to 95% of the carbon they fix in exchange for nitrogenous compounds, phosphates, CO_2, and protection from ultraviolet light from their coral hosts. In addition to dinoflagellates, corals host distinct bacterial communities in three habitats (figure 32.3*b*). The surface mucus layer supports the growth of nitrogen-fixing and chitin-degrading bacteria, while the animal tissue within the gastrodermal cavity features another population of bacteria (although little is known about these microbes). The coral skeleton hosts yet another group of bacteria. These microbial communities are responsible for extremely efficient nutrient cycling and tight coupling of trophic levels, which accounts for the stunning success of reef-building corals in developing vibrant ecosystems.

During the past several decades, the number of coral bleaching events has increased dramatically. **Coral bleaching** is defined as a loss of either the photosynthetic pigments from the zooxanthellae or the complete expulsion of the dinoflagellates from the coral. Damage to photosystem II of the zooxanthellae generates reactive oxygen species (ROS); these ROS appear to directly damage many corals (recall that photosystem II uses

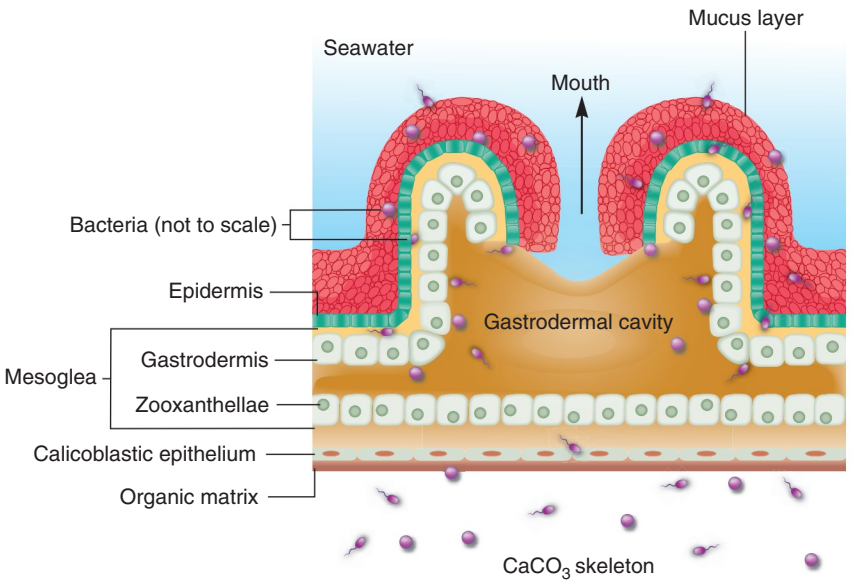
(b)

Figure 32.2 Mutualism. (a) Light micrograph of *Trichonympha* sp., a multiflagellated protozoan from the termite's gut (×135). The ability of *Trichonympha* to break down cellulose allows termites to use wood as a food source. (b) Proposed interaction between the termite endosymbiotic protist *Trichonympha* and its bacterial endosymbiont *Elusimicrobium* sp.. Within the termite gut, bacteria convert N_2 to ammonia, which is taken up and converted to glutamine (Gln) by *Trichonympha* sp. The protist relies on *Elusimicrobium* sp. to convert Gln to other amino acids, which are released with other cofactors that the protist cannot synthesize. Both the protist and *Elusimicrobium* sp. ferment glucose to acetate, H_2, and CO_2. These products are exported by the protist and made available to the termite, which also relies on free-swimming gut bacteria to boost acetate levels through reductive acetogenesis (*see figure 20.3*).

MICRO INQUIRY *What methanogenic substrates are also available in the termite gut?*

(a)



(b)

Figure 32.3 Zooxanthellae. (a) The green color of this rose coral (*Manicina* sp.) is due to the abundant zooxanthellae within its tissues. (b) Corals provide three distinct habitats for bacterial growth: the mucus layer at the surface, the gastrodermal cavity, and the coral skeleton. Calicoblastic epithelial cells precipitate calcium carbonate ($CaCO_3$) from the water to build exoskeleton. Zooxanthellae inhabit gastrodermal cells and are shown in green.

water as the electron source, resulting in the evolution of oxygen). Coral bleaching appears to be caused by a variety of additional stressors, but one important factor is temperature. Temperature increases as small as 2°C above the average summer maxima can trigger coral bleaching. Increased temperature has also been correlated with coral infectious diseases. Some disease-causing microbes are thought to reside in the coral mucus layer, where their numbers are normally kept in check. But during and following bleaching, the coral microbial community is in disequilibrium, and stressed corals become more susceptible to pathogenic attack. Conditions such as white plague and yellow blotch disease have been noted to follow bleaching events in the Caribbean, reducing corals by roughly a third. Finally, ocean acidification caused by increased CO_2 dissolution in seawater also threatens coral health (*see figures 30.1 and 30.2*). Sadly, evidence suggests that as many as one-third of corals and their zooxanthellae will be unable to evolve quickly enough to keep pace with predicted ocean acidification and warming if global climate change continues unchecked. ⏮ *Light reactions in oxygenic photosynthesis (section 11.11); Global climate change (section 28.2); Water is the largest microbial habitat (section 30.1)*

Sulfide-Based Mutualisms

Several thousand meters below the surface of the ocean, hydrothermal vents are found where the Earth's crustal plates are spreading apart (**figure 32.4**). Vent fluids are anoxic, contain high concentrations of hydrogen sulfide, and can reach a temperature of 350°C. The seawater surrounding these vents has sulfide concentrations around 250 μM and temperatures 10 to 20°C above the ambient seawater temperature of about 2°C. Although the high pressure at such depths prevents the water

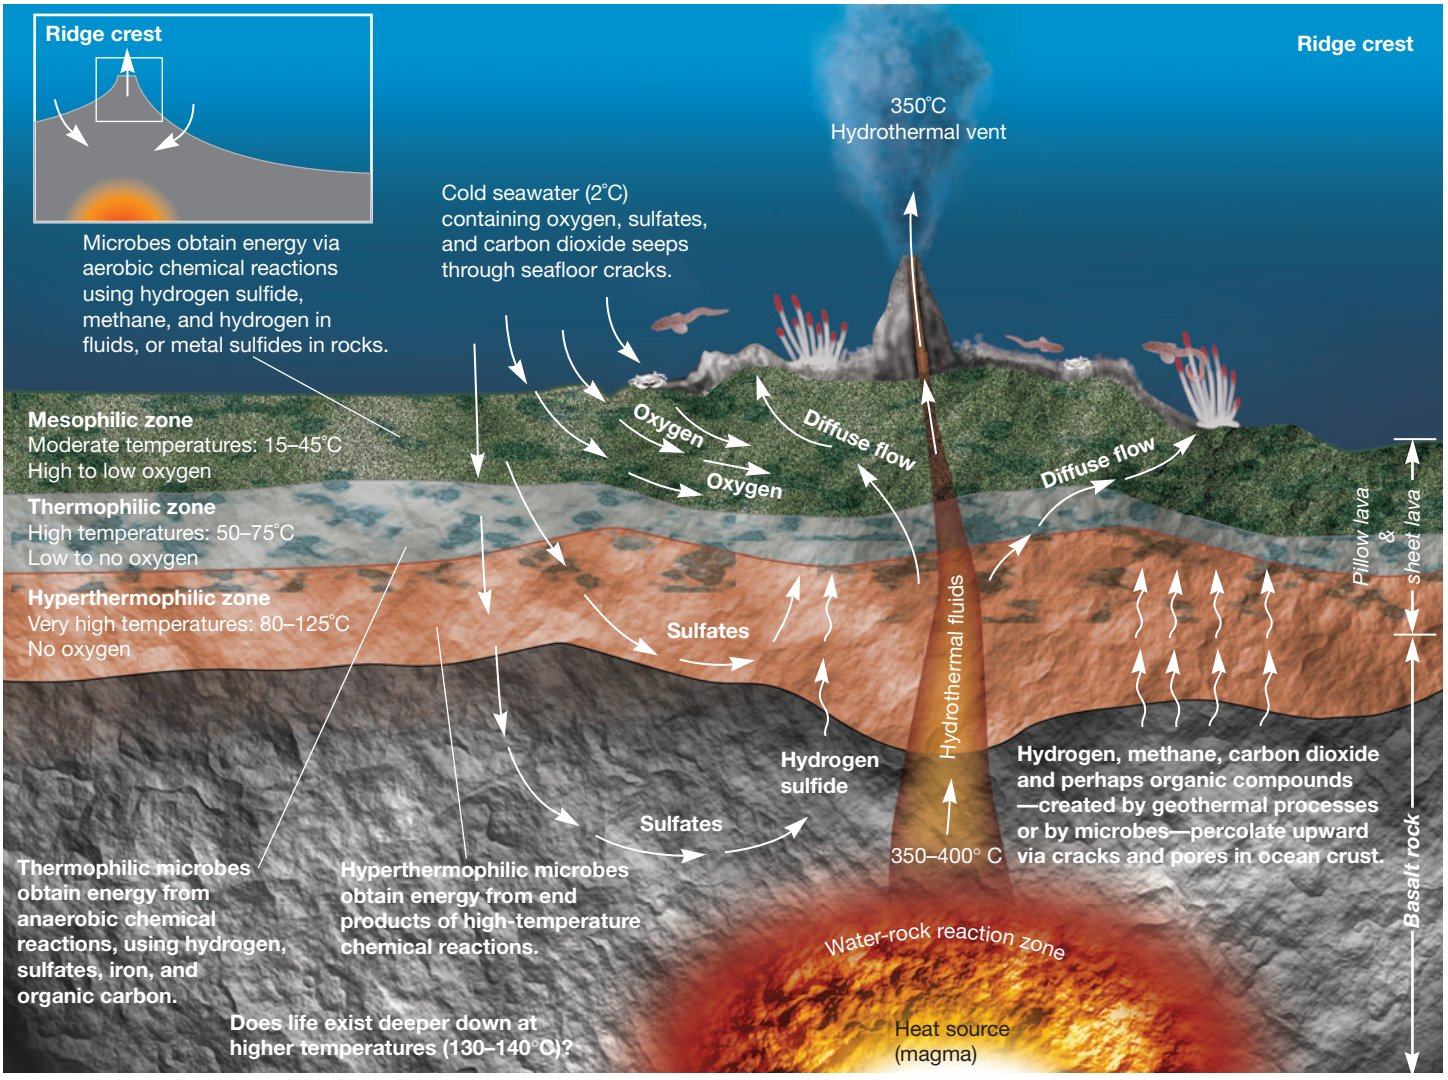


Figure 32.4 Hydrothermal Vents and Related Geological Activity. The chemical reactions between seawater and rocks that occur over a range of temperatures on the seafloor supply the carbon and energy that support a diverse collection of microbial communities in specific niches within the vent system.

from boiling, one might think these conditions are inhospitable to life. But nothing could be further from the truth.

Giant (>1 m in length), red, gutless tube worms (*Riftia* spp., **figure 32.5*a***) growing near hydrothermal vents exemplify a remarkably successful mutualism in which bacterial endosymbionts are maintained within specialized cells of the tube worm host (figure 32.5*b,c,d*). *Riftia* worms live at the interface between hot, anoxic, sulfide-containing fluids of the vents and cold, oxygenated seawater. The worm lacks a mouth and gut and relies on endosymbiotic bacteria to provide organic carbon. The bacteria are chemolithotrophic, using sulfide as an electron donor and oxygen as a terminal electron acceptor. In fact, *Rifta* worms have unique hemoglobin that provides both reduced sulfur and oxygen to the endosymbionts. Hydrogen sulfide (H_2S) and O_2 are removed from the seawater by the worm's hemoglobin and delivered to an organ called the trophosome. The trophosome is packed with chemolithotrophic bacterial endosymbionts that reach densities of up to 10^{11} cells per gram of worm tissue. The endosymbionts use the Calvin-Bensen cycle to fix CO_2 (*see figure 12.4*), which they reduce with electrons provided by H_2S. The CO_2 is carried to the endosymbionts in three ways: (1) freely in the bloodstream, (2) bound to hemoglobin, and (3) as organic acids such as malate and succinate. When these acids are decarboxylated, they release CO_2. This CO_2 is then fixed using the same pathway used by plants and cyanobacteria, but it occurs in the deepest, darkest reaches of the ocean. This mutualism enables *Riftia* worms to grow to an astounding size in densely packed communities.

An interesting, more complex mutualism occurs between the gutless marine oligochaete *Olavius algarvensis* and bacterial endosymbionts that reside just below the outer surface (cuticle) of this worm. Like *Riftia* tube worms, these worms

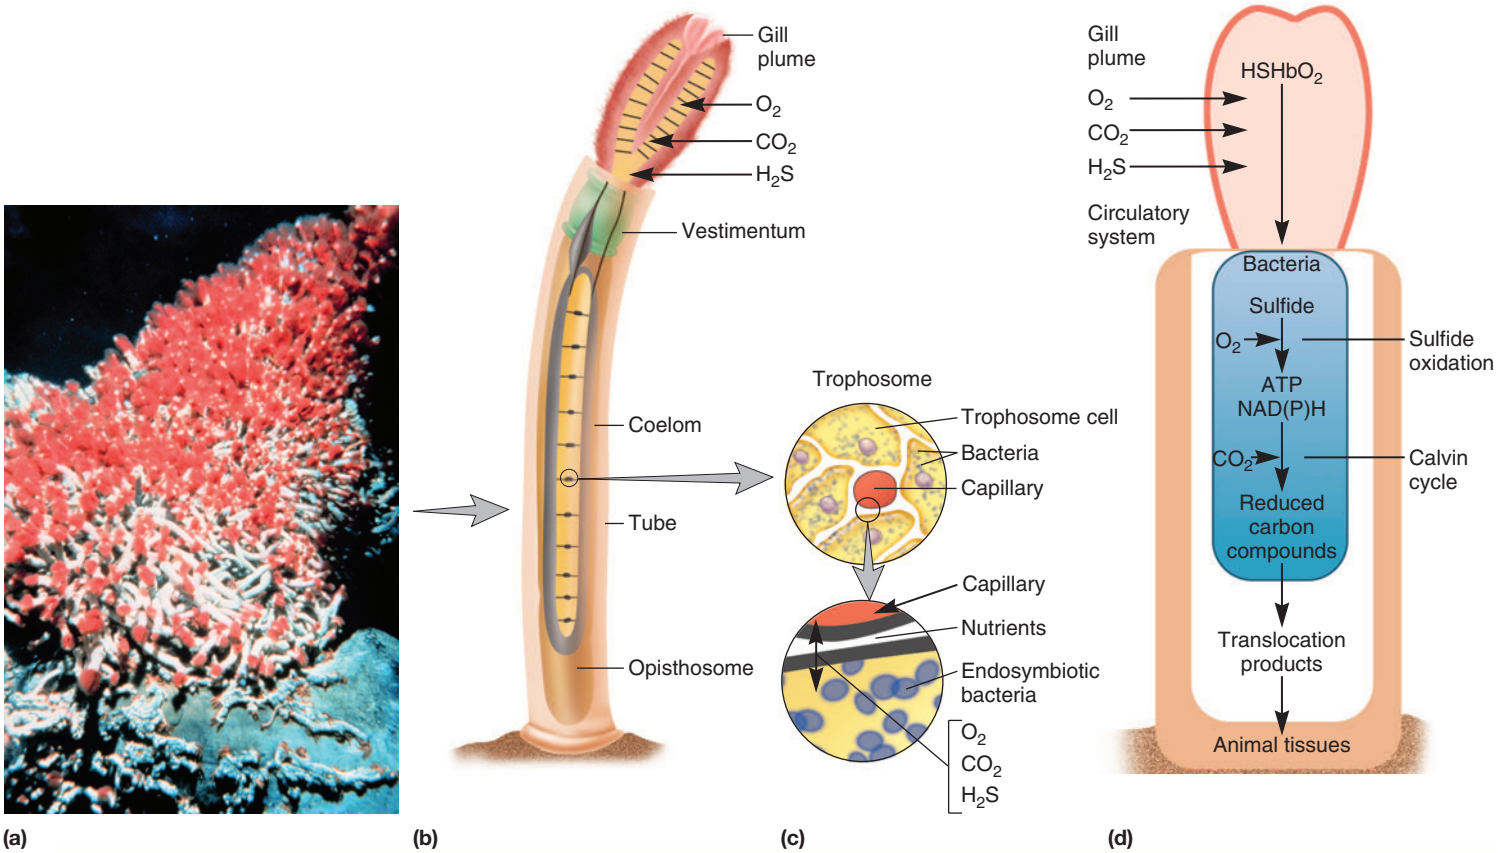

Figure 32.5 The Tube Worm–Bacterial Relationship. (a) A community of tube worms (*Riftia pachyptila*) at the Galápagos Rift hydrothermal vent site (depth 2,550 m). Each worm is more than a meter in length and has a 20-cm gill plume. (b, c) Schematic illustration of the anatomical and physiological organization of the tube worm. The animal's heart and brain is housed within the vestimentum. At its anterior end is a respiratory gill plume. Inside the trunk of the worm is a trophosome consisting primarily of endosymbiotic bacteria, associated cells, and blood vessels. At the posterior end of the animal is the opisthosome, which anchors the worm in its tube. (d) Oxygen, carbon dioxide, and hydrogen sulfide are absorbed through the gill plume and transported to the blood cells of the trophosome. Hydrogen sulfide is bound to the worm's hemoglobin ($HSHbO_2$) and carried to the endosymbiont bacteria. The bacteria oxidize the hydrogen sulfide and use some of the released energy to fix CO_2 in the Calvin cycle. Some of the reduced carbon compounds synthesized by the endosymbiont are translocated to the animal's tissues.

MICRO INQUIRY *What is the nutritional type of the endosymbiotic bacteria?*

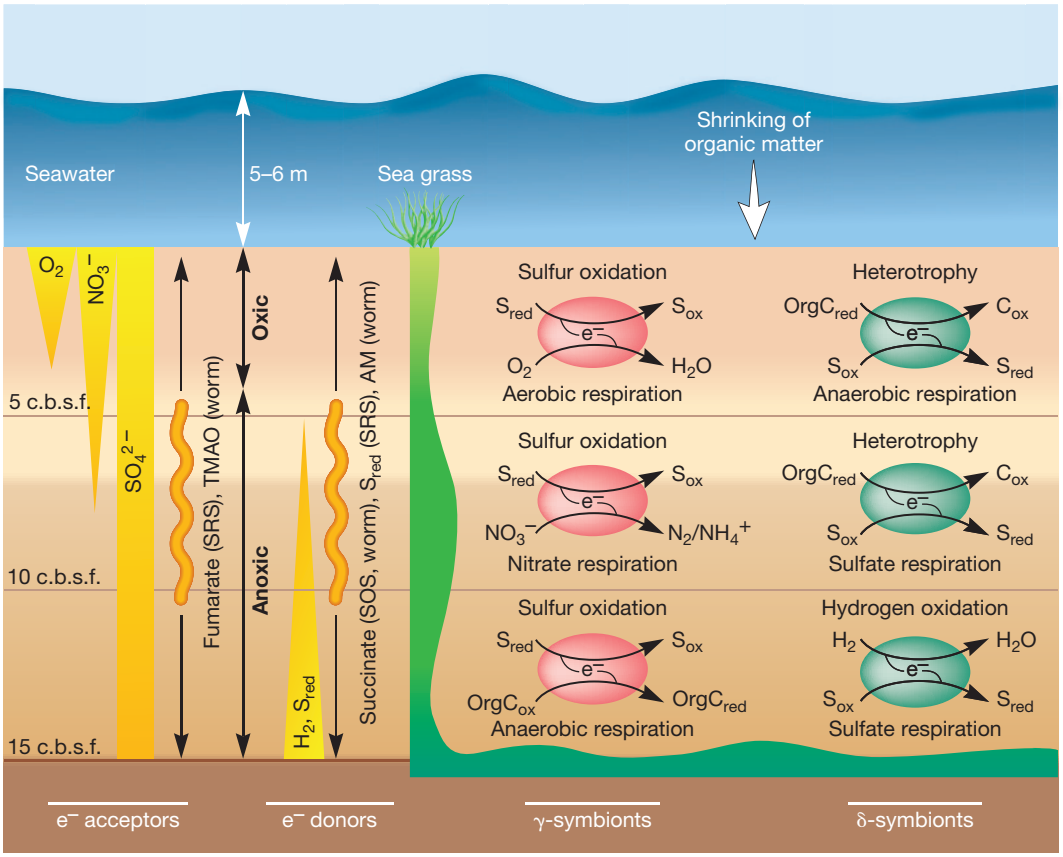

Figure 32.6 Proposed Energy Metabolism of Bacterial Endosymbionts of the Mediterranean Worm *Olavius algarvensis*. Electron donors and acceptors change with increasing sediment depth, as measured in centimeters below seafloor (c.b.s.f.). As the worm moves vertically through the sediments, the δ- and γ-proteobacterial endosymbionts switch their metabolism to match the available electron donors and acceptors. OrgC, organic carbon; S_{ox}, oxidized sulfur compounds; S_{red}, reduced sulfur compounds; SOS, sulfur-oxidizing symbionts; SRS, sulfate-reducing symbionts; TMAO, trimethylamine *N*-oxide—an organic electron acceptor produced by the host.

MICRO INQUIRY *Why do the δ-proteobacterial symbionts switch to H_2 as an electron donor only in the deepest sediments inhabited by* O. algarvensis*?*

lack any digestive tract so they obtain all organic carbon from their endosymbionts. The endosymbiont community is dominated by two δ-proteobacterial and two γ-proteobacterial species. The δ-proteobacteria are metabolically flexible. They use sulfate as their terminal electron acceptor and are chemoorganotrophic, with genes for the uptake and oxidation of a variety of carbohydrates. In addition, they can also function chemolithoautotrophically using H_2 as an electron and energy source and fixing CO_2 using both the acetyl-CoA pathway and reductive TCA cycle *(see figures 20.3 and 12.5, respectively)*. The γ-proteobacteria are chemolithoautotrophs, using reduced sulfur compounds as electron donors and O_2, nitrate, or organic substrates such as fumarate as electron acceptors. ◀◀ *Anaerobic respiration uses the same three steps as aerobic respiration (section 11.7); Chemolithotrophy (section 11.10); Other CO_2-fixation pathways (section 12.3)*

Why does *O. algarvensis* have four endosymbiotic species? Harboring symbionts is energetically expensive, so it can be argued that all four are needed for the worm to survive. Like all mutualisms, the role of each symbiont reflects the environment the host inhabits. In this case, as the worm migrates vertically, three different microhabitats are encountered: oxic, anoxic with nitrate and sulfate available, and anoxic with H_2 and reduced sulfur present (**figure 32.6**). This requires that the bacterial endosymbionts adjust their metabolism to fit the prevailing electron acceptors and donors. So at the oxic surface, the γ-proteobacteria use O_2 as the terminal electron acceptor and the δ-proteobacteria rely on heterotrophy. Because there is little sulfur at the surface, the bacteria rely on each other to provide reduced sulfur as an electron donor and oxidized sulfur as electron acceptor. In the intermediate zone, the γ-proteobacteria use nitrate as the terminal electron acceptor and may rely on a combination of externally and internally produced reduced sulfur as electron donor. Meanwhile the δ-proteobacteria find plenty of external sulfate to respire. Finally, in the deepest zone, the γ-proteobacteria have access to lots of sulfur in the sediments but must use organics as the terminal electron acceptor. Meanwhile, the δ-proteobacteria may switch to chemolithotrophy and use H_2 as the electron donor and the oxidized sulfur generated by the γ-proteobacteria as the electron acceptor. This complex interplay between bacteria, host, and environment has resulted from millions of years of coevolution.

The Rumen Ecosystem

Ruminants are the most successful and diverse group of mammals on Earth today. Examples include cattle, deer, elk, bison, water buffalo, camels, sheep, goats, giraffes, and caribou. These animals spend vast amounts of time chewing their cud—a small ball of partially digested grasses that the animal has consumed but not yet completely digested. It is thought that ruminants evolved an "eat now, digest later" strategy because their grazing can often be interrupted by predator attacks.

These herbivorous animals have stomachs that are divided into four chambers (**figure 32.7**). The upper part of the stomach is expanded to form a large pouch called the rumen and a smaller, honeycomb-like region, the reticulum. The lower portion is divided into an antechamber, the omasum, followed by the "true" stomach, the abomasum. The rumen is a highly muscular, anaerobic fermentation chamber where grasses eaten by the animal are digested by a diverse microbial community that includes bacteria, archaea, fungi, and protists. This microbial community is large—about 10^{12} organisms per milliliter of digestive fluid. When the animal eats plant material, it is mixed with saliva and swallowed without chewing to enter the rumen. Here, microbial attack and further mixing coats the grass with microbes, reducing it to a pulpy, partially digested mass. At this point, the mass moves into the reticulum, where it is regurgitated as cud, chewed, and reswallowed by the animal. As this process proceeds, the grass becomes progressively more liquefied and flows out of the rumen into the omasum and then the abomasum. Here the nutrient-enriched grass meets the animal's digestive enzymes, and soluble organic and fatty acids are absorbed into the animal's bloodstream.

The microbial community in the rumen is extremely dynamic and, as a whole, forms a mutualistic relationship with the animal host. The rumen is slightly warmer than the rest of the animal, and with a redox potential of about −30 mV, all resident microorganisms must carry out anaerobic metabolism. Very specific interactions occur between microbes. One group of bacteria produces extracellular cellulases that cleave the β(1→4) linkages between successive D-glucose molecules that form plant cellulose. The D-glucose is then fermented to organic acids such as acetate, butyrate, and propionate. These organic acids, as well as fatty acids, are the true carbon and energy sources for the animal. ⏮ *Fermentation does not involve an electron transport chain (section 11.8)*

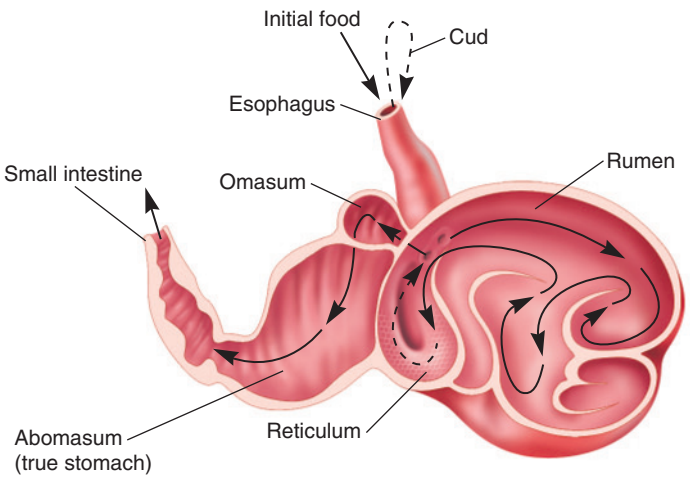

Figure 32.7 Ruminant Stomach. The stomach compartments of a cow. The microorganisms are active mainly in the rumen. Arrows indicate direction of food movement.

In some ruminants, organic matter processing stops with the production of short-chain fatty acids. In others, such as cattle, CO_2, H_2, and to a lesser extent acetate are used by methanogenic archaea to generate methane (CH_4). Methanogens provide two services: they synthesize many of the vitamins needed by their animal host, and they efficiently remove H_2. This is important because the microbial oxidation of a wide range of organic compounds is thermodynamically feasible within rumen and many other anoxic environments only if H_2 is kept at very low levels. The oxidation of these organic substrates, which results in the generation of H_2 quickly consumed by methanogens, is termed **syntrophy** (Greek *syn*, together, and *trophe*, nourishment). Syntrophy is an association in which the growth of one organism either depends on, or is improved by, growth factors, nutrients, or substrates provided by another organism growing nearby.

In addition to the rumen ecosystem, syntrophic relationships occur in anoxic methanogenic ecosystems such as sludge digesters, anoxic freshwater sediments, and flooded soils. Obligate proton-reducing acetogens live in these environments. These microbes oxidize ethanol, butyrate, propionate, and other fermentation end products to H_2, CO_2, and acetate (hence the name "acetogen"). Although the enzymology is not well understood, it is clear that these reactions are thermodynamically unfavorable under standard conditions; that is, they have a positive ΔG. However, because methanogens consume the H_2 as it is generated, the reaction becomes thermodynamically possible. This type of syntrophy is called **interspecies hydrogen transfer.** Thus when fermentative bacteria produce low molecular weight fatty acids (e.g., propionate), anaerobic bacteria such as δ-proteobacteria in the genus *Syntrophobacter* produce H_2 as follows:

$$\text{Propionate}^- + 3H_2O \rightarrow \text{acetate}^- + HCO_3^- + H^+ + 3H_2 \quad (\Delta G^o = +76.1 \text{ kJ/mol})$$

Syntrophobacter spp. use protons ($2H^+ + 2e^- \rightarrow H_2$) as terminal electron acceptors. The products H_2 and CO_2 (HCO_3^-) are then used by methanogenic archaea such as those in the genus *Methanospirillum*:

$$4H_2 + CO_2 \rightarrow CH_4 + 2H_2O \ (\Delta G^o = -25.6 \text{ kJ/mol})$$

By synthesizing methane, *Methanospirillum* spp. consume H_2, keeping it at a low concentration in the immediate environment of both microbes. As a consequence, the reaction becomes exergonic, with a ΔG between −20 to −25 kJ/mol (compare to +76.1 kJ/mol under standard H_2 concentrations). Continuous removal of H_2 promotes further fatty acid fermentation and H_2 production. Because increased H_2 production and consumption stimulate the growth of *Syntrophobacter* and *Methanospirillum* spp., all participants in the relationship benefit. The syntrophic nature of this relationship is further illustrated by the observation that the propionate-oxidizing bacterium *Pelotomaculum thermopropionicum* tethers itself to the methanogen *Methanothermobacter*

thermautotrophicus. Remarkably, the flagellar tip protein FliD serves as an interspecies signal to increase the rate of methanogenesis by *M. thermautotrophicus*. ◀◀ *Methanogens and methanotrophs (section 20.4)*

Cooperation: Nonobligatory Positive Interactions Between Host and Microbe

For most microbial ecologists, the nonobligatory aspect between host and symbiont differentiates **cooperation** from mutualism (figure 32.1). Unfortunately, it is often difficult to distinguish obligatory from nonobligatory because that which is obligatory in one habitat may not be in another (e.g., the laboratory). Nonetheless, the most useful distinction between cooperation and mutualism is the observation that cooperating organisms can grow independently, although they may not function as well.

So far all our examples have featured symbionts that promote the growth of hosts in exchange for a safe, nutrient-rich home. The example of the Gram-negative bacterium *Xenorhabdus nematophila* and its nematode (worm) host *Steinernema carpocapsae* is remarkable because the bacterium contributes directly to the reproductive success of its host. Juvenile nematodes harboring *X. nematophila* within their guts live in the soil. In order to mature, the juvenile nematode must find an insect to infect and consume; this is when things get really interesting (**figure 32.8**). As the hungry juvenile nematode consumes insect blood (haemolymph), *X. nematophila* is excreted in nematode feces. These are now free-living *X. nematophila* and as these bacteria replicate, they secrete chemicals that kill the already miserable insect. Once the insect is dead, the bacteria switch to the production of different compounds that protect the insect from degradation by other bacteria and from attack by ants, thereby protecting the home of their host nematode. Amazingly, as the process continues, *X. nematophila* produces yet a different set of molecular signals that trigger *S. carpocapsae* development to adulthood. A single insect cadaver may host many adult nematodes that mate, yielding a cadaver that ultimately teems with *S. carpocapsae* eggs. As these eggs mature to the juvenile stage with *X. nematophila* symbionts, they leave to find new insect homes and start the cycle anew. Because the partners can be grown separately in the laboratory, it has been possible to dissect these events at the structural, molecular, and biochemical level, making this an important model system.

Certainly the most provocative cooperative associations to receive recent attention are those between the human host and our gut microbiota. Although the typical human gut hosts 500 to 1,000 different microbial species (most of which have not been cultured), the Gram-negative bacterium *Akkermansia muciniphila* is particularly interesting. This microorganism is critical to maintaining the mucosal barrier that separates microbes within the gut and the underlying, sterile structures. It accomplishes this in several ways, including the stimulation of host mucus and antimicrobial peptide production and promoting tight junction formation between epithelial cells. This is important because recent evidence suggests that the lipopolysaccharide from Gram-negative gut bacteria that enters the host's bloodstream contributes a state of sustained inflammation, called metabolic endotoxemia. This has been linked to conditions such as obesity, type 2 diabetes, and

1. How does cooperation differ from mutualism? What might be some of the evolutionary implications of both types of symbioses?
2. Why is the *X. nematophila–S. carpocapsae* symbiosis considered a cooperation? What other types of microbial interactions are in play during the nematode life cycle?

Commensalism: Microbe Benefits Without Affecting Host

Commensalism (Latin *com,* together, and *mensa,* table) is a relationship in which one symbiont, the **commensal,** benefits, while the host is neither harmed nor helped, as shown in figure 32.1. This is a unidirectional process. The spatial proximity of the two partners permits the commensal to feed on substances captured or ingested by the host, and the commensal often obtains shelter by living either on or in the host. The commensal is not directly dependent on the host's metabolism, so when it is separated from the host experimentally, it can survive without the addition of factors of host origin.

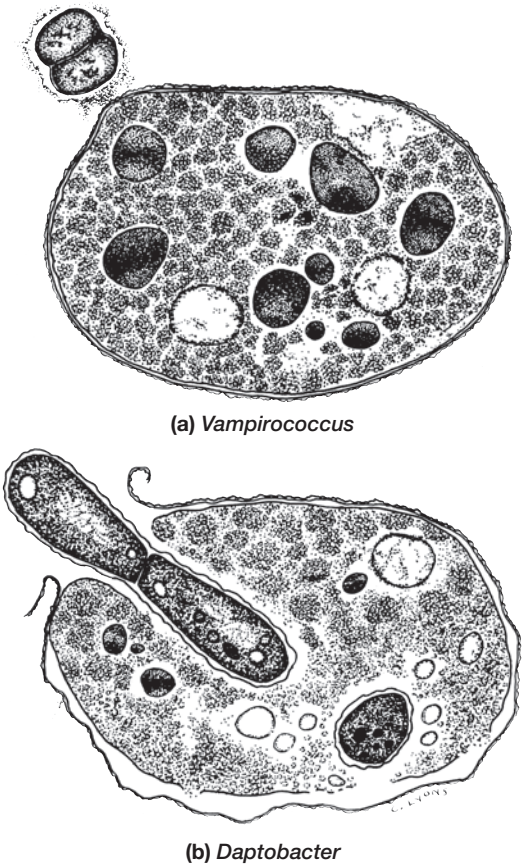
Commensalistic associations also occur when one microbial group modifies the environment to make it better suited for another organism. For instance, the synthesis of acidic waste products during fermentation stimulates the proliferation of more acid-tolerant microorganisms, which may be only a minor part of the microbial community at neutral pH. A good example of this is the succession of microorganisms during milk spoilage (*see figure 41.3*). Biofilm formation provides another example. The colonization of a newly exposed surface by one type of microorganism (an initial colonizer) makes it possible for other microorganisms to attach to the microbially modified surface. This is a good example of the unidirectional interaction that defines commensalism. ⏮ *Biofilms are common in nature (section 7.5)*

The microorganisms that live in and on humans, known as our microbiome, have traditionally been called commensals. Although this term is still applied broadly to these microbes, it is important to keep in mind that the more we learn about the vast microbial ecology of our bodies, the more we come to understand that we depend on our microbes for a myriad of important functions that we cannot achieve without them. These include the synthesis of vitamins, maturation of our immune systems, maintaining a healthy body weight, and prevention of and recovery from disease. The term commensals does not apply to our microbiome, and it is slowly being replaced by the more appropriate term, mutualists.

Predation: Microbes Harming Other Microbes

As is the case with larger organisms, predation among microbes involves a predator species that attacks and kills its prey. Over the last several decades, microbiologists have discovered a number of fascinating microbes that survive by their ability to prey upon others.

In addition to bdellovibrios, described in chapter 22 *(see figure 22.34),* members of the genera *Vampirococcus* and *Daptobacter* also kill their prey (**figure 32.9**). *Vampirococcus* cells



(a) *Vampirococcus*

(b) *Daptobacter*

Figure 32.9 Examples of Predatory Bacteria Found in Nature.
(a) *Vampirococcus* has a unique epibiotic mode of attacking a prey bacterium; and (b) *Daptobacter* showing its cytoplasmic location as it attacks a susceptible bacterium.

attach to the outer membrane of prey and secrete degradative enzymes, which result in the release of the prey's cytoplasmic contents. In contrast, a *Daptobacter* cell penetrates the prey cell and consumes the cytoplasmic contents directly. ⏮ *Order* Bdellovibrionales *includes predators that invade other Gram-negative bacteria (section 22.4)*

In contrast to the predatory bacteria shown in figure 32.9, some bacteria are facultative predators. Sometimes they consume organic matter released from dead organisms, whereas at other times, they actively prey on other microbes. Two good examples are members of the γ-proteobacterial genus *Lysobacter* and the δ-proteobacterial genus *Myxococcus*. Both display what has been called "wolf pack" predation whereby populations of cells use gliding motility to creep toward and cover their prey while releasing an arsenal of degradative enzymes. *M. xanthus* fruiting body formation can be triggered when its prey has been exhausted (**figure 32.10**).

Importantly, predation has many beneficial effects, especially when one considers predators and prey at the population and community levels. Ingestion and assimilation of a prey bacterium can lead to increased rates of nutrient cycling, critical for the functioning of the microbial loop (*see figure 30.6*). Although here we focus on bacterial predators, the impact of viral predation on communities, ecosystems, and even the global carbon budget is vast. As such, it is an active area of research. ⏮ *Aquatic viruses (section 30.2)*

Figure 32.10 Wolf Pack Predation by *Myxococcus xanthus*. (a) In this demonstration, a drop of *M. xanthus cells* is placed to the left of a colony of prey bacteria (*Escherichia coli*). (b) The *E. coli* cells lyse as *M. xanthus* glides over and consumes them; thus the colony becomes clear. (c) As *M. xanthus* cells swarm over the prey bacteria they move in waves. They will go on to form fruiting bodies (not shown; *see figure 22.35*).

MICRO INQUIRY *How does myxobacterial predation differ from that of* Vampirococcus?

Parasitism: Microbes Harm the Host

Parasitism is one of the most complex microbial interactions; the line between parasitism and predation is difficult to define (figure 32.1). In both cases, the relationship between two organisms is beneficial for one and harmful for the other. However, **parasite** and host must coexist, at least temporarily, so the microbe has enough time to reproduce and colonize a new host. Coexistence may involve nutrient acquisition, physical maintenance in or on the host, or both. But what happens if the host-parasite equilibrium is upset? If the balance favors the host (perhaps by a strong immune defense or antimicrobial therapy), the parasite loses its habitat and may be unable to survive. On the other hand, if the equilibrium is shifted to favor the parasite, the host becomes ill and, depending on the specific host-parasite relationship, may die.

On the other hand, a controlled parasite-host relationship can be maintained for long periods of time and the parasitic nature of the relationship may not be obvious. For example, lichens (**figure 32.11**) are the association between specific ascomycetes (fungi) and either green algae or cyanobacteria. The fungal partner is termed the **mycobiont** and the algal or cyanobacterial partner, the **phycobiont.**

Figure 32.11 Lichens. (a) The flattened leaf-shaped genus *Umbilicaria* is a common foliose lichen. (b) A thin slice of *Umbilicaria* viewed with a compound microscope shows that the green algae occur in a thin upper layer and fungal hyphae make up the rest of the lichen.

The fungus obtains nutrients from its partner by projections of fungal hyphae called haustoria, which penetrate the phycobiont cell wall. It also uses O_2 produced by the phycobiont for respiration. In turn, the fungus protects the phycobiont from high light intensities, provides water and minerals, and creates a firm substratum within which the phycobiont can grow protected from environmental stress. This is an ancient association, having developed prior to the evolution of vascular plants. Based on the above description, one could easily conclude that the relationship is mutualistic. However, those lichens where the cyanobacteria and algae phycobionts grow more quickly when cultured without their mycobiont are considered to be in a relationship in which the mycobiont is the parasite. This is in contrast to positive interactions such as cooperation, in which the symbiont often grows more slowly without its host. ⏮ Ascomycota *includes yeasts and molds (section 26.5)*; *Phylum* Cyanobacteria *(section 21.4)*

An important aspect of many symbiotic relationships, including parasitism, is that over time, the symbiont will discard excess, unused genomic information, a process called **genomic reduction** (*see figure 18.20*). This occurs when the symbiont has become dependent on the host for specific functions, such as synthesis of key metabolites. It is observed in the aphid endosymbiont *Buchnera aphidicola*; it has also occurred in the human pathogens *Mycobacterium leprae, Mycoplasma genitalia,* and *Encephalitozoon cuniculi,* a microsporidium. These microorganisms now can only survive inside their host cells. ⏮ *Comparative genomics (section 18.7)*; *Order* Corynebacteriales *includes important human pathogens (section 24.1)*; Microsporidia *are intracellular parasites (section 26.7)*

Amensalism: Microbial Products Harm Other Microbes

Amensalism describes the adverse effect that one organism has on another organism (figure 32.1). This is a unidirectional process based on the release of a specific compound by one organism that has a negative effect on another. A classic example of amensalism is the microbial production of antibiotics that can inhibit or kill other, susceptible microorganisms (**figure 32.12*a***).

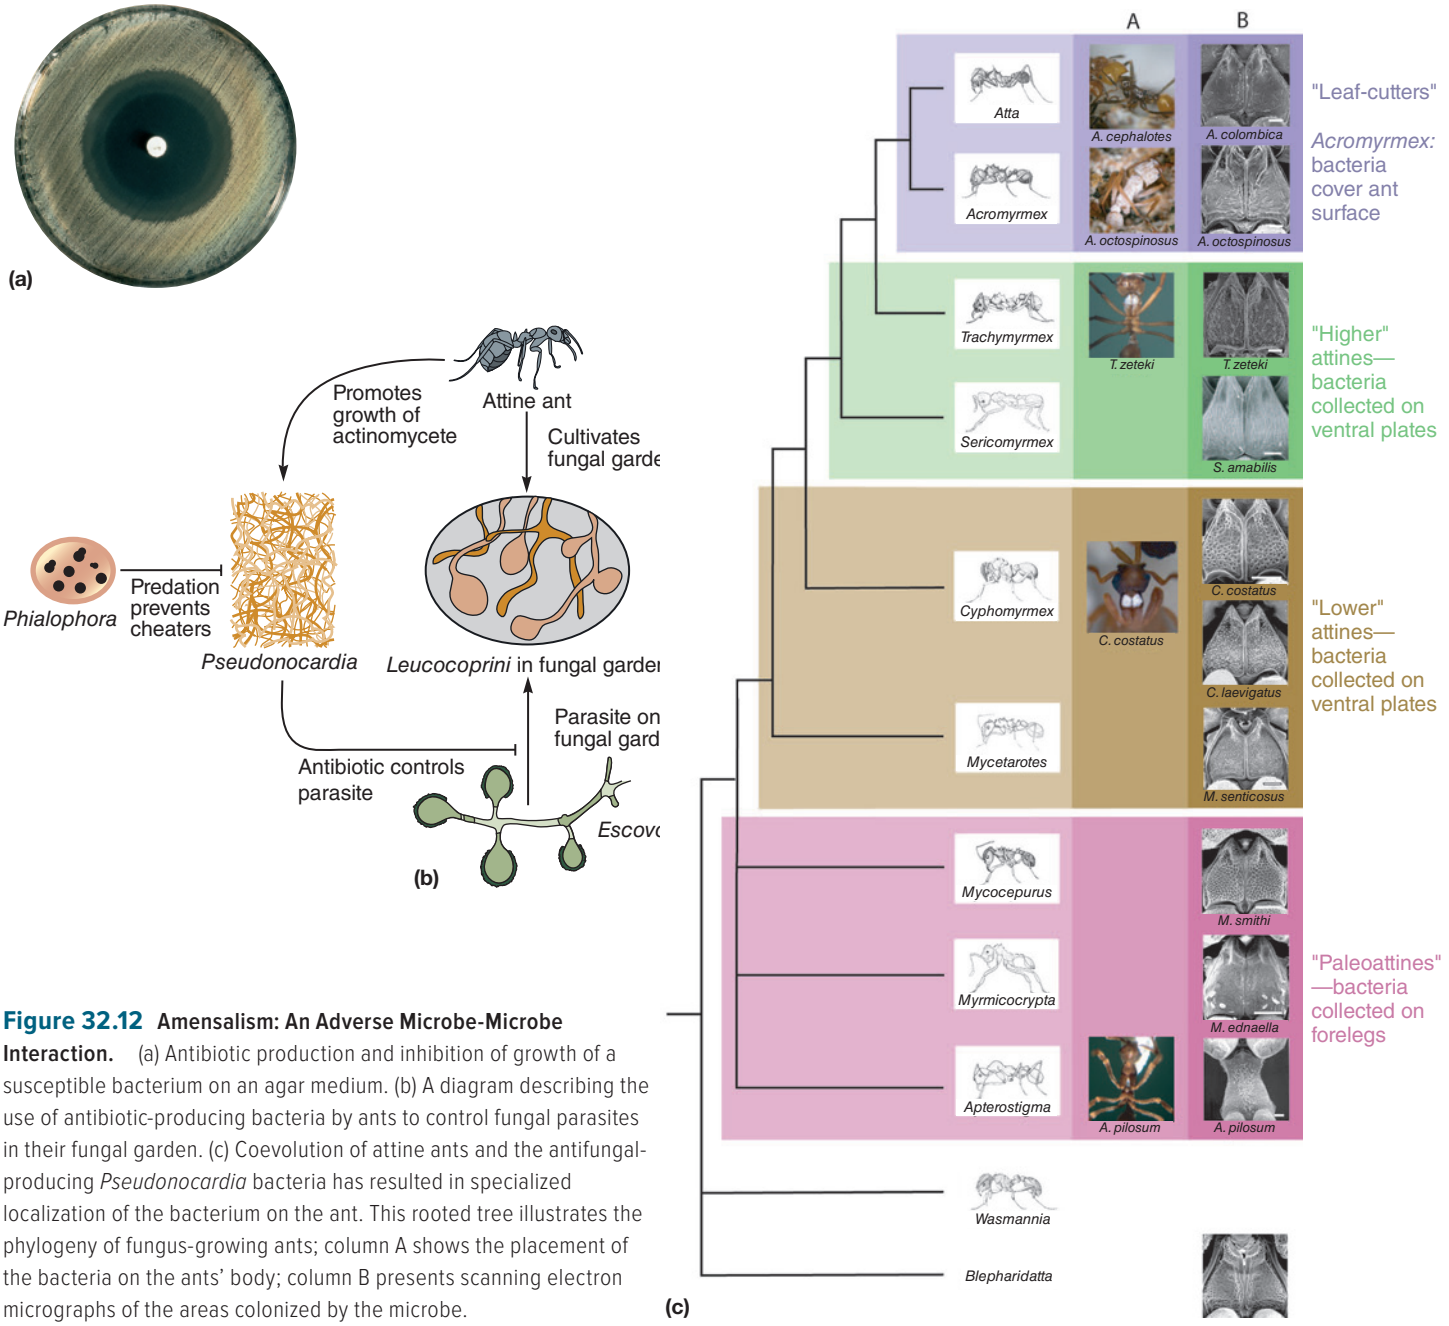

Figure 32.12 Amensalism: An Adverse Microbe-Microbe Interaction. (a) Antibiotic production and inhibition of growth of a susceptible bacterium on an agar medium. (b) A diagram describing the use of antibiotic-producing bacteria by ants to control fungal parasites in their fungal garden. (c) Coevolution of attine ants and the antifungal-producing *Pseudonocardia* bacteria has resulted in specialized localization of the bacterium on the ant. This rooted tree illustrates the phylogeny of fungus-growing ants; column A shows the placement of the bacteria on the ants' body; column B presents scanning electron micrographs of the areas colonized by the microbe.

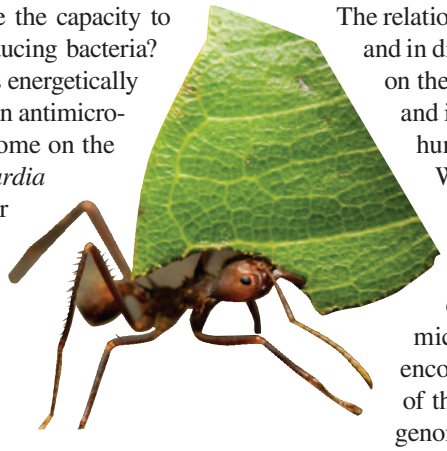
Amensalisms can be quite complex. Attine ants (ants belonging to a New World tribe) are perhaps the most fascinating example. These ants cultivate for their own nourishment a garden of fungi belonging to the genus *Leucocoprini* (figure 32.12*b*). Their ability to accomplish this advanced task depends upon actinobacteria in the genus *Pseudonocardia.* These bacteria produce inhibitory compounds that prevent the growth of *Escovopsis* spp., a predatory fungus that would otherwise destroy the "crop" *Leucocoprini* fungi.

These unique interactions appear to have evolved 50 million to 65 million years ago in South America. Millions of years of coevolution have resulted in particular groups of ants that cultivate specific strains of *Leucocoprini* fungi, which are then subject to different groups of *Escovopsis* parasites. To promote the amensalistic interaction between *Pseudonocardia* and *Escovopsis,* the ants have developed intricate crypts within their exoskeletons for the growth of the antifungal-producing *Pseudonocardia*. As shown in figure 32.12*c*, these crypts have been modified throughout the ants' evolutionary history. The most primitive "paleoattine" ants carry the bacterium on their forelegs, "lower" and "higher" attines have evolved special plates on their ventral surfaces, while the entire surface of the most recent attines, leaf-cutter ants of the genus *Acromyrmex*, are covered with the bacterium. Related ants that do not cultivate fungal gardens (e.g., *Atta* spp.) do not host *Pseudonocardia* cells.

Surprisingly, this four-membered symbiosis is even more complicated, as a fifth member of the symbiosis is found in some cases. This member is a black ascomycete yeast of the genus *Phialophora*. It grows in association with the *Pseudonocardia* symbiont, on which

it also preys. But why would attine ants evolve the capacity to tolerate a fungus that eats their antifungal-producing bacteria? The answer has to do with cheating. Briefly, it is energetically expensive for *Pseudonocardia* cells to produce an antimicrobial compound, but its production ensures a home on the ant. However, some members of the *Pseudonocardia* population could get a "free ride" by letting their neighbors produce the antifungal agent. It is thought that only antifungal-producing bacteria can keep the *Phialophora* fungus in check; this prevents cheaters from thriving.



Competition: Microbes Vying for Common Goods

Competition arises when different organisms within a population or community try to acquire the same resource, whether this is a physical location or a particular limiting nutrient (figure 32.1). If one of the two competing organisms can dominate the environment, whether by occupying the physical habitat or by consuming a limiting nutrient, it will overtake the other organism. This phenomenon was studied by E. F. Gause, who in 1934 described it as the **competitive exclusion principle.** In chemostats, competition for a limiting nutrient may occur among microorganisms with transport systems of differing affinity. This can lead to the exclusion of the slower-growing population under a particular set of conditions. If the dilution rate in the chemostat is changed, the previously slower-growing population may become dominant. Often two microbial populations that appear to be similar nevertheless coexist. In this case, they share the limiting resource (space, a nutrient) and coexist while surviving at lower population levels. Competitive exclusion most likely accounts, at least in part, for the phenomenon of colonization resistance—the capacity of gut microflora to prevent pathogen growth. ⏮ *Chemostats (section 7.9)*

3. What is the competitive exclusion principle? List another example where this principle is demonstrated in the natural world.

32.2 The Human-Microbe Ecosystem

After reading this section, you should be able to:

- Explain the role of germfree mice in evaluating how microorganisms regulate health and disease
- Summarize the importance of the human microbiome in maintaining homeostasis
- Infer how data from the Human Microbiome Project might contribute to the development of new disease treatments

The relationship people have with the microbes that live on and in diverse human environments (e.g., skin and gut) is on the forefront of science. Progress in metagenomics and immunology has altered the long-held belief that human-microbe interactions are commensalistic. We are beginning to understand the many ways in which our microbes keep us healthy. After all, the average adult carries about three times more microbial cells (10^{14}) than human somatic cells (average about 4×10^{13}). With a combined microbial contribution of over 8 million protein-encoding genes, we have come to realize that many of these gene products serve valuable functions our genome is not capable of providing.

From the early days of microbiology until the beginning of the twenty-first century, microbiologists relied on the culture of microorganisms for their identification and analysis. For example, the ability to isolate and grow microbes is key to determining the causative agent of infectious disease using Koch's postulates. The observation that the vast majority of microbes associated with healthy humans cannot be grown in pure culture demonstrates that these microorganisms are not the commensals we once thought them to be. The role of metagenomics has been paramount in determining the taxa present; studies involving proteomics, metabolomics, and other omics are used to explore what (and how) microbes affect our health. ⏮ *Koch's postulates (section 1.3); Metagenomics provides access to uncultured microbes (section 18.3).*

Although our understanding of the microbial contribution to human physiology will take years to tease apart, most studies point to the ecological principle of "niche fulfillment" to define the "who and what" of our microbial partners. This means that microbes colonize specific regions of our bodies in response to the physical and biological parameters found there, and that over time, their activities help shape the structure and function of that environment. However, microbial residency is dynamic, and our microbes must negotiate structural, hormonal, and immunological challenges as humans grow and change. Simply put, we could not live without our microbial flora.

Microorganisms commonly associated with the human body are known as the **normal microbiota** (more traditionally, the "normal flora"). The acquisition of a normal microbiota is a selective process, where a niche may depend on cellular receptors, surface properties, or secreted products. In humans, each microbial niche is also related to age, gender, diet, nutrition, and environment. For instance, many microorganisms revealed by 16S ribosomal RNA sequencing (e.g., members of *Clostridiales* and *Bacteroidales*) can survive only within the anoxic and nutritionally unique environments established in or on the human host, thus preventing their culture in the lab. Furthermore, some organisms long thought to be normal flora turn out to be transient associates or laboratory contaminants.

One method for determining the impact of the normal microbiota is to evaluate the consequences of their absence in and on other organisms. This is accomplished using **germfree** animals, born by cesarean delivery and reared in sterile environments. These animals

(usually mice) provide suitable experimental models for investigating the interactions between the vertebrate host and its microbiota. Comparing animals possessing normal microbiota (conventional animals) with germfree animals allows scientists to explore many of the complex relationships between microorganisms, hosts, and specific environments. Germfree experiments also extend and challenge the microbiologist's "pure culture concept" to in vivo research. Data from numerous germfree studies demonstrate that colonization of the vertebrate host intestine with bacteria stimulates the host immune system, assists in digestion of complex dietary components, and triggers anatomical changes of the intestine. Also, association of specific microorganisms with germfree host skin helps explain their role in colonization strategies and some disease states. Overall, association of microorganisms with germfree animals has helped microbiologists understand complex interactions that cannot be readily studied in conventional hosts, or interpreted just from "-omics" data. Together with genomic studies, data from germfree studies have helped to redefine "normal" in terms of microbiota composition and consequence of microbial association.

In December 2007 the National Institutes of Health launched the two-phase Human Microbiome Project (HMP) to better understand the symbiotic relationships that result in human health and disease. The term **microbiome** was coined to define all the microbes associated with the healthy host. Phase 1 of the HMP (FY2007–2012) characterized the composition and diversity of human microbial communities with specific emphasis on identification of the metabolic potential of taxa found in specific body sites. Phase 2 of the HMP (FY2013–2015) employed cohort studies to establish the relationship between the microbiomes of healthy individuals and those of individuals with a disease.

As of April 2014, whole metagenomic sequencing data from ~800 healthy human cohort samples, 16S sequence data from ~5,000 healthy human cohort samples, and associated metadata from these reads have been released. All told, the total amount of HMP data available has surpassed 14 terabytes. Of note are the results of the many HMP projects indicating that there is no single healthy microbiome. Rather, each person harbors a unique and varied collection of microorganisms that assemble over a person's interactive history with their environment, diet, medications, and many other factors. Furthermore, identification of microbial "community types" that are associated with disease risk are clearly emerging. The ongoing task is the association of community types with the myriad of demographic factors (gender, education, being breast-fed, lifestyle attributes, etc.) to identify relationships that will be useful in predicting health and disease, and ultimately to develop therapies (like pre- and probiotics) that would alter community types to obtain healthy outcomes. Importantly, evaluation of human and microbial proteins and metabolites should answer many questions regarding the biochemical processes regulated by the microbial-human symbioses, the diseases resulting from dysfunctional human-microorganism relationships (dysbiosis), and potential biological and therapeutic approaches to treat human disease. ▶▶| *Probiotics (section 41.6)*

Several microbiome-associated health and disease correlations are known. For example, the microbiome (1) assists in the digestion of food and other ingested products, (2) stimulates our immune system to mature and then regulates it, (3) protects against microorganisms that cause disease, and (4) produces the essential vitamins B12, thiamine, and riboflavin, as well as vitamin K. The microbiome also metabolizes bile acids and sterols. Other associations are interesting but require further study. For example

- Type 1 diabetes is an autoimmune disease associated with a less diverse gut microbiome. Bacteria play a role in developing diabetes, in animal studies.
- The presence of a relatively high number of gut firmicutes is strongly correlated with obesity and type 2 diabetes (**Microbial Diversity & Ecology 32.2**).
- Obesity has also been associated with poor microbial diversity in the intestine. Obese twins have a lower diversity of bacteria as compared with lean twins.
- Intestinal disease caused by *Clostridium difficile* infections has been cured using fecal transplants to restore healthy intestinal microbiota.
- Autoimmune disease appears to be passed in families not just by genetic factors but by inheritance of the family microbiome.
- Autoimmune diseases such muscular dystrophy and rheumatoid arthritis are associated with dysfunction of the microbiome.

Clearly our survival depends on an elaborate network integrating microbial gene expression with that of our own. This network extends beyond "metabolism sharing" to the more utilitarian as microbes defend their human ecosystem. This host-microbial interplay is essential in keeping harmful microorganisms and other foreign material from entering the body. Should microorganisms gain access to internal tissues, additional host defenses are summoned to prevent them from establishing another type of relationship, one of parasitism or pathogenicity. **Pathogenicity** (Greek *pathos,* emotion or suffering, and *gennan,* to produce) is the ability to produce pathologic changes or disease. A **pathogen** is any disease-producing microorganism. Although the normal microbiota offer some protection from invading microorganisms, its members may themselves become pathogenic and produce disease under certain circumstances (dysbiosis); they then are termed **opportunistic microorganisms** or **pathogens.** Opportunistic pathogens are adapted to the noninvasive mode of life defined by the environment in which they live. If they are removed from their environment and introduced into different tissues or the bloodstream, disease can result. For example, some streptococci are the most common resident bacteria in the mouth and oropharynx. But if they are introduced into the bloodstream in large numbers (e.g., following tooth extraction), they may settle on deformed or prosthetic heart valves and cause endocarditis. ▶▶| *Pathogenicity and infection (chapter 35)*

Opportunistic microorganisms often cause disease in compromised hosts. A **compromised host** is seriously debilitated and has a lowered resistance to infection. There are many causes of this condition, including malnutrition, alcoholism, illness, trauma from surgery or an injury, an altered normal microbiota

MICROBIAL DIVERSITY & ECOLOGY

32.2 Do Bacteria Make People Fat?

The prevalence of human obesity has increased steadily since 1960. In fact, in the United States, the incidence of obesity increased from 13% to 34% between 1960 and 2006. According to the National Center for Health Statistics, approximately one-third of adults in the United States are obese. As a result, the U.S. Public Health Service has labeled obesity an epidemic. While a sedentary lifestyle coupled with poor nutritional choices probably drives the prevalence of obesity, new evidence suggests that obesity is also related to the bacteria in your gut.

A number of studies show that the relative amounts of two bacterial phyla can determine body weight. Through the use of metagenomic techniques examining intestinal bacteria, higher relative concentrations of members of *Firmicutes* (low G + C Gram-positive bacteria) to *Bacteroidetes* (Gram-negative bacteria) are correlated with obesity. Conversely, lean people have many fewer firmicutes in their intestines as compared to bacteroidetes. Interestingly, obese people who lost at least 25 pounds over 1 year by eating diets low in fat or carbohydrates altered their gut microbiota and subsequently had bacterial profiles that more closely resembled those of lean people.

Critics of this research suggest that this observation is not causal, just coincidence. To address this, investigators used germfree mice (p. 698) as test subjects. They discovered that such mice are inherently resistant to weight gain despite a high fat content in their diet. In fact, in an 8-week study, germfree mice consuming a diet containing 40% fat gained 50% less weight than conventional (having their normal microbiota) mice fed the same amount and type of food. However, when investigators transplanted intestinal bacteria from obese mice into germfree mice, the germfree mice gained more weight than germfree mice controls that received bacteria from lean mice. Thus it appears that unique bacterial profiles occur in obese mice and that specific bacteria are highly correlated with obesity. But what could be the mechanism by which intestinal bacteria drive obesity?

In evaluating the microbiome, investigators have determined that the bacteria from obese mice produced more soluble degradation products from catabolizing complex carbohydrates. Firmicutes thereby release more energy from dietary nutrients than do bacteroidetes. Furthermore, the firmicutes were able to trigger the expression of host genes that slowed fat catabolism and increased fat accrual in various host tissues. It is thus not surprising that their catabolic activity has also been associated with the development of the insulin resistance that characterizes type 2 diabetes.

While these recent data suggest a simplistic view of weight gain, decades of other data support the absolute requirement for aerobic exercise and proper nutrition as part of achieving and maintaining a healthy weight. It seems that our role is to create a selective medium for the right kind of bacterial growth. Remember, a high-fat, high-carbohydrate environment favors firmicute overgrowth, while a low-fat, low-carbohydrate environment favors bacteroidetes. Which bacteria do you want to cultivate?

from the prolonged use of antibiotics, and immunosuppression by various factors (e.g., drugs, viruses [HIV], hormones, and genetic deficiencies). For example, *Bacteroides* spp. are one of the most common residents in the large intestine (table 32.2) and are quite harmless in that location. If introduced into the peritoneal cavity or pelvic tissues as a result of trauma, they cause suppuration (the formation of pus) and bacteremia (the presence of bacteria in the blood). Importantly, the normal microbiota is harmless and is often beneficial in its normal location in the host and in the absence of coincident abnormalities. However, these microbes can produce disease if introduced into foreign locations or compromised hosts. Chapters 38–40 discuss the consequences of human interaction with pathogens. We now describe the normal human microbiota that function as mutualistic and commensal symbionts.

Retrieve, Infer, Apply

1. How might a microbial symbiont affect the uptake and metabolism of amino acids needed by its host?
2. Cite three reasons a germfree mouse would be more susceptible to pathogens when compared to a normal mouse.
3. People who suffer from colitis often find that their symptoms improve if they increase the amount of fiber in their diet. Why might this be the case?

32.3 Normal Microbiota of the Human Body Adapt to Many Sites

After reading this section, you should be able to:

- Report the common culturable organisms associated with various body sites
- Predict the environmental host conditions that favor the association of acidophilic, anaerobic, lactic acid fermenting, and halophilic bacteria
- Discuss the mechanism by which the normal microbiota mediates resistance to pathogens

Development of the Normal Microbiota

The human body provides numerous habitats that differ in terms of the environmental conditions they provide. These conditions dictate the microbes that reside at each site. Importantly, the normal microbiota is not static. It begins developing at birth and changes as the human ages. In this section, we begin by describing this development and then discuss the microbiota observed at various body sites of adult humans.

Newborns are initially colonized by microorganisms from the immediate environment. For example, babies born vaginally acquire most of their microorganisms from their mother, whereas babies born by cesarean delivery acquire the microorganisms of their initial caretakers (nurses, doctors, midwives, parents, etc.).

The early colonization of the infant intestinal tract by *E. coli* and streptococci appears to establish a reducing environment for the growth of strict anaerobes such as bifidobacteria and bacteriodetes. Data also suggest that human milk may act as a selective medium for nonpathogenic bacteria, as bottle-fed babies appear to have a much smaller proportion of intestinal bifidobacteria. Furthermore, bifidobacteria appear to be able to synthesize all amino acids and other required growth factors from simple nutrients such as glucose and inorganic sources of nitrogen, sulfur, and phosphorus. Thus bifidobacteria are well adapted for growth in the colonic environment, which has very low concentrations of these nutrients. Bifidobacteria and bacteroidetes have surface proteins that bind sugars, called glycans, present in the diet as well as produced by the host (**figure 32.13**). In the case of bifidobacteria, operons encoding enzymes for the catabolism of starch, pullulan, and amylopectin (necessary for weaning from milk to complex carbohydrates) are also found. Switching to cow's milk or solid food (mostly polysaccharide) appears to result in the loss of bifidobacteria predominance; proteobacteria, firmicutes, and bacteroidetes—specifically enterobacteria, enterococci, lactobacilli, clostridia, and *Bacteroides* spp.—increase and outcompete actinobacteria in a polysaccharide-rich environment.

The initial microbiota changes with its host; age and gender, along with their associated physiological and anatomical differences, substantially contribute to defining the evolving microbiota until a stable resident (normal) microbiota becomes established (**table 32.1**). Each individual cultivates his or her own microbial population that is heavily influenced by genetics, developmental change (e.g., immune system maturity, puberty, and menopause), diet (high protein versus high fat versus high carbohydrate content), personal hygiene (frequency of washing, type of soap, use of cosmetics, use of occlusive bandages, clothing choice, etc.), anatomical site, and "life events" (antimicrobial use, travel, occupation, sexual partners, etc.).

Interestingly, once established, the adult microbiota permits only transient changes in diversity. These changes only occur with substantial host environmental change (like going through puberty or adopting a long-term vegetarian diet) so as to support the new resident taxa. Supporting this observation is the effect that infectious disease and its treatment have on an individual's microbiota. Infection and antimicrobial chemotherapy result in short-term flora shifts (growth of pathogens causing disease and loss of taxa sensitive to the antimicrobial agent) but may not alter the long-term composition of the adult microbiota as long as the drugs eradicate the pathogen and are discontinued. However, long-term shifts in the microbiota can occur with sustained use of antimicrobial agents, as seen with treatment of chronic infectious disease. Thus, most infectious agents are better characterized as transient microorganisms with which the host interacts.

While the adult human microbiota is relatively stable over time, it is highly variable from person to person and at different sites within the same person. In other words, there are relatively few species of microorganisms common to all humans; each human has a relatively unique microbiota. Based on 16S rRNA and whole genome metagenomic data, bacteria common to human skin, the intestinal tract, and the other mucosal surfaces appear to represent five phyla: *Actinobacteria, Bacteroidetes, Firmicutes, Fusobacteria*, and *Proteobacteria* (**figure 32.14**). Additionally, DNA from a number of archaea (euryarchaeotes), fungi, and viruses are consistently recovered. Despite limited diversity at this taxonomic level, each phylum is represented by an enormous number of species.

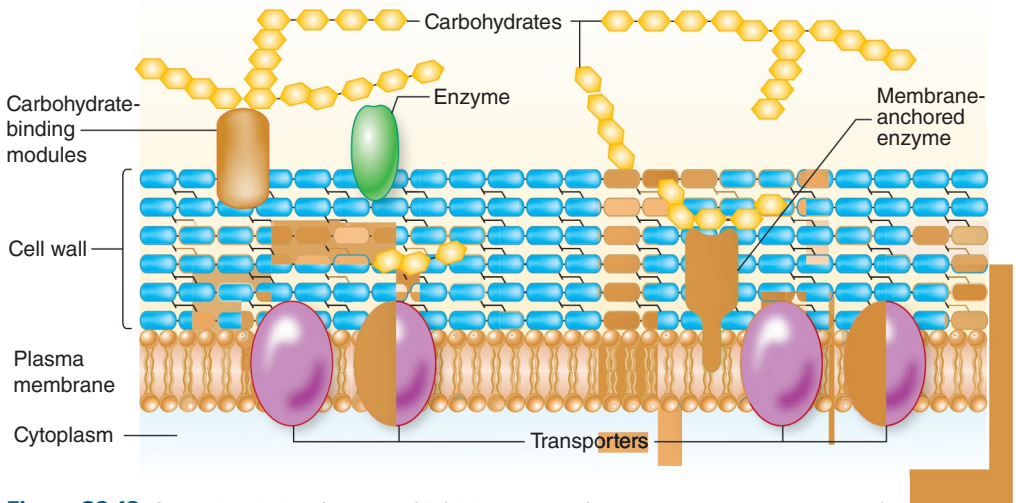

Figure 32.13 Sugar Acquisition Strategy of Bifidobacteria. Carbohydrates are bound to the bifidobacterial cell by use of an enzyme "docking station." Anchored to the cell surface, modular glycanases degrade complex carbohydrates to oligosaccharides, which are then transported across the plasma membrane. Bacteroidetes use a similar strategy to bind glycans to the outer membrane of their Gram-negative cell walls.

Table 32.1 Innate and Environmental Factors That Impact Microbial Diversity and Human Immunity

Relative Age	Innate Factors[1]	Environmental Factors	Microbial Diversity[2]	Immunity[3]
Birth	Genetics	Multiple caregivers, breast milk/ formula, immunizations	Mother's vaginal & intestinal flora, transient species from caregivers	Activation of innate systems
Infant	Developing immunity	Solid foods, crawling, mouth contact, first infections, first antibiotics	40–100 species, 7–8 phyla, transient fungi and virus	Induction of acquired systems
Child	Body growth	Changing diet, socialization/contact with peers, play, adventure	40–100 species, 7–8 phyla, rare fungi, rare virus	Challenges of both systems, secondary lymphoid structure development
Teen	Puberty, sexual activity	Travel, sports, fitness	Species change, 7–8 phyla, increasing fungi, increasing virus	Functional tuning with continued antigen exposure
Adult	Weight gain, pregnancy, metabolic disease diagnosis, stress	Stable cohabitation, job changes, shift work, relocations, children, medications	Stable population ~500–1,000 species, 7–8 phyla, 1–10% fungi, 10–40% virus	Colonization resistance, maintenance of lymphocyte reservoir
Senior Citizen	Muscle atrophy, declining immunity, system failures	Day care, diet change, menopause, declining fitness, loss of motility, incontinence, cardiopulmonary disorders, age-related infections, hospital, nursing care	Less stable population, 7–8 phyla, variable fungi, variable virus	Declining responses, increased permissiveness to pathogens

1 Each factor included in subsequent age groups.
2 Type and relative frequency of taxa.
3 Each event may include or yield to subsequent age-group observations.

What We Know About Microbiota at Various Body Sites

In a healthy human, regardless of age, the internal tissues (e.g., brain, blood, cerebrospinal fluid, muscles) are normally free of microorganisms. Conversely, the surface tissues (e.g., skin and mucous membranes) are constantly in contact with environmental microorganisms and become readily colonized by various microbial species. An overview of the culturable microbiota typically native to different regions of the body is presented in **table 32.2**. Because bacterial and archaeal species make up most of the normal microbiota, they are emphasized over fungi, protists, viruses (including phages), and arthropods that are also part of the microbial assemblage and about which we are just beginning to learn.

Skin

The adult human is covered with approximately 1.8 m^2 of skin. The skin surface or epidermis has a slightly acidic pH, a high concentration of sodium chloride, a lack of moisture in many areas, and the oily lubricant sebum and antimicrobial peptides in other areas. It has been estimated that this surface area supports about 10^{10} bacteria dwelling in different microenvironments with distinct moisture, pH, sebum content, temperature, and topography. Microorganisms colonize discrete skin sites dictated by skin physiology (figure 32.14). Those that are temporarily present are transient microorganisms. Transients usually do not become firmly entrenched and are typically unable to multiply.

The skin surface can be divided into three environmental niches: dry, moist, and sebaceous (containing sebum). In general, bacterial diversity is greatest at dry sites (forearm, buttocks, hands, for example), harboring a mixture of Gram-positive and Gram-negative organisms from the phyla *Actinobacteria*, *Bacteroidetes*, *Firmicutes*, and *Proteobacteria*. Moist areas (umbilicus, underarm, inguinal and gluteal creases, and inside the elbow, for example) exhibit less diversity, supporting mostly members of *Firmicutes* and *Actinobacteria* (*Staphylococcus* and *Corynebacterium* spp., respectively), in addition to low numbers of other bacteria. The skin surfaces with the lowest bacterial diversity are the oily sebaceous sites (forehead, behind the ear, and the back, for example), where members of *Actinobacteria* (*Propionibacterium* spp.) dominate (figure 32.14).

▶▶| *Antimicrobial peptides and proteins (section 33.3)*

Most skin bacteria are found on superficial cells, colonizing dead cells, or closely associated with the oil and sweat glands. Secretions from these glands provide the water, amino acids, urea, electrolytes, and specific fatty acids that serve as nutrients primarily for resident bacteria such as *S. epidermidis*. The oil glands secrete complex lipids that may be partially degraded by the enzymes from certain Gram-positive bacteria, in particular

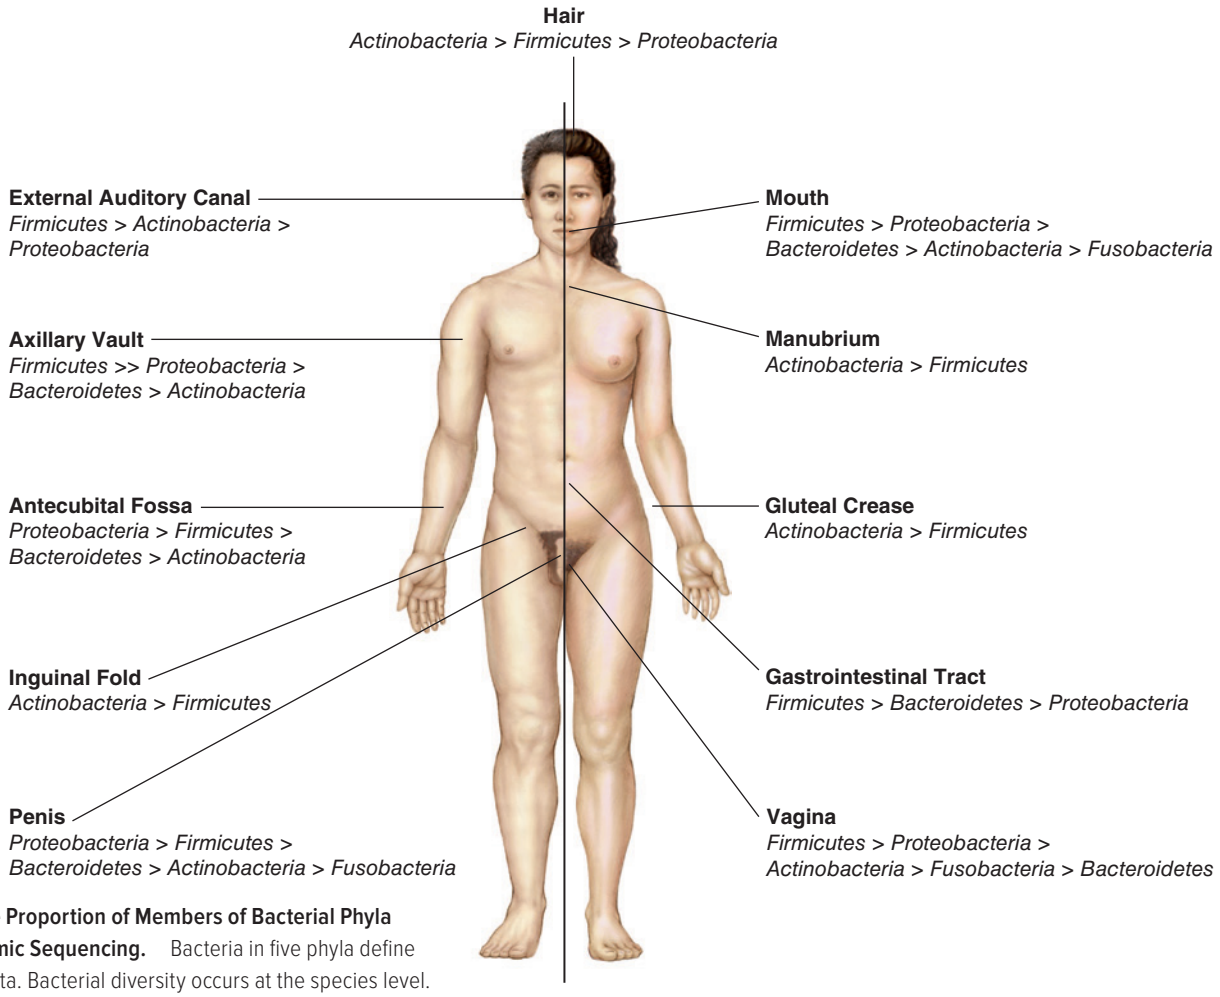

Figure 32.14 Relative Proportion of Members of Bacterial Phyla Identified by Metagenomic Sequencing. Bacteria in five phyla define the adult human microbiota. Bacterial diversity occurs at the species level.

Propionibacterium acnes. These bacteria usually are harmless; however, they are associated with the skin condition acne vulgaris. They convert lipids secreted by the oil glands to unsaturated fatty acids such as oleic acid that have strong antimicrobial activity against Gram-negative bacteria and some fungi. Some of these fatty acids are volatile and may have a strong odor. This is why many deodorants contain antibacterial substances that act selectively against Gram-positive bacteria to reduce the production of volatile unsaturated fatty acids and body odor.

Retrieve, Infer, Apply

1. Why is it important to understand the normal human microbiota?
2. Why is the skin not always a favorable microenvironment for colonization by bacteria?
3. How do microorganisms contribute to body odor?
4. What physiological role does *P. acnes* play in the establishment of acne vulgaris?

Nose, Pharynx, and Mouth

The normal microbiota of the nose, pharynx, and mouth are similar. Just inside the nostrils, *Staphylococcus aureus* and *S. epidermidis* are the predominant culturable bacteria and are found in approximately the same numbers as on the skin of the face.

The nasopharynx, that part of the pharynx lying above the soft palate, may contain small numbers of potentially pathogenic bacteria such as *Streptococcus pneumoniae, Neisseria meningitidis,* and *Haemophilus influenzae*. Diphtheroids, a large group of nonpathogenic Gram-positive bacteria that resemble *Corynebacterium* spp., are commonly found in both the nose and nasopharynx.

The oropharynx is that division of the pharynx lying between the soft palate and the upper edge of the epiglottis. The most important bacteria found in the oropharynx are various α-hemolytic streptococci (*S. oralis, S. milleri, S. gordonii, S. salivarius; see figure 23.15*); large numbers of diphtheroids; *Branhamella catarrhalis*; and small, Gram-negative cocci related to *N. meningitidis.* The palatine and pharyngeal tonsils harbor a similar microbiota, except within the tonsillar crypts, where there is an increase in *Micrococcus* spp. and anaerobic members of the genera *Porphyromonas, Prevotella*, and *Fusobacterium.*

Soon after an infant is born, the mouth is colonized by microorganisms from the surrounding environment. Initially the microbiota belongs mostly to the genera *Streptococcus, Neisseria, Actinomyces, Veillonella,* and *Lactobacillus,* as well as some yeasts. Most microorganisms that initially invade the oral cavity are aerobes and obligate anaerobes. When the first teeth erupt, anaerobes (*Porphyromonas, Prevotella,* and *Fusobacterium* spp.) become dominant due to the anoxic nature of the space between the teeth and gums. As the teeth grow, *Streptococcus parasanguis* and *S. mutans* attach to enamel surfaces; *S. salivarius* attaches to the buccal and gingival epithelial surfaces and colonizes the saliva. These streptococci produce a glycocalyx

Table 32.2 Normal Human Microbiota Routinely Cultured from Various Body Sites. Knowing the Identity of These Resident Microorganisms Assists in the Rapid Identification and Treatment of Pathogens.

Body System	Body Site	Microorganisms	
Eye	Conjunctiva	Coagulase-negative staphylococci *Hemophilus* spp.	*Staphylococcus aureus* *Streptococcus* spp.
	Outer ear	Coagulase-negative staphylococci Diphtheroids	*Pseudomonas* spp. Enterobacteria (occasionally)
Skin	Nonmucous membrane surfaces	Coagulase-negative staphylococci Diphtheroids *Propionibacterium acnes* *Staphylococcus aureus* *Streptococcus* spp.	*Bacillus* spp. *Malassezia furfur* *Candida* spp. *Mycobacterium* spp. (occasionally)
Respiratory tract	Nose	Coagulase-negative staphylococci *Streptococcus* spp. (including *S. pneumoniae*) *Staphylococcus aureus*	*Neisseria* spp. *Haemophilus* spp.
Gastrointestinal tract	Mouth and oropharynx	*Streptococcus* spp. (including *S. pneumoniae*) Coagulase-negative staphylococci *Veillonella* spp. *Fusobacterium* spp. *Treponema* spp. *Porphyromonas* spp. *Prevotella* spp. *Neisseria* spp.	*Branhamella* spp. *Hemophilus* spp. Diphtheroids *Candida* spp. *Actinomyces* spp. *Eikenella corrodens* *Staphylococcus aureus*
	Stomach	*Streptococcus* spp. *Staphylococcus* spp.	*Lactobacillus* spp. *Peptostreptococcus* spp.
	Small intestine	*Lactobacillus* spp. *Bacteroides* spp. *Clostridium* spp.	*Mycobacterium* spp. *Enterococcus* spp. Enterobacteria
	Large intestine	*Bacteroides* spp. *Fusobacterium* spp. *Clostridium* spp. *Peptostreptococcus* spp. *Escherichia* coli *Klebsiella* spp. *Proteus* spp. *Lactobacillus* spp.	*Enterococcus* spp. *Streptococcus* spp. *Pseudomonas* spp. *Acinetobacter* spp. Coagulase-negative staphylococci *Staphylococcus aureus* *Mycobacterium* spp. *Actinomyces* spp.
Genitourinary tract	Distal urethra	Coagulase-negative staphylococci Diphtheroids *Streptococcus* spp. *Mycobacterium* spp.	*Bacteroides* spp. *Fusobacterium* spp. *Peptostreptococcus* spp.
	Vagina	*Lactobacillus* spp. *Peptostreptococcus* spp. Diphtheroids *Streptococcus* spp.	*Clostridium* spp. *Bacteroides* spp. *Gardnerella vaginalis* *Candida* spp.

and various other adherence factors that enable them to attach to oral surfaces. The presence of these bacteria contributes to the eventual formation of dental plaque, caries, gingivitis, and periodontal disease. ▶▶| *Dental disease (section 39.6)*

In many ways, the mouth provides an ideal habitat for microbes. It has a ready supply of water and nutrients. It also has a neutral pH and moderate temperature. However, it subjects the normal microbiota to mechanical perturbations that can dislodge

microbes from the mouth. Thus the normal microbiota of the mouth consists of organisms that resist mechanical removal by adhering to surfaces such as the gums and teeth. These removal mechanisms include flushing of the oral cavity contents to the stomach, where they are destroyed by hydrochloric acid, and the continuous desquamation (shedding) of epithelial cells.

Respiratory Tract

The lower respiratory tract does not have normal microbiota. This is because microorganisms are removed in at least three ways. First, a continuous stream of mucus is generated by the goblet cells. This entraps microorganisms, and the ciliated epithelial cells continually move the entrapped microorganisms out of the respiratory tract (*see figure 33.5*). Second, alveolar macrophages phagocytize and destroy microorganisms. Finally, a bactericidal effect is exerted by the enzyme lysozyme, present in nasal mucus.

Eye and External Ear

At birth and throughout human life, a small number of bacteria are found on the conjunctiva of the eye. The predominant bacterium is *S. epidermidis*, followed by *S. aureus, Haemophilus* spp., and *S. pneumoniae*. By contrast, the normal microbiota of the external ear resembles that of the skin, with coagulase-negative staphylococci and *Corynebacterium* spp. predominating.

Gastrointestinal Tract

The very acidic pH (2 to 3) of the gastric contents kills most microorganisms. As a result, the stomach usually contains less than 10 viable bacteria per milliliter of gastric fluid. These are mainly *Streptococcus, Staphylococcus, Lactobacillus, Peptostreptococcus* spp. and yeasts such as *Candida* spp. Microorganisms may survive if they pass rapidly through the stomach or if the organisms ingested with food are particularly resistant to gastric pH (e.g., mycobacteria).

The small intestine is divided into three anatomical areas: duodenum, jejunum, and ileum. The duodenum (the first 25 cm of the small intestine) contains few microorganisms because of the combined influence of the stomach's acidic juices and the inhibitory action of bile and pancreatic secretions that are added here. Of the bacteria present, Gram-positive cocci and rods comprise most of the microbiota. *Enterococcus faecalis,* lactobacilli, diphtheroids, and the yeast *Candida albicans* are occasionally found in the jejunum. In the distal portion of the small intestine (ileum), the microbiota begins to take on the characteristics of the colon microbiota. It is within the ileum that the pH becomes more alkaline. As a result, anaerobic Gram-negative bacteria and members of the family *Enterobacteriaceae* become established.

The large intestine or colon has the largest microbial community in the body. Microscopic counts of feces approach 10^{12} organisms per gram wet weight. Over 1,000 different bacterial species have been identified in human feces. In fact, some argue that the human colon is home to one of the most diverse microbial communities on Earth. These microorganisms consist primarily of anaerobic, Gram-negative bacteria and Gram-positive rods (figure 32.14). Not only are the vast majority of microorganisms anaerobic, but many different species are present in large numbers. The metagenomic profile of colonic bacteria in healthy adults includes 60–80% firmicutes, 20–40% bacteriodetes, with the remaining largely proteobacteria and actinobacteria.

Various physiological processes move the microbiota through the colon so an adult eliminates about 3×10^{13} microorganisms daily. These processes include peristalsis, desquamation of the surface epithelial cells to which microorganisms are attached, and continuous flow of mucus that carries adhering microorganisms with it. To maintain homeostasis, the body must continually replace lost microorganisms. The bacterial population in the human colon usually doubles once or twice a day. Under normal conditions, the resident microbial community is self-regulating. Competition and mutualism between different microorganisms and between the microorganisms and their host maintains a status quo.

Genitourinary Tract

The upper urinary tract (kidneys, ureters, and urinary bladder) is usually free of microorganisms. In both males and females, a few common bacteria (*S. epidermidis, E. faecalis,* and *Corynebacterium* spp.) usually are cultured from the distal portion of the urethra. In the male, metagenomic sequencing also suggests several anaerobic Gram-negative bacteria are present.

In contrast, the adult female genital tract, because of its large surface area and mucous secretions, has a complex microbiota that constantly changes with a woman's menstrual cycle. The culturable microorganisms are acid-tolerant lactobacilli, primarily *Lactobacillus acidophilus*, often called Döderlein's bacillus. They ferment glycogen produced by the vaginal epithelium, forming lactic acid. As a result, the pH of the vagina and cervix is maintained between 4.4 and 4.6, inhibiting other microorganisms. In addition to *L. acidophilus,* metagenomic sequencing has identified a variety of anaerobic Gram-negative and Gram-positive bacteria in the female genitourinary tract. Some of these include those that normally inhabit moist skin areas (figure 32.14 and table 32.2).

Key Concepts

32.1 Many Types of Microbial Interactions Exist

- Symbiotic interactions include mutualism (mutually beneficial and obligatory), cooperation (mutually beneficial, not obligatory), and commensalism (product of one organism can be used beneficially by another organism). Predation involves one organism (the predator) ingesting or killing a larger or smaller prey, parasitism (a longer-term internal maintenance of another organism or acellular infectious agent), and amensalism (a microbial product inhibiting another organism) (**figure 32.1**).
- Mutual advantage is central to many organism-organism interactions. These interactions can be based on material transfers related to energetics or the creation of physical environmental changes that offer protection. With several important mutualistic interactions, chemolithotrophic microorganisms play a critical role in making organic matter available for use by an associated organism (e.g., endosymbionts in *Riftia* tube worms) (**figure 32.5**).
- The rumen is an excellent example of a mutualistic interaction between an animal and a complex microbial community. In this microbial community, complex plant materials are broken down to simple organic compounds that can be absorbed by the ruminant, as well as forming waste gases such as methane that are released to the environment.
- Commensalism or syntrophism simply means growth together. It does not require physical contact and involves a mutually positive transfer of materials, such as interspecies hydrogen transfer.
- Predation and parasitism are closely related. Predation has many beneficial effects on populations of predators and prey. These include recycling immobilized minerals in organic matter for reuse by chemotrophic and photosynthetic primary producers, and protection of prey from heat and damaging chemicals.

32.2 The Human-Microbe Ecosystem

- The average human adult carries about three times more microbial cells than human cells. Microorganisms that take up residence on a human host are called the normal microbiota.
- The Human Microbiome Project is evaluating the role microbial genes and their products have in maintaining homeostasis in the host.
- Metagenomic analysis of the human microbiome has revealed an enormous diversity of microorganisms living on and in the human body. These microbes are essential in establishing and maintaining the health of the host.
- A pathogen is any disease-producing microorganism.
- Opportunistic pathogens are microorganisms that cause disease if introduced into a sterile site of a healthy host or gain access to an immunologically compromised host.

32.3 Normal Microbiota of the Human Body Adapt to the Human Condition

- Various microbes have adapted to specific niches found on the human host. These niches are uniquely able to support microbial growth by maintaining a relatively constant environment (**figure 32.14**).
- Microorganisms living on or in the skin can be characterized as either transients or residents. The normal microbiota have evolved the ability to tolerate vastly different conditions found on skin; for example, oily, moist, and dry.
- The oral cavity provides a nutrient-rich habitat but subjects microbes to physical processes that can dislodge them. The normal microbiota of the oral cavity is composed of those microorganisms able to resist this mechanical removal.
- The stomach contains very few microorganisms due to its acidic pH.
- The distal portion of the small intestine and the entire large intestine have the largest microbial community in the body. Over 400 species have been cultured, the vast majority of them anaerobic; metagenomic studies suggest that approximately 12,000 different genera inhabit the large intestine (**table 32.2**).
- The upper urinary tract is usually free of microorganisms. The tip of the urethra (a mucus membrane) harbors numerous skin bacteria. In contrast, the adult female genital tract has a more complex microbiota that prevents other microorganisms from colonization.

Compare, Hypothesize, Invent

1. Describe an experimental approach to determine if a plant-associated microbe is a commensal or a mutualist.
2. Some patients who take antibiotics for acne develop yeast infections of the mouth or genitourinary tract. Explain.
3. How does knowing the anatomical location of normal microbiota help clinicians diagnose infection?
4. Compare and contrast the microbial communities that reside in a ruminant with those in the human gut.
5. The fruit fly *Drosophila melanogaster* is an excellent model system. *D. melanogaster* hosts the ubiquitous insect symbiont *Wolbachia pipientis,* but unlike most other insect hosts, it is not subject to reproductive manipulation by the bacterium. Surprisingly, infection with *W. pipientis* protects the fruit fly from infection by three unrelated viruses that otherwise cause 100% mortality. Discuss the differences in this rickettsial-insect symbiosis with that described in Microbial Diversity & Ecology 32.1. Do you think it is likely that *W. pipientis* also protects wasps against other pathogens, such as viruses? Explain your answer from the point of view of the bacterium and from the insect's point of view.

Innate Host Resistance

Obesity is an epidemic, rapidly spreading across nations. Excess dietary fat, as often found in fast foods, is implicated in several metabolic diseases. Of great interest is how fat cells produce chemical signals that control inflammatory processes.

Supersize Me!

About one-third of the U.S. population is obese, with 60% considered overweight. This is a staggering statistic, and it has been increasing steadily over the past 50 years. Interestingly, obesity rates correlate to diets high in saturated fats, as found in many fast food products. The fats in foods are not the only problem, though. Increasing portion size has added dramatically to the obesity issue. In many ways, the American diet is supersized. These facts prompted a number of scientists to study the impact of obesity on the immune system. Results of studies have provided additional insight into the mechanisms by which the innate resistance arm of the mammalian immune system functions.

Innate resistance is an elegant system of sensory and response molecules that detect invasion by microorganisms. Capture of microbial pieces and parts by toll-like and NOD-like receptors (TLRs and NLRs, respectively) triggers an ancient gene activation response that upregulates the inflammatory process. This response synthesizes chemical messengers (cytokines) that alert the host to combat the alien invaders by recruiting an army of proteins and cells. An equally elegant system has recently gained attention whereby TLRs and NLRs detect and respond to host cell damage by recognizing damage- or danger-associated molecular patterns (DAMPs), which are typically released from stressed or dying host cells. Recognition of DAMPs likewise stimulates cytokine expression to facilitate cellular repair. Both systems activate the same inflammatory process but usually with very different outcomes. In a series of revealing papers, scientists from Tokyo to Boston studying obesity and its associated problems have pieced together the amazing story of how the intricate system for the detection of MAMPs and DAMPs by TLRs and NLRs is upset when we "supersize."

Originally thought to just be an energy reserve, visceral (belly) fat is a specialized tissue composed of lipid-laden adipocytes (fat cells), preadipocytes, phagocytes called macrophages, innate lymphoid cells, and other cells held in a web of extracellular matrix proteins. Normal adipocytes make pro- and anti-inflammatory cytokines, striking a delicate balance between opposing inflammatory functions to maintain homeostasis needed for tissue repair and regeneration functions.

However, studies now show strong correlations between increasing visceral adipose (obese conditions) and increased serum levels of pro-inflammatory cytokines (adipokines). This is because saturated fatty acids are recognized as DAMPs by visceral adipocytes and their associated macrophages. One of the pro-inflammatory adipokines, interleukin (IL)-18, and a macrophage marker of inflammation, C-reactive protein (CRP), are especially elevated in the obese. These and other data suggest that a low level of homeostatic inflammation is maintained in normal adipose tissue, balancing inflammatory mediators for tissue sustainability. However, shifting from lean to obese conditions causes the visceral adipocytes along with recruited macrophages and lymphocytes, to secrete pro-inflammatory cytokines that alter the structure and function of the adipose tissue. This promotes chronic and systemic, low-grade inflammation with severe consequences for the cardiovascular system. Importantly, return to a leaner mass and increasing exercise reverses the effect. Thus, understanding how tissue-specific inflammation is induced and regulated by MAMPs and DAMPs offers insight into how human disease reflects behavioral choices.

The integrity of any host organism depends on its ability to recognize foreign invading substances and other life forms and provide an appropriate response to prevent invasion by the foreign material. When microorganisms inhabit a multicellular host, competition for resources at the cellular level occurs. In this chapter, we explore the mechanisms by which mammals (principally humans) express and use innate resistance factors to defend themselves against invasion by foreign substances.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Explain basic eukaryotic cell biology (sections 5.1–5.7)
- ✔ Diagram the flow of information in eukaryotes from DNA to protein and regulation of this flow (sections 15.2–15.5)
- ✔ Explain microbe-human interactions (sections 32.2–32.3)

33.1 Immunity Arises from Innate Resistance and Adaptive Defenses

After reading this section, you should be able to:

- Identify the major components of the mammalian host immune system
- Integrate the major immune components and their functions to explain in general terms how the immune system protects the host

To establish an infection, an invading microorganism must first overcome many surface barriers, such as skin, degradative enzymes, and mucus, that have either direct antimicrobial activity or inhibit attachment of the microorganism to the host. Because neither the surface of the skin nor the mucus-lined body cavities are ideal environments for the vast majority of microorganisms, most **pathogens,** or disease-causing microorganisms, must breach these barriers and reach underlying tissues to cause disease. However, any microorganism that penetrates these barriers encounters two levels of host defenses: other innate resistance mechanisms and an adaptive immune response.

Animals (including humans) are continuously exposed to microorganisms that can cause disease. Fortunately animals are equipped with an immune system that usually protects against adverse consequences of this exposure. The **immune system** is composed of widely distributed proteins, cells, tissues, and organs that recognize foreign substances, including microorganisms. Together they act to neutralize or destroy them, maintaining host integrity.

Immunity

The term **immunity** (Latin *immunis,* free of burden) refers to the general ability of a host to resist infection or disease. **Immunology** is the science focused on immune responses and how these responses are used to resist infection. It includes the distinction between "self" and "nonself" and all the biological, chemical, physiological, metabolic, and physical aspects of the immune response.

There are two fundamentally different yet complementary components of the mammalian immune response. The first component is common to all vertebrate animals, which have evolved unique features that inherently protect against invasion by foreign substances. Some of these features are physical and act as barriers. Others are chemical in nature and directly kill or inhibit invaders. Still other features result when specialized cells recognize generic yet highly conserved chemical motifs (e.g., those expressed on bacteria, fungi, and viruses) and initiate processes to engulf and degrade the foreign substance. These features are collectively called the **innate resistance mechanisms.** The second component of the mammalian immune response is much more sophisticated, being directed by highly specialized cells that can respond to specific invaders through receptor-mediated capture events, be programmed to "remember" their encounters with foreign substances, and amplify individual responses, recruiting other components of the host immune system to eliminate or reduce the threat posed by the invader. This component is the **adaptive immune response.** It is the focus of chapter 34.

The innate resistance mechanisms, also known as **nonspecific resistance** and **innate, nonspecific,** or **natural immunity,** are the first line of defense against any foreign material, including microorganisms, encountered by the host. It includes general mechanisms such as skin, mucus, and constitutively produced antimicrobial chemicals such as lysozyme. Innate resistance mechanisms defend against foreign invaders equally and to the same maximal extent each time a foreign invader is encountered.

In contrast, the adaptive immune response, also known as **acquired** or **specific immunity,** defends against a particular foreign agent. The effectiveness of adaptive immune responses increases on repeated exposure to foreign agents such as viruses, bacteria, or toxins; that is to say, adaptive responses have "memory." The adaptive immune response relies on interactions between antigens and antibodies. **Antigens** are substances recognized as foreign. They provoke immune responses and are also called immunogens (immunity generators). **Antibodies** are host proteins produced by certain immune system cells (B cells). Antibodies bind specific antigens and either inactivate them or contribute to their elimination. The binding of antibodies to antigens forms a complex called an antigen-antibody complex. These complexes initiate other immune responses that help eliminate the antigen. These are described in more detail in chapter 34.

The distinction between innate and adaptive systems is somewhat artificial. Although innate systems predominate immediately upon initial exposure to foreign substances, multiple bridges occur between the two immune system components (**figure 33.1**). Importantly, a variety of **white blood cells** (leukocytes) function in both innate and adaptive immunity. Some of these are important because they link the innate arm of the immune system to the adaptive. Thus, leukocytes form the basis for immune responses to invading microbes and foreign substances. Many of these cells reside in specialized tissues and organs. Some tissues and organs provide supportive functions in nurturing the cells so that they can mature and respond correctly.

The bridges that interconnect the innate and adaptive immune responses are numerous and present challenges for anyone studying immunology. However, the amazing complexity of the mammalian immune system and its capacity to prevent infection from the billions of microorganisms encountered every day drive numerous "how" questions, whose answers we explore in this chapter. We begin our discussion with an introduction to the physical and chemical barriers that microbes face when encountering a host. We then present the various cells, tissues, and organs of innate defenses, discussing the mechanism by which they detect and respond to foreign invaders. In this discussion, reference is made to processes and chemicals that are described in detail either later in this chapter or in chapter 34 (adaptive defenses). To help you navigate this information, cross-references to the detailed discussion are provided.

Retrieve, Infer, Apply

1. Define each of the following: immune system, immunity, immunology, antigen, antibody.
2. Compare and contrast the adaptive and innate immune responses.

33.2 Innate Resistance Starts with Barriers

After reading this section, you should be able to:

- Identify the barriers that help prevent microbial invasion of the host
- Explain how physical and mechanical barriers function to prevent microbial invasion of the host
- Relate host anatomy and secretions to the success of innate resistance strategies

Innate and nonspecific	Structure	Effect	Time
Barriers Microbial (commensal organisms) Physical (epithelium, mucus membrane) Chemical (AMPs, APRs, cytokines)[1]		Compete for resources Block entry Neutralize invasion	0–1 hr 0–1 hr 0–6 hr
Cells Dendritic, Macrophage, Granulocytic, NK		Phagocytosis, apoptosis	6–12 hr
Processes Opsonization, Inflammation, Cell Communication		Recruit, combine, integrate responses	6–72 hr

Adaptive and specific		Effect	Time
Cells T cells, B cells, Dendritic Macrophage		Education, activation, Tissue repair/remodel	2–21 days 21+ days
Chemical Antibody, cytokine		Effector response	21–60 days
Memory T cell, B cell		Future response	20+ years

Figure 33.1 Some Major Components of the Mammalian Immune System. Double-headed arrow indicates potential bridging events that unite innate and acquired forms of immunity. Note the relational timing as innate and acquired aspects of immunity progress.

With few exceptions, a microbial pathogen attempting to invade a human host immediately confronts a vast array of innate defense mechanisms (**figure 33.2**). Although the effectiveness of an individual mechanism may not be great, collectively they are formidable. As we learned in chapter 32, many direct factors (nutrition, physiology, fever, age, genetics) and equally as many indirect factors (personal hygiene, socioeconomic status, living conditions) influence all host-microbe relationships. In addition to these direct and indirect factors, a vertebrate host has some specific physical and mechanical barriers. These barriers, along with the host's flushing mechanisms (coughing, urinating, etc.), are the first line of defense against chemical, microbiological, and physical assaults. Protection of body surfaces and the mucus-membrane interfaces between the host and its environment is essential in preventing microbial access to the host.

Skin

Skin is stratified, cornified (converted into keratin) epithelium (**figure 33.3*a***). It is therefore an effective barrier that prevents unregulated loss of water and solutes and blocks microbial invasion and most other chemical and physical assaults. It is also home to a

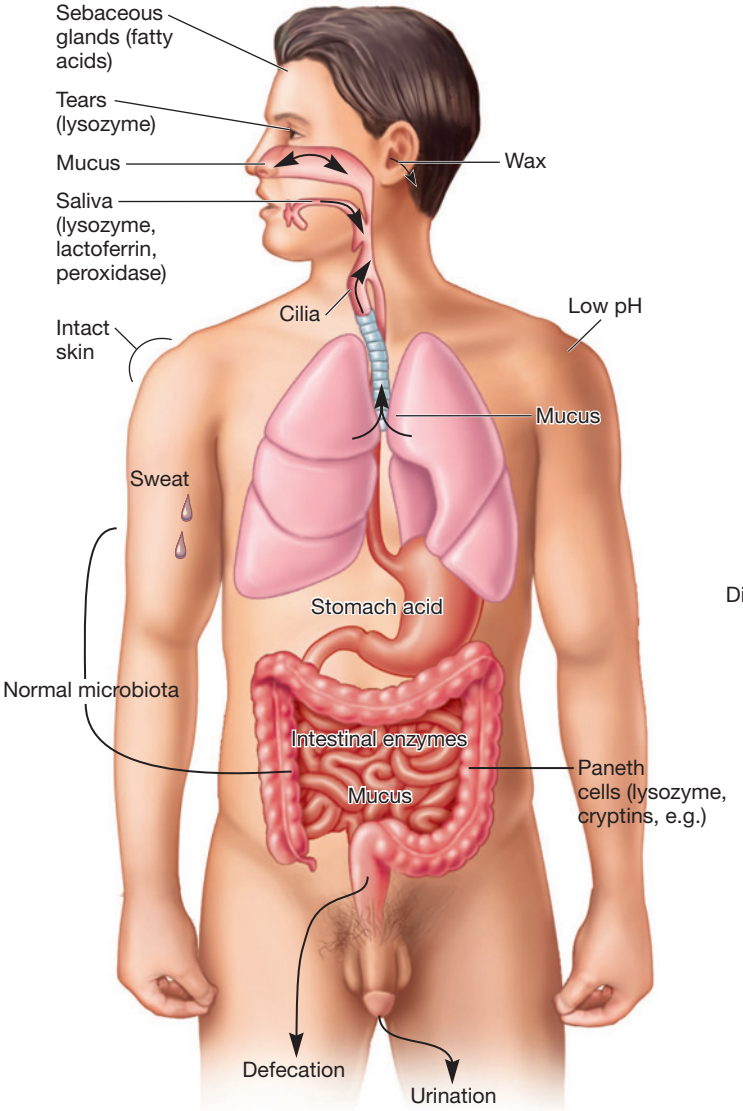

Figure 33.2 Host Defenses. Some nonspecific host defense mechanisms that help prevent entry of microorganisms into the host's tissues.

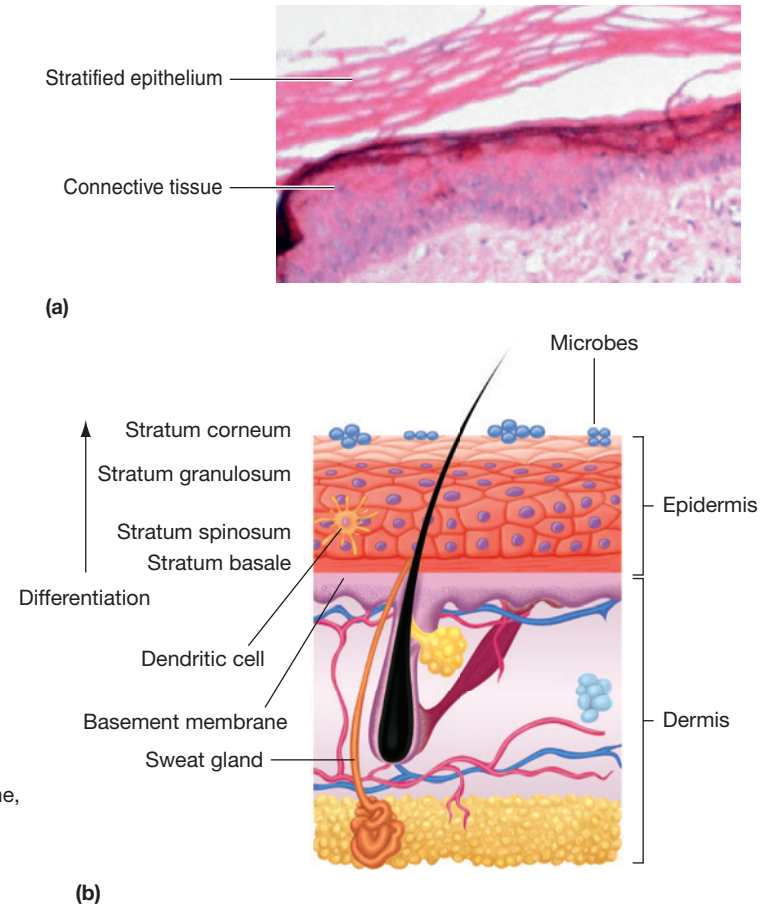

Figure 33.3 Human skin. Skin is composed of protein and cellular tiers. (a) Photomicrograph of human skin. Note the stratified cell layers, epidermis composed of kera-tinocytes, and dermis composed of fibroblasts and connective tissue. The outer layers slough away, taking attached microorganisms with them. (b) This schematic identifies the interlocking tiers that create the antimicrobial barrier of skin.

myriad of microorganisms that reside on the outside of a human. Skin cells undergo a 4-week differentiation process ending in the cells becoming enucleated, cross-linked shells of proteins (the cornification process) tiled together by extruded lipids (figure 33.3*b*).

Intact skin contributes greatly to innate host resistance because it is a very effective mechanical barrier, and its associated microbiota defend against invaders. Its outer layer consists of thick, closely packed cells called **keratinocytes,** which produce keratins. Keratins are insoluble proteins that are the main components of hair, nails, and the outer skin cells. These outer skin cells shed continuously. Select areas of the skin are bathed in sebum, a lubricating oil produced by the sebaceous glands. The skin surface is topographically, ecologically, and physiologically diverse; there are numerous microenvironments, each with distinct moisture, pH, temperature, and sebum content. These niches influence microbial populations to become resident (figure 32.3). Additionally, the skin surface is cool, acidic (pH 5–6), desiccated, and periodically bathed in sweat. Skin cells subsist on sebum, lipids, and stratum corneum peptides. The resident microbiota co-evolved to survive these conditions.

Mucous Membranes

The mucous membranes are skin modifications at sites that interface internal structures. Together, they comprise about 4,300 square feet of surface area in the average adult human. Specialized cells at these sites produce mucus (a glycoprotein-rich watery fluid), which bathes the membrane surface, making it slippery for protection from air, food, feces, and so on. The eye (conjunctiva) and the respiratory, digestive, and urogenital systems withstand microbial invasion because the intact stratified epithelium and mucus form a protective covering that resists penetration and traps microorganisms. Many mucosal surfaces are bathed in specific antimicrobial compounds secreted by specialized cells called Paneth cells also found in the mucosa. For example, cervical mucus, prostatic fluid, and tears are toxic to many bacteria. The conjunctiva that lines the interior surface of each eyelid and the exposed surface of the eyeball is a good example of how a mucous membrane

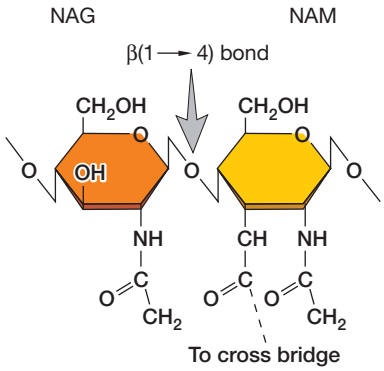

Figure 33.4 Action of Lysozyme on Peptidoglycan. This enzyme degrades the cell wall peptidoglycan by hydrolyzing the β(1⟶4) bonds that connect alternating *N*-acetylglucosamine (NAG) with *N*-acetylmuramic acid (NAM) residues.

functions to provide chemical as well as physical protection from microorganisms. It is kept moist by the continuous flushing action of tears from the lacrimal glands. Tears contain large amounts of lysozyme, lactoferrin, and other antimicrobial chemicals.

Lysozyme (muramidase) is an enzyme that lyses bacteria by hydrolyzing the bond connecting *N*-acetylmuramic acid and *N*-acetylglucosamine of the bacterial cell wall peptidoglycan—especially in Gram-positive bacteria (**figure 33.4**). Tears and other mucous secretions also contain significant amounts of the iron-binding protein lactoferrin. **Lactoferrin** is released by activated phagocytic cells called macrophages and polymorphonuclear leukocytes (PMNs). It sequesters iron from the blood plasma, reducing the amount of iron available to invading microbial pathogens thereby limiting their ability to multiply. Finally, mucous membranes produce lactoperoxidase, an enzyme that catalyzes the production of superoxide radicals, a reactive oxygen species that is toxic to many microorganisms. ◀◀ *Peptidoglycan structure (section 3.4); Oxygen concentration (section 7.4)*

Respiratory System

The average person inhales at least eight microorganisms a minute, or 10,000 each day. Once inhaled, a microorganism must first survive and penetrate the air-filtration system of the upper and lower respiratory tracts. Because the airflow in these tracts is very turbulent, microorganisms are deposited on the moist, sticky mucosal surfaces. Microbes larger than 10 μm usually are trapped by hairs and cilia lining the nasal cavity. The cilia in the nasal cavity beat toward the pharynx, so that mucus with its trapped microorganisms is moved toward the mouth to be expelled (**figure 33.5**). Humidification of the air within the nasal cavity causes many microorganisms to swell, and this aids phagocytosis. Microbes smaller than 10 μm (i.e., most bacterial cells) often pass through the nasal cavity and are trapped by the **mucociliary blanket** that coats the mucosal surfaces of lower portions of the respiratory system. The trapped microbes are transported by ciliary action—the mucociliary escalator—that moves them away from the lungs toward the mouth (figure 33.5). Coughing and sneezing reflexes clear the respiratory system of

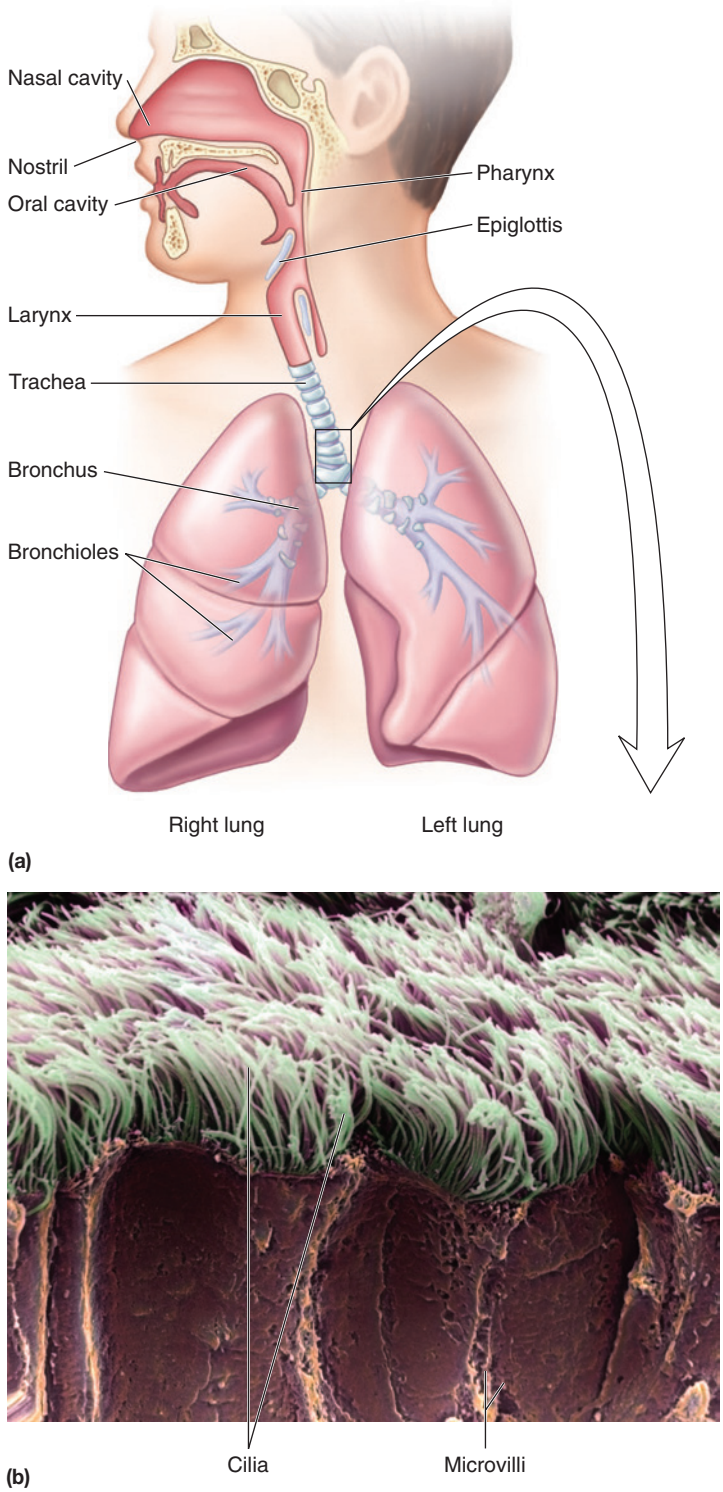

Figure 33.5 Respiratory Tract. (a) A schematic of the respiratory tract showing its components. (b) The respiratory tract is lined with a mucous membrane of ciliated epithelial cells. SEM of cilia; these specialized structures sweep particles toward the mouth to be expectorated or swallowed (X5,000).

microorganisms by expelling air forcefully from the lungs through the mouth and nose, respectively. Salivation also washes microorganisms from the mouth and nasopharyngeal areas into the stomach. Microorganisms that succeed in reaching the alveoli

of the lungs encounter a population of specialized cells called **alveolar macrophages.** These cells ingest and kill most inhaled microorganisms by phagocytosis (p. 729).

Gastrointestinal Tract

Most microorganisms that reach the stomach are killed by the acidic gastric juice (pH 2–3), which is a mixture of hydrochloric acid, proteolytic enzymes, and mucus. However, some microorganisms and their products (e.g., protozoan cysts, *Helicobacter pylori, Clostridium* spp., and staphylococcal toxins) can survive the stomach acidity. Furthermore, organisms embedded in food particles may be protected from gastric juice and reach the small intestine. There, these microorganisms may be damaged by various pancreatic enzymes, bile, enzymes in intestinal secretions, and the specialized immune cells within the gut-associated lymphoid tissue (GALT) (p. 726). **Peristalsis** (Greek *peri,* around, and *stalsis,* contraction) and the normal shedding of columnar epithelial cells act in concert to purge intestinal microorganisms. As discussed in chapter 32, the microbiota that inhabit the GI tract are tightly linked to human health and homeostasis. These microbes (see table 32.2) stimulate the maturation of the immune system, regulate immunity, and prevent the growth of potential pathogens. Within the small intestine, our microbiota stimulate the release of antimicrobial peptides (AMP) from host Paneth cells (figure 33.2).

Genitourinary Tract

The normal sterility of the kidney, ureters, and urinary bladder is maintained by a complex set of factors. In addition to removing microbes by flushing action, urine kills some bacteria due to its low pH and the presence of urea and other metabolic end products (e.g., uric acid, fatty acids, mucin, enzymes). Portions of the kidney are so hypertonic that few organisms can survive there. In males, the anatomical length of the urethra (20 cm) provides a distance barrier that excludes microorganisms from the urinary bladder. Conversely, the short urethra (5 cm) in females is more readily traversed by microorganisms; this explains why urinary tract infections are 14 times more common in females than in males.

The innate defense of the vagina consists primarily of the normal microbiota combined with the protective measures provided by the mucous membrane. The vaginal microbiota of nonpregnant women is more complex in that there appears to be no single group of organisms that define a normal flora. Rather, 16S rRNA gene-sequence-based surveys suggest that more than 20 vaginal phylotypes of *Lactobacillus* are consistent—forming a number of community state types (CSTs) with *Lactobacillus vaginalis, L. crispatus, L. iners, L. gasseri*, and *L. jensenii* dominating. These lactic-acid-forming bacteria generate an acidic vaginal environment that is inhospitable to pathogenic organisms. Cervical mucus also has antibacterial activity from added defensins, lysozyme, lactoferrin, and other natural AMPs. Adding to the innate defense of the vagina are the phagocytes that migrate through the mucous membrane.

Retrieve, Infer, Apply

1. Why is the skin such a good first line of defense against pathogenic microorganisms?
2. How do intact mucous membranes resist microbial invasion of the host?
3. Describe one specific antimicrobial defense mechanism that operates within the respiratory, gastrointestinal, and genitourinary systems of mammals. Explain how it protects against pathogenic microorganisms.

33.3 Innate Resistance Relies on Chemical Mediators

After reading this section, you should be able to:

- Discuss host mediators that have antimicrobial actions
- Describe in general terms the activation of the host complement system and its three outcomes
- List the three categories of cytokines and discuss their major functions
- Correlate host protection from microbial invasion with specific mediators

Mammalian hosts have a chemical arsenal with which to combat the continuous onslaught of microorganisms. Some of these chemicals (gastric juices, salivary glycoproteins, lysozyme, oleic acid on the skin, urea) have already been discussed with respect to the specific body sites they protect. In addition, blood, lymph, and other body fluids contain a potpourri of antimicrobial chemicals such as defensins and other polypeptides. Importantly, the normal microbiota also assist in host resistance by contributing their own chemicals to fend off competitors. How chemical defenses protect the host is the next topic.

Antimicrobial Peptides and Proteins

Peptides and low molecular weight proteins that exhibit broad-spectrum antimicrobial activity are generally considered to be the most ancient primary defense mechanism of animals. Many are positively charged, and therefore electrostatically attracted to microbial cell surfaces. Antimicrobial peptides are amphipathic; that is, they have hydrophobic and hydrophilic components so they are soluble in both aqueous and lipid-rich environments. Antimicrobial peptides kill target cells through diverse mechanisms after interacting with their membranes. The proteins lysozyme and lactoferrin have broad antimicrobial action, and we discuss these in the context of phagocytosis later in the chapter (p. 727). Another notable antimicrobial protein is granzyme, used by immune system cells called natural killer (NK) cells to lyse their targets (p. 723). Two major types of antimicrobial peptides are cationic peptides and bacteriocins.

Cationic Peptides

Humans produce three generic classes of cationic peptides whose biological activity is related to their ability to damage bacterial plasma membranes. Most form pores or transient gaps, thereby altering membrane permeability, often leading to lysis.

The first group of cationic peptides includes linear, α-helical peptides that lack cysteine amino acid residues. An important

example is **cathelicidin** LL37, so named because it is 37 amino acids long, beginning with a pair of leucines. Cathelicidin LL37 is translated from a single transcript but cleaved into a number of antimicrobial fragments that are produced by a variety of cells (e.g., neutrophils, respiratory and urogenital epithelial cells, and alveolar macrophages). ▶▶| *Protein structure (appendix I)*

A second group, called **defensins,** are similarly produced from precursor proteins that mature through protease activity. These peptides are rich in arginine and cysteine, and are thus disulfide linked. Two types of defensins have been reported in humans—α and β. α defensins tend to be slightly smaller than β defensins and are found in the granules of certain immune system cells (neutrophils and intestinal Paneth cells), where they are called cryptidins, and in intestinal and respiratory epithelial cells, where they assist in bacterial degradation. β defensins are larger because they have an additional helical region. They are typically found in epithelial cells and are known to stimulate release of immune system chemical mediators by cells called mast cells (p. 720).

A third group contains larger peptides that exhibit regular structural repeats. **Histatin,** one such peptide isolated from human saliva, has antifungal activity. It translocates to the fungal cytoplasm, where it targets mitochondria.

Other natural antimicrobial products (about 20) are derived from chemokines found in platelets. Still others are fragments from (1) histone proteins, (2) lactoferrin, and (3) immune mediators that recruit cells to specific locations. A number of antibacterial peptides are produced by bacteria as well. The most notable of these are the bacteriocins, as discussed next.

Bacteriocins

Many of the normal bacterial microbiota release toxic proteins called bacteriocins that kill other strains of the same species as well as other closely related bacteria. Bacteriocins are peptides that may give their producers, which are naturally immune to their bacteriocins, an adaptive advantage against other bacteria. Ironically, they sometimes increase bacterial virulence by damaging host immune cells. An example of a bacteriocin-producing bacterium is *Escherichia coli*. It synthesizes bacteriocins called **colicins,** which are encoded on several different Col plasmids (*see table 3.3*). Some colicins bind to specific receptors on the cell envelope of sensitive target bacteria and cause cell lysis; others attack specific intracellular sites such as ribosomes or disrupt energy production. Other examples include the lantibiotics produced by genera such as *Streptococcus, Bacillus, Lactococcus*, and *Staphylococcus*. |◀◀ *Normal microbiota of the human body adapt to the human condition (section 32.3)*

Complement Is a Cascading Enzyme System

Complement refers to a collection of over 30 heat-labile proteins found in human blood plasma. The proteins act in a cascading fashion to lyse cell membranes, augment phagocytosis, and promote inflammation. These activities were said to "complement" the other antibacterial activities of the host; hence the name complement. The **complement system** is complex and has a somewhat confusing nomenclature. We therefore examine each process before considering the complete mechanisms of action. Complement activation can be initiated by three different signals, but all three lead to a common final pathway that (1) defends against bacterial infections by facilitating and enhancing phagocytosis (opsonization), chemotaxis, activation of leukocytes, and lysis of bacteria; (2) bridges innate and specific immune functions by enhancing antibody responses and immunologic memory; and (3) disposes of wastes such as dead host cells and immune complexes, the products of inflammatory injury.

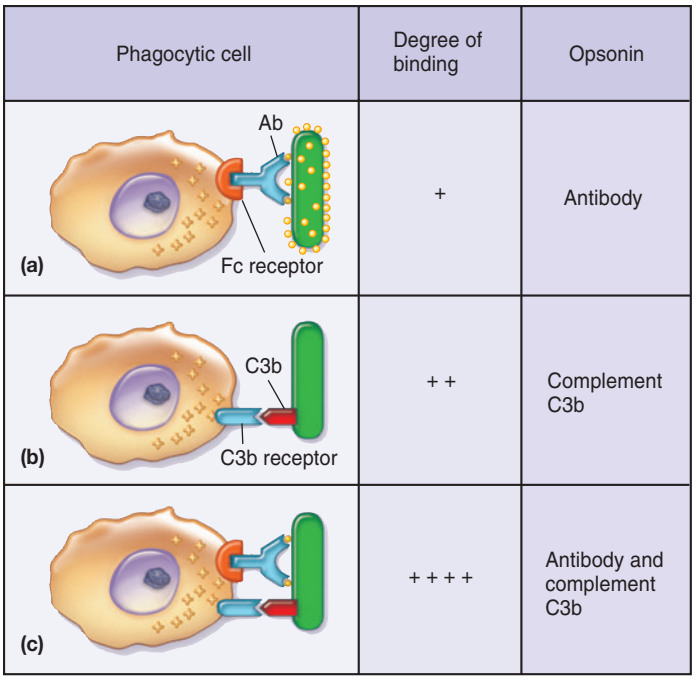

Figure 33.6 Opsonization. (a) The intrinsic ability of a phagocyte to bind to a microorganism is enhanced if the microorganism elicits the formation of antibodies (Ab) that act as a bridge to attach the microorganism to the Fc antibody receptor on the phagocytic cell. (b) If the activated complement (C3b) is bound to the microbe, the degree of binding is further increased by the C3b receptor. (c) If both antibody and C3b opsonize, binding is maximal.

As mentioned earlier, one of the major outcomes of complement activation is enhancement of phagocytosis, a process called opsinization. **Opsonization** (Greek *opson,* to prepare victims for) coats microorganisms or inanimate particles with serum components, thereby preparing them for recognition and ingestion by phagocytic cells. Pathogen clearance by phagocytes increases dramatically when they are coated with opsonins (**figure 33.6**). As the first opsonins to be produced, complement proteins are important in connecting the microoroganism with the phagocyte, which bears specific complement receptors.

Complement Activation

Complement proteins are produced in an inactive form; they become active following enzymatic cleavage. There are three pathways of complement activation: the alternative, lectin, and classical pathways (**figure 33.7**). Although each pathway employs

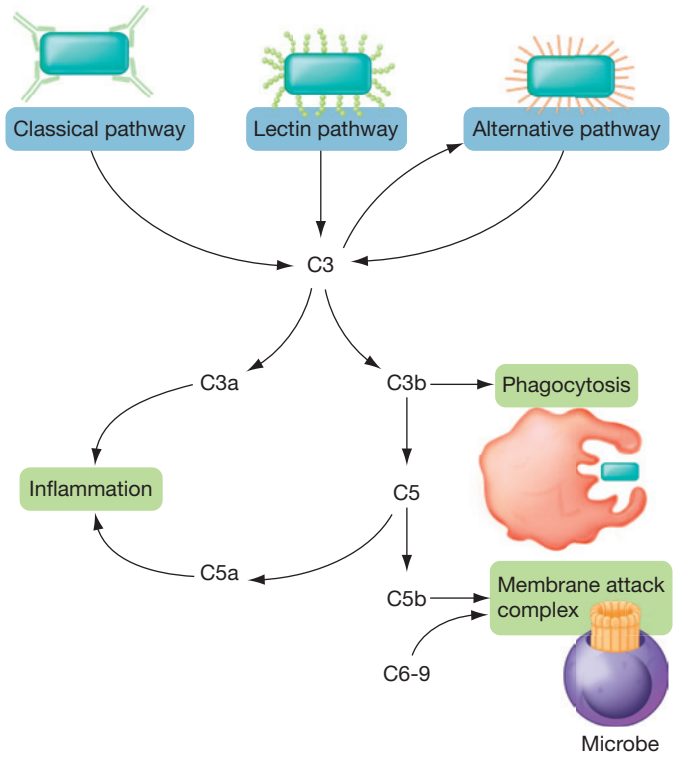

Figure 33.7 Complement Activation and Action. Complement activation involves a series of enzymatic reactions that culminate in the formation of C3 convertase, which cleaves complement component C3 into C3b and C3a. The three pathways converge at C3 convertase production. C3a is a peptide mediator of local inflammation. C3b binds covalently to bacterial cells and opsonizes the bacteria, enhancing phagocytosis. C5a and C5b are generated by the cleavage of C5 by a C5 convertase. C5a is also a powerful peptide mediator of inflammation. C5b promotes assembly of a membrane attack complex from the terminal C6–9 complement components.

similar mechanisms, specific proteins are unique to the first part of each pathway (**table 33.1**). Each complement pathway is activated in a cascade fashion: the activation of one component results in the activation of the next. Thus complement proteins are poised for immediate activity when the host is challenged by an infectious agent.

The **alternative complement pathway** (figure 33.7) is thought to have evolved first. It is initiated in response to bacterial and some fungal molecules with repetitive structures, such as the lipopolysaccharide (LPS) from Gram-negative bacteria. LPS activates complement (C) protein 3 (C3), causing it to cleave into fragments C3a and C3b. C3b becomes stable when it binds to the microbial cell surface, and once bound, C3b acts as an opsonin and enhances phagocytosis (figure 33.6). C3b is also involved in increasing the amount of active complement. This is achieved when C3b interacts with two blood proteins (Factor B and Factor D) to form a complex called C3bBb. This complex functions as the C3 convertase of the alternative complement pathway. It proceeds to cleave more C3 to C3a and C3b, thereby increasing the rate at which C3 is converted and the amount of C3b coating the microbial structure.

The **lectin complement pathway** (also called the mannose-binding lectin pathway) also begins with the activation of C3 convertase. However, in this case, a lectin—a protein that binds to specific carbohydrates—initiates the proteolytic cascade. A lectin of major importance is **mannose-binding protein** (**MBP**). This protein is produced when phagocytic cells called macrophages ingest viruses, bacteria, or other foreign material. MBP, as its name implies, binds mannose, a sugar that is a major component of bacterial cell walls, some virus envelopes, and antigen-antibody complexes. MBP enhances phagocytosis and is therefore an opsonin. MBP forms a complex with another blood protein known as *m*annose-binding lectin-*a*ssociated *s*erine *p*rotease (MASP). When the MBP component of the complex binds to mannose on pathogens, MASP is activated. MASP cleaves the C4 and C2 complement proteins, also circulating in the blood, to produce a C3 convertase. The C3 convertase is the same as that used in the classical complement pathway, discussed next.

Activation of the **classical complement pathway** typically depends on the presence of antibody specific to the pathogen. However, it can also be activated nonspecifically by a few microbial products (e.g., lipid A, staphylococcal protein A). Antibody secretion is part of the adaptive immune response (and is discussed in chapter 34); antibodies are glycoproteins that bind to specific antigens. When the appropriate antibody binds its cognate antigen, the antibody-antigen complex binds C1, a complement component composed of three proteins (q, r, s). This forms a trimolecular complex (C1qrs + antibody + antigen), which has esterase activity. The activated C1s subcomponent attacks and cleaves two other complement proteins (C4 and C2). This leads to binding of a portion of each molecule (C4b and C2a) to the antigen-antibody-C1 complex and the release of C4a and C2b fragments. With the binding of C4b to C2a, an enzyme with trypsinlike proteolytic activity is generated. The natural substrate for this enzyme is C3; thus C4b2a (that is, the antigen-antibody-C1-C4b-C2a complex) is a C3 convertase. Just as we saw with the alternative and lectin pathways, the C3 convertase cleaves C3 into a bound subcomponent C3b and a C3a soluble component. Thus each of the complement pathways is activated by different substrates, all of which signal the presence of a foreign invader.

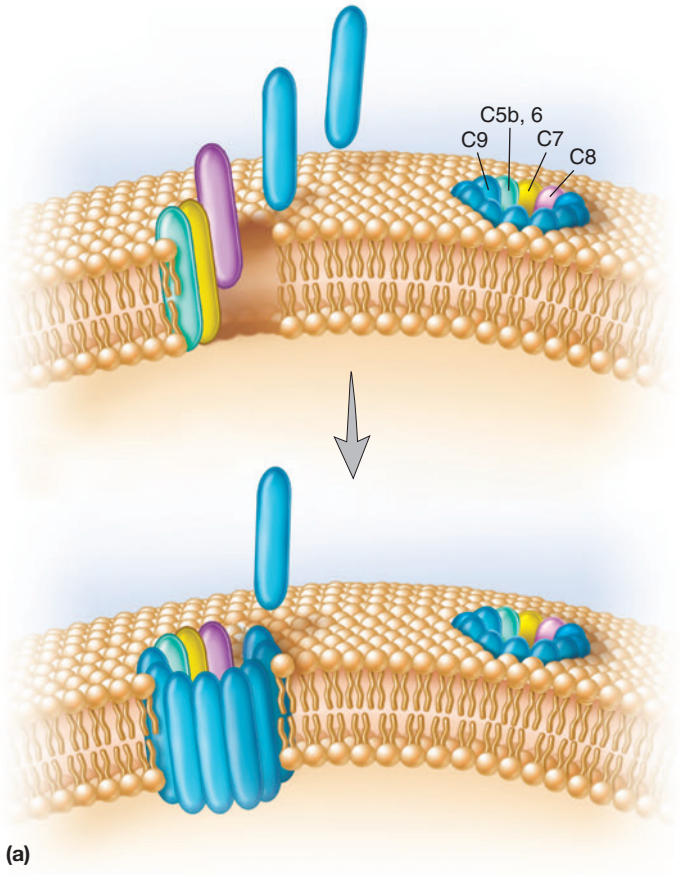
Complement Action

In each complement activation pathway (alternative, lectin, and classical), the cleavage of C3 into C3a and C3b sets into motion other cascading enzymatic events leading to formation of the membrane attack complex, additional opsonins, and the release of chemical mediators that influence inflammation (figure 33.7).

In each complement pathway, stabilization of C3b and subsequent creation of a C5 convertase lead to the production of C5b. The two proteins, C6 and C7, rapidly bind to C5b, forming a C5b67 complex that is stabilized by binding to a membrane. C8 and C9 then bind, forming the **membrane attack complex** (**MAC**), which creates a pore in the plasma membrane or outer membrane of the target cell (**figure 33.8**). The MAC is very effective against Gram-negative bacteria, less so against Gram-positive

Table 33.1 Key Complement Proteins and Their Functions

	Protein	Function
COMPLEMENT ACTIVATION (initiation through three unique pathways)		
Alternative Pathway	C3	C3 is activated by repeating patterns within microbial structures and then is spontaneously cleaved into C3a and C3b; C3b binds to nearby membrane.
	Factor D	Factor D is activated by C3b to become an active enzyme, which activates Factor B.
	Factor B	Factor B adsorbs to C3b, forming a C3 convertase (protease).
	C3bBb	C3bBb (the active C3 convertase) cleaves additional C3 into its a and b fragments; C3b binds to the nearby membrane.
	Properidin	Properidin stabilizes the C3 convertase.
Lectin Pathway	Mannose-binding protein (MBP)	MBP binds to mannose on microorganisms, then recruits and binds plasma esterase to become mannose-associated serine protease (MASP).
	MASP	MASP (the active C3 convertase) cleaves C3 into C3a and C3b; C3b binds to the nearby membrane.
Classical Pathway	Antibody (Ab) formed by adaptive immune system upon exposure to antigen (Ag)	Ab binds to Ag on microorganism, causing three-dimensional shift in Ab structure, which reveals cryptic amino acids near carboxy-terminus (Fc region); the newly revealed amino acids attract plasma C1 protein.
	C1 (trimer of polypeptides q, r, and s)	C1q binds to Fc region of Ab-Ag complex; C1r,s binds plasma calcium.
	Ag-Ab-C1q,r,s-(Ca^{2+}) complex	Ag-Ab-C1-(Ca^{2+}) complex is an activated enzyme (called the C2/C4 esterase) that cleaves plasma C2 and C4 into their a and b fragments, respectively.
	C2a	C2a binds the Ag-Ab-C1-(Ca^{2+}) complex.
	C4b	C4b binds the Ag-Ab-C1-(Ca^{2+})-C2a complex, forming a C3 convertase (protease).
	Ag-Ab-C1-C2a-C4b	Ag-Ab-C1-C2a-C4b (the active C3 convertase) cleaves plasma C3 into its a and b fragments; C3b binds to the nearby membrane.
COMPLEMENT ACTION (common effector pathway; convergence point for alternative, lectin, and classical activation pathways)	C3b-membrane complex (stabilized C3b)	C3b stabilized in a membrane becomes an active C5 convertase (protease), cleaving plasma C5 into its respective a and b fragments.
	C5b	C5b binds plasma C6 and C7, forming a new, membrane-binding complex.
	C5b-C6-C7-membrane complex	Membrane-bound C5b-C6-C7 recruits plasma C8 and C9, which insert into the membrane adjacent to C5b-C6-C7.
	C5b-C6-C7-C8-C9 complex	C5b-C6-C7-C8-C9 complex forms transmembrane pore known as the membrane attack complex (MAC); MAC formation leads to cell lysis.



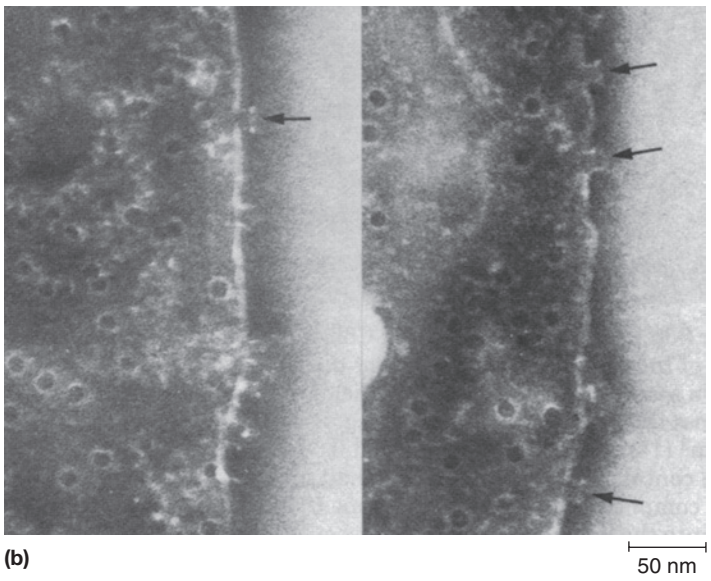


Figure 33.8 The Membrane Attack Complex. The membrane attack complex (MAC) is a tubular structure that forms a transmembrane pore in the target cell's membrane. (a) This representation shows the subunit architecture of the membrane attack complex. The transmembrane channel is formed by a C5b678 complex and 10 to 16 polymerized molecules of C9. (b) MAC pores appear as craters or donuts by electron microscopy.

MICRO INQUIRY *What strategies could a Gram-negative bacterium use to protect itself against lysis by complement?*

bacteria and fungi. If the target cell is eukaryotic, Na^+ and H_2O enter through the pore and the cell lyses.

Importantly, the generation of complement fragments C3a and C5a leads to several pro-inflammatory effects. For example, binding of C3a and C5a to receptors on specific host cells induces the release other biological mediators. These amplify the inflammatory signals by dilating vessels, increasing permeability, stimulating nerves, and recruiting phagocytic cells. C5a also induces chemotactic migration of neutrophils to the site of complement activation, where they are among the first cells to phagocytose invading microorganisms. Other phagocytes in the area synthesize even more complement components to interact with the invading microbes. All of these defensive events promote the ingestion and ultimate destruction of the microbe by dendritic cells, neutrophils, and macrophages.

Our overview of the alternative and lectin complement pathways (figure 33.7) provides a basis for consideration of the function of complement as an integrated system during an animal's defensive effort. Bacteria arriving at a local tissue site for the first time interact with components of the alternative and lectin pathways, resulting in the generation of biologically active fragments, opsonization of the bacteria, and initiation of the lytic sequence. Importantly, and if the bacteria persist or if they invade the host a second time, antibody responses also will activate the classical complement pathway.

Cytokines Are Chemical Messages Between Cells

Communication between members of any complex network requires a clear signal and a common language. So it is no surprise to learn that both innate resistance and adaptive defenses use a highly specialized communication system. The "language" used by the mammalian immune system is based on small, soluble proteins whose binding to their receptors initiates a signal transduction pathway that ultimately regulates specific transcription and translation events. The resulting cellular behaviors therefore depend on which commands (signals) are received, how many receptors become occupied, and interference from either external or internal sources.

Cytokine (Greek *cyto*, cell, and *kinesis*, movement) is a generic term for any soluble, low molecular weight protein or

glycoprotein released by one cell population that acts as an intercellular (between cells) mediator or signaling molecule. Cytokines are produced by a large number of different cells. Once released, cytokines impact a broad range of cells, resulting in a variety of cellular responses. Cytokine synthesis is inducible, resulting from nonspecific stimuli such as a viral, bacterial, or parasitic infection; cancer; inflammation; or the activation of specific immune cells. Some cytokines also induce the production of other cytokines.

The naming of cytokines has been one of those stories with the left hand not knowing what the right has done. Historically, as new proteins were discovered, a scientist would name it based on its function. As protein biochemistry became more exact, scientists would group proteins based on structure. This resulted in an unfortunate list of proteins with different names yet the same function and proteins with same structures but different names. Thus, cytokines released from mononuclear phagocytes are called **monokines,** cytokines released from T lymphocytes are called **lymphokines,** cytokines that stimulate chemotaxis and chemokinesis (i.e., they direct cell movement) are called **chemokines,** cytokines produced by one leukocyte acting on another leukocyte are called **interleukins,** regulatory cytokines produced by certain eukaryotic cells in response to a viral infection are called **interferons,** and cytokines that stimulate the growth and differentiation of immature leukocytes in the bone marrow are called **colony-stimulating factors** (CSFs).

As noted earlier, cytokines produce biological actions only when bound to specific receptors on the surface of target cells. Most cells have hundreds to a few thousand cytokine receptors, but a maximal cellular response results even when only a small number of these are occupied by cytokine molecules. This is because the affinity of cytokine receptors for their specific cytokines is very high; consequently cytokines are effective at very low concentrations. Because cytokines tend to affect specific aspects of the overall immune response, three categories based on cytokine function have been recently proposed. The three groups are (1) cytokines that regulate innate resistance mechanisms, (2) cytokines that regulate adaptive immunity, and (3) cytokines that stimulate hematopoiesis (**table 33.2**).

The binding of a cytokine to its receptor activates specific intracellular signaling pathways, which results in the transcription of genes encoding proteins essential for a specific cellular function. For example, cytokine binding may result in the cell's production of other cytokines, cell-to-cell adhesion receptors, proteases, lipid-synthesizing enzymes, and nitric oxide synthase (the production of nitric oxide has potent antimicrobial activity). In addition, cytokines can activate cell proliferation or cell differentiation. They also can inhibit cell division and cause **apoptosis** (programmed cell death).

Acute-Phase Proteins

In addition to chemical mediators from leukocytes, a number of biologically active molecules from other somatic cells can cause dramatic physiological changes in the host. Generalized trauma and localized tissue injury result in the release of tissue factors, chemokines, and neurotransmitters. Importantly, macrophages responding to sites of injury are critical in recruiting assistance by releasing pro-inflammatory cytokines that stimulate the liver to rapidly produce **acute-phase proteins.** These mediators assist in the prevention of blood loss and ready the host for microbial invasion. They include C-reactive protein (CRP), mannose-binding protein (MBP; p. 720), and surfactant proteins A (SP-A) and D (SP-D), all of which bind bacterial surfaces and act as opsonins. In addition, CRP interacts with C1q to activate the classical complement pathway and MBP binds to bacteria and fungi to activate complement. SP-A, SP-D, and C1q are also known as collectins—proteins composed of a collagen-like motif connected by α-helices to globular binding sites. These proteins (along with others) police host tissues by binding to ("collecting") foreign materials, thus assisting in the removal of microorganisms and their products.

1. Describe the role of cytokines in innate immunity.
2. How might cytokines work to bridge the innate and adaptive immune responses?
3. How might acute-phase reactants assist in pathogen removal? How might collectins do this?

33.4 Cells, Tissues, and Organs Work Collectively to Form an Immune System

After reading this section, you should be able to:

- Recognize the different types of leukocytes involved with innate resistance
- Outline the leukocyte response to microbial invasion
- Integrate leukocyte distribution within the host with host resistance
- Differentiate between primary and secondary lymphoid organs and tissues in terms of structure and function
- Predict connections between innate host resistance and specific immune responses

Blood cell development occurs in the **bone marrow** of mammals during the process of **hematopoiesis.** The immune system is a network of molecules, cells, tissues, and organs, each with a specialized role in defending the host against extracellular microorganisms, cancer cells, and intracellular parasites. While we discuss innate defenses and adaptive immunity separately for clarity, the recognition and removal of damaged host cells and foreign substances is an interconnected and highly regulated symphony of events, connecting both arms of the immune system. We previously discussed some of the protein mediators that signal specific responses. We now examine the cells and tissues that respond to the mediators and to the damaged cells and invading substances. As you read, make note of how host cells function in innate resistance and the linkages to the adaptive defenses.

Table 33.2 Examples of Cytokines Grouped by Function

	Cytokine[1]	Source	Role
Innate Resistance	IL-1	Macrophages, endothelial and epithelial cells	Upregulates inflammatory response, including fever
	IL-6	Macrophages, T cells, endothelial cells, and adipocytes	Upregulates acute phase response, including fever; stimulates neutrophil maturation
	IL-8	Neutrophils, macrophages, dendritic cells, endothelial and epithelial cells	Activates neutrophils, induces chemotaxis, enhances inflammation, stimulates B cells
	IL-15	Monocytes, macrophages	Activates T cells, upregulates NK cell production
	IL-22	Activated dendritic cells, $CD4^+$ helper T_{17} and T_{22} cells, innate lymphoid cells	Links and coordinates innate and adaptive responses, promotes hepatocyte and epithelial cell survival
	IL-23	Macrophages and dendritic cells	Upregulates inflammatory response via IL-17 from T cells; stimulates IL-1, IL-6, TNF, and chemokine production; enhances T-cell activation and memory response
	IL-27	Macrophages and dendritic cells	Enhances antigen recognition by T and B cells
	Type I IFN (IFN α/β)	Somatic cells, especially plasmacytoid dendritic cells, macrophages, and NK cells	Induces broad-spectrum antiviral and anti-tumor activity, enhances other cytolytic function, promotes inflammation
	TNF-α	Monocytes/Macrophages	Upregulates inflammatory response, including fever; stimulates acute-phase protein synthesis; induces tumor regression; mediates septic shock
Adaptive Immunity	IL-2	T cells (autocrine process)	Stimulates growth and differentiation of T cells and NK cells; promotes antibody secretion from B cells
	IL-4	T-cell subset (and putatively basophils)	Induces differentiation of a T-cell subset; stimulates production of antibody, especially antibody associated with allergies; inhibits IL-12 production
	IL-5	T-cell subset and mast cells	Stimulates growth of B cells; enhances antibody secretion; activates eosinophils
	IL-12	Macrophages, dendritic cells, and a T-cell subset	Stimulates growth and function of T-cell subsets, stimulates killing functions of NK cells and cytotoxic lymphocytes
	IL-17	T-cell subset	Monocyte and neutrophil chemokine; induces pro-inflammatory cytokines IL-6, TNF-α, IL-1, chemokines, and prostaglandins from various cells
	Type II IFN (IFN γ)	T-cell subset and NK cells	Enhances phagocytic functions of macrophages; upregulates cytolytic function of NK cells; stimulates antiviral functions
	LT α/β (TNF)	Numerous somatic cells	Upregulates T- and B-cell development; activates neutrophils; lyses tumor cells; upregulates CSF-2 and CSF-3
Hematopoiesis	IL-3	Basophils and activated T cells	Stimulates pluripotent hematopoietic stem cells to become myeloid progenitor cells; stimulates myeloid cell proliferation
	IL-7	Bone marrow and thymic stromal cells, dendritic and epithelial cells, and hepatocytes	Stimulates pluripotent hematopoietic stem cells to become lymphoid progenitor cells; stimulates lymphoid cell proliferation
	CSF-1	Osteoblasts	Induces hematopoietic stem cells to proliferate and differentiate into monocytes/macrophages; promotes monocyte survival
	CSF-2	Macrophages, T cells, endothelial and mast cells, and fibroblasts	Induces hematopoietic stem cells to proliferate and differentiate into granulocytes and monocytes
	CSF-3	Numerous cells and tissues	Induces hematopoietic stem cells to proliferate and differentiate into neutrophils; stimulates neutrophil function and survival

1 Cytokine: IL, interleukin; IFN, interferon; TNF, tumor necrosis factor; CSF, colony-stimulating factor

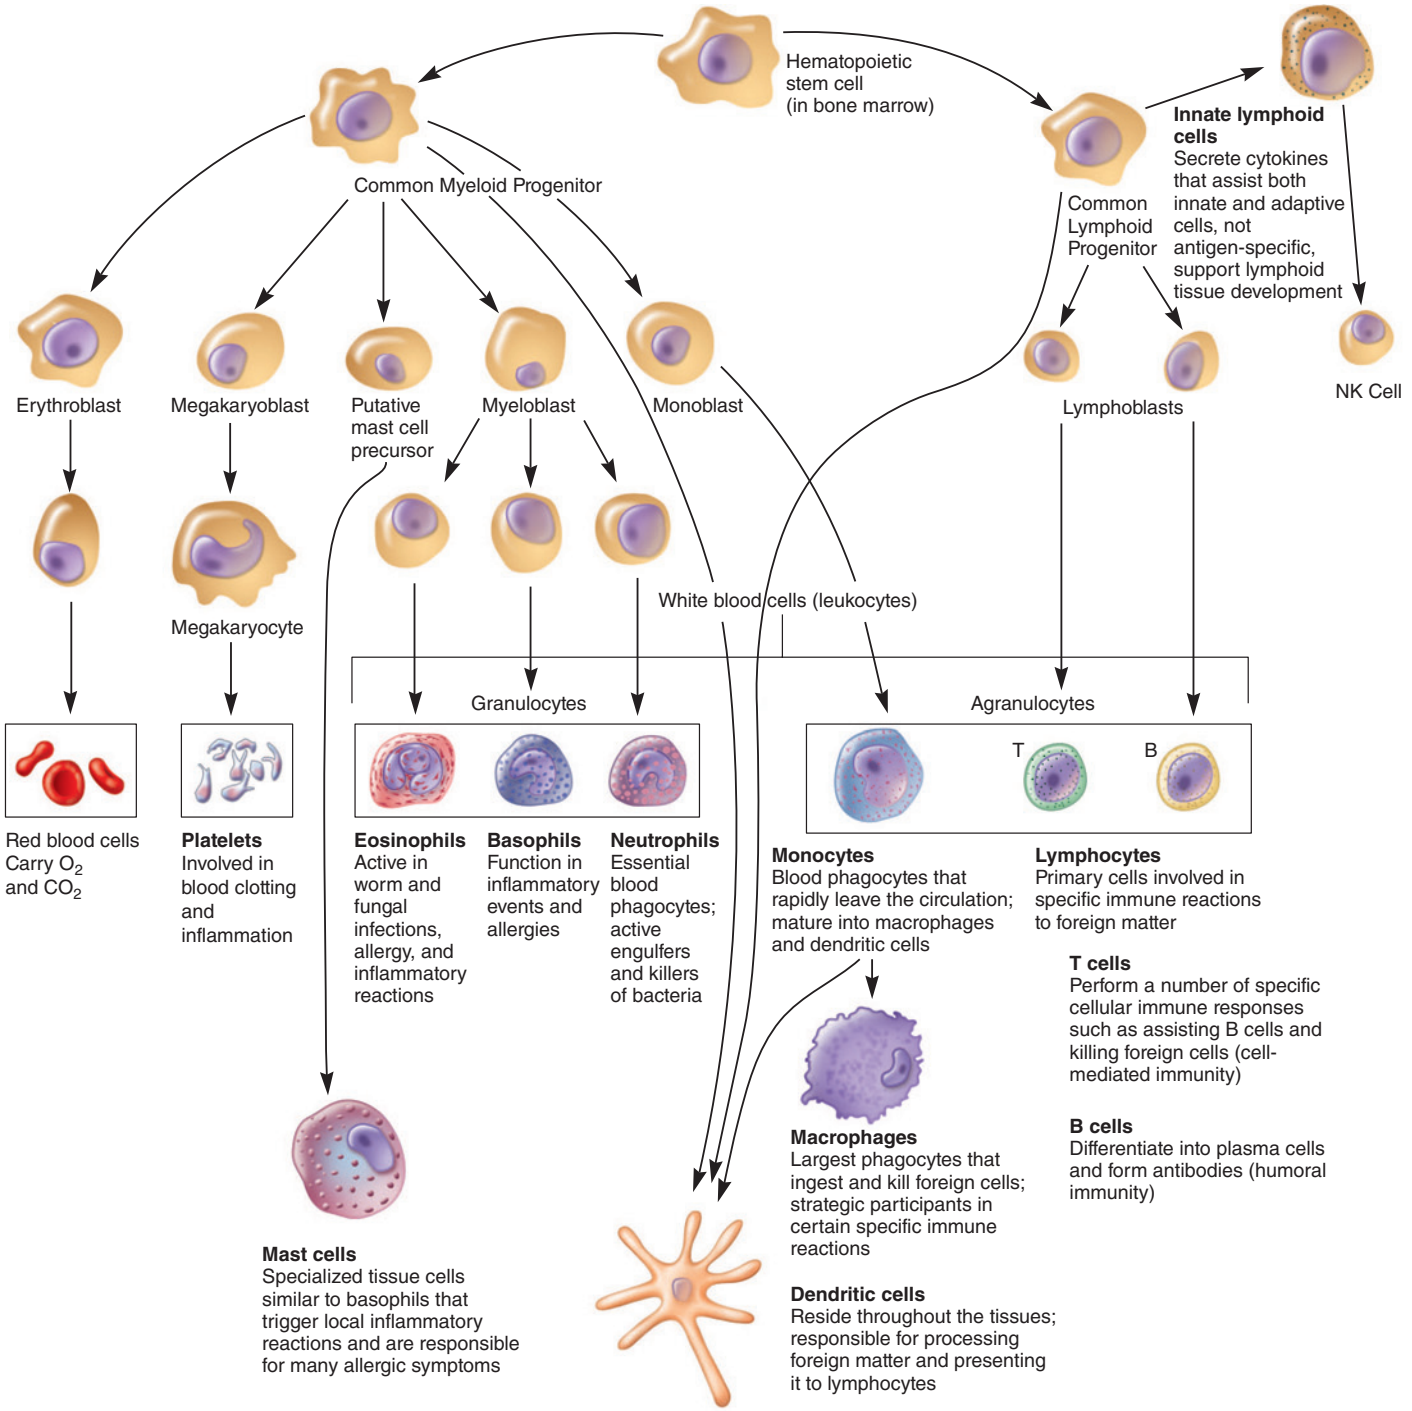

Figure 33.9 The Different Types of Human Blood Cells. Pluripotent stem cells in the bone marrow divide to form two blood cell lineages: (1) the common myeloid progenitor cell gives rise to the erythroblast that produces erythrocytes (red blood cells), megakaryocytes that produce platelets, an unknown precursor that gives rise to mast cells, the granulocytes (eosinophils, basophils, and neutrophils), monocytes that give rise to dendritic cells (DCs) and macrophages, and a separate lineage of DCs; and (2) the lymphoid progenitor cell gives rise to innate lymphoid cells that can differentiate into natural killer (NK) cells, a separate lineage of DCs, B cells, and T (regulatory, helper, and cytotoxic) cells. Note that DCs can arise directly from myeloid and lymphoid progenitor cells and from nonproliferating monocytes.

Cells of the Immune System

The cells responsible for both innate defenses and adaptive immunity are the **leukocytes** (Greek *leukos,* white, and *kytos,* cell). All leukocytes originate from pluripotent stem cells in the fetal liver and in the bone marrow (**figure 33.9**). Pluripotent stem cells have not yet committed to differentiating into one specific cell type. Some differentiate into hematopoietic precursor cells that are destined to become blood cells. When stimulated to undergo further development, some leukocytes become residents within tissues, where they respond to local trauma. These cells may sound the alarm that signals invasion by foreign organisms.

Table 33.3 Normal Adult Blood Count

Cell Type	Cells/mm^3	Percent WBC
Red blood cells	5,000,000	
Platelets	250,000	
White blood cells	7,400	100
Neutrophils	4,320	60
Lymphocytes	2,160	30
Monocytes	430	6
Eosinophils	215	3
Basophils	70	1

Other leukocytes circulate in body fluids and are recruited to the sites of infection after the alarm has been raised.

The average adult has approximately 7,400 leukocytes per cubic millimeter of blood (**table 33.3**). This average value shifts substantially during an immune response. For example, in most infections the white blood cell count may increase as leukocytes migrate from the bone marrow to the blood, then to the site of invasion. This transient increase in blood-borne leukocytes (leukophilia, also called leukocytosis) may result until the infection subsides.

For leukocytes to respond to pathogens, they must detect their presence. Many leukocytes detect repeating molecular patterns found in microbial macromolecules. These unique microbial signatures (originally called pathogen-associated molecular patterns, or PAMPs) are now also referred to as ***m*icrobe-*a*ssociated *m*olecular *p*atterns** (**MAMPs**). MAMPs are specific regions within common microbial macromolecules, such as lipopolysaccharide [LPS], peptidoglycan, fungal cell wall components, viral nucleic acids, and other microbial structures. MAMPs do not define a specific microorganism, but they do inform the host of a microbial presence, sounding the alarm of potential infection.

The receptors that bind to MAMPs are both soluble and membrane bound; they are called ***p*attern *r*ecognition molecules** (**PRMs**) or pattern recognition receptors (PRRs). Soluble PRMs include the acute-phase proteins, mannose-binding protein (of the lectin complement pathway), and C-reactive protein (CRP). The membrane-bound PRMs are found on phagocytic cells, enabling them to (1) distinguish between potentially harmful microbes and other host molecules, and importantly, (2) respond by ingesting and degrading the source of the MAMP. Additional details of MAMP recognition and removal are discussed in section 33.5. The different types of leukocytes, including those that detect MAMPs, are now briefly examined (in the order presented in figure 33.9).

Mast Cells

Mast cells are bone marrow–derived cells that differentiate in connective tissue. Mast cells (figure 33.9) have an indented nucleus and a cytoplasm filled with specialized organelles called granules. Mast cells are nonphagocytic, but when stimulated, they rapidly release the contents of their granules into the extracellular environment, a process called degranulation. Mast cell granules contain histamine, prostaglandins, serotonin, heparin, dopamine, platelet-activating factor, and leukotrienes. Because these compounds influence the tone and diameter of blood vessels, they are termed **vasoactive mediators.** Additionally, mast cells possess high-affinity receptors for the type of antibody associated with allergic responses. When they become coated with this type of antibody, binding of antigen to the antibody triggers the release of preformed vasoactive mediators. As discussed in chapter 34, vasoactive mediators play a major role in certain allergic responses such as eczema, hay fever, and asthma. ▶▶| *Antibodies are proteins that bind to specific 3-D molecules (section 34.7); Hypersensitivities (section 34.10)*

Granulocytes

Granulocytes also have irregularly shaped nuclei with two to five lobes (figure 33.9). Their cytoplasm has granules that contain reactive substances that kill microorganisms and enhance inflammation. Three types of granulocytes exist: basophils, eosinophils, and neutrophils.

Basophils (Greek *basis,* base, and *philein,* to love) have irregularly shaped nuclei with two lobes (figure 33.9). The granules contain histamine and other substances similar to those in mast cells. However, basophils arise from a different cellular lineage (figure 33.9). Like mast cells, though, basophils tend to infiltrate specific tissue sites rather than circulate through the bloodstream. Basophils are also important in the development of allergies and hypersensitivities, because like mast cells, they possess high-affinity receptors for the type of antibody associated with allergic responses and release preformed vasoactive mediators.

Eosinophils (Greek *eos,* dawn, and *philein*) have a two-lobed nucleus connected by a slender thread of chromatin (figure 33.9). Eosinophil granules contain hydrolytic enzymes (e.g., nucleases and glucuronidases), in addition to peroxidases and a caustic protein called major basic protein. Unlike basophils, eosinophils circulate in low numbers and migrate from the bloodstream into tissue spaces, especially mucous membranes, when recruited by soluble chemotactic mediators. They defend against protozoan and helminth parasites, mainly by releasing enzymes, cationic peptides (p. 712), and reactive oxygen species (p. 729) into the extracellular fluid. These molecules damage the parasite's plasma membrane, killing it. Eosinophils also play a role in allergic reactions, as they have granules that contain histaminase and aryl sulphatase, downregulators of the inflammatory mediators histamine and leukotrienes, respectively. Thus their numbers in the bloodstream often increase during allergic reactions, especially type 1 hypersensitivities. ▶▶| *Type I hypersensitivity (section 34.10)*

Neutrophils (Latin *neuter,* neither, and *philein*) are highly phagocytic cells with a nucleus that has three to five lobes connected by slender threads of chromatin (figure 33.9). Because of the irregularly shaped nuclei, neutrophils are also called

polymorphonuclear neutrophils, or **PMNs.** Neutrophils have inconspicuous organelles known as primary and secondary granules. Primary granules contain peroxidase, lysozyme, defensins, and various hydrolytic enzymes, whereas the smaller secondary granules have collagenase, lactoferrin, cathelicidin LL37, and lysozyme. These enzymes and other molecules help digest foreign material after it is phagocytosed (section 33.5). Neutrophils also use oxygen-dependent and oxygen-independent pathways to generate additional antimicrobial substances to kill ingested microorganisms.

Mature neutrophils leave the bone marrow and circulate in blood so they can rapidly migrate to a site of tissue damage and infection, where they become the principal phagocytic and microbicidal responders. Neutrophils have toll-like pattern recognition molecules (PRMs), as well as receptors for antibodies and complement proteins, so that MAMPs and opsonized particles, respectively, can be more readily phagocytosed. Neutrophils have a limited life span that shortens upon activation of the phagocytic processes. Neutrophils and their antimicrobial compounds are described in more detail in the context of phagocytosis (section 33.5) and the inflammatory response (section 33.6).

Monocytes, Macrophages, and Dendritic Cells

Monocytes (Greek *monos,* single, and *cyte,* cell) are mononuclear leukocytes with an ovoid- or kidney-shaped nucleus and granules in the cytoplasm (figure 33.9). They are produced in the bone marrow and enter the blood, circulate for about 8 hours, enlarge, migrate into tissues, and mature into macrophages or dendritic cells.

Macrophages (Greek *macros,* large, and *phagein,* to eat) are classified as mononuclear phagocytic leukocytes. However, they are larger than monocytes, contain more organelles that are critical for phagocytosis, and have a plasma membrane covered with microvilli.

Macrophages are similar to dendritic cells in their ability to bridge innate resistance and adaptive immunity. They have PRMs that recognize specific MAMPs, and binding of their PRMs induces phagocytosis. Macrophages spread throughout the host and take up residence in specific tissues, where they are sometimes referred to as "fixed" or resident macrophages. They often serve as sentinel cells in tissues, sounding the chemical alarm when a microbial invader is present. This results in the recruitment of neutrophils to aid in the removal of the pathogen, and preventing its spread to other body sites. Activated macrophages also migrate to lymphoid tissues to present antigen to lymphocytes. Because macrophages are highly phagocytic, their function in innate resistance is discussed in more detail in the context of phagocytosis (section 33.5).

Dendritic cells (DCs) are not a single cell type; they are a heterogeneous group of cells that are crucial in initiating and augmenting immune responses (**figure 33.10**). They arise from various hematopoietic cell lineages; both lymphoid and myeloid DC subtypes are known that differ in location, migration patterns, and specific immunological roles. Immature dendritic cells constitute about 0.2% of peripheral blood leukocytes and can be stimulated to mature by specific cytokines. Most DCs, however, are tissue-bound, where they play an important role in bridging innate resistance and adaptive immunity. They are present in the skin and mucous membranes of the nose, lungs, and intestines, where they constantly survey their environment. DCs are highly specialized cells that are programmed to detect and phagocytose foreign substances, especially pathogens. Dendritic cells have numerous membrane-bound receptors, including pattern recognition molecules (PRMs). The end product of phagocytosis is the proteolytic degradation of the ingested particles. Once degraded, the resulting remnants of phagocytosis (antigens) are further processed and displayed on the dendritic cell surface. DCs then migrate to lymphoid tissues to "present" the antigens to lymphocytes, sharing vital information about invaders and stimulating the specific immune response. In presenting antigen, DCs are capable of eliciting specific immune responses from naïve T cells (i.e., T cells that have never encountered a specific antigen). DCs can also capture foreign materials with their cell surface receptors that recognize antibodies and complement (figure 33.6). Recall that these opsonins enhance phagocytosis (section 33.5). Importantly, not only do dendritic cells destroy invading pathogens as part of the innate resistance process, they also help trigger specific immune responses. ▶▶| *Molecules that elicit specific immunity are called antigens (section 34.2); T cells oversee and participate in immune functions (section 34.5)*; *Antibodies are proteins that bind to specific 3-D molecules (section 34.7)*

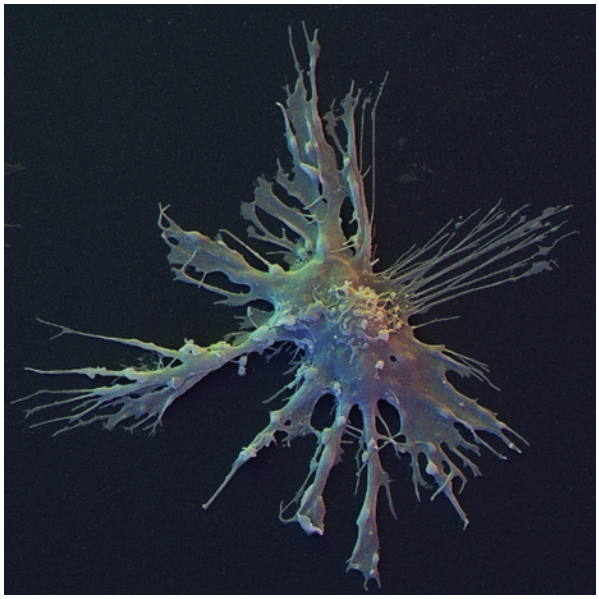

Figure 33.10 The Dendritic Cell. The dendritic cell was named for its cellular extensions, which resemble the dendrites of nerve cells. Dendritic cells reside in most tissue sites, where they survey their local environments for pathogens and altered host cells.

MICRO INQUIRY *For what does the dendritic cell use its cellular extensions?*

Retrieve, Infer, Apply

1. Describe the structure and function of each of the following blood cells: basophil, eosinophil, neutrophil, monocyte, macrophage, and dendritic cell. Which cells are phagocytic?
2. What is the significance of the respective blood cell percentages in blood?
3. How does a dendritic cell bridge the innate and adaptive arms of immunity?

Lymphocytes

Lymphocytes (Latin *lympha,* water, and *cyte,* cell) are major cells of the adaptive immune system and are divided into three populations: T cells, B cells, and innate lymphoid cells (figure 33.9). B and T lymphocytes differentiate from their respective lymphoid precursor cells in a kind of cellular stasis—not actively replicating until stimulated by foreign substances called antigens (**figure 33.11**). They are the primary responders of the adaptive arm of immunity, and are discussed in chapter 34.

Innate Lymphoid Cells

The **innate lympoid cell (ILC)** is thought to be a pivotal bridge between the innate and adaptive arms of immunity because it amplifies and relays information about infection and tissue damage. There are diverse ILCs, each with specific functions and target cells. Some recognize and kill infected cells while activating T cells to enhance inflammatory activities. Some respond to injured cells to help drive tissue repair and regulate **inflammation.** Yet others assist in homeostasis by regulating antibody production and killing tumor cells.

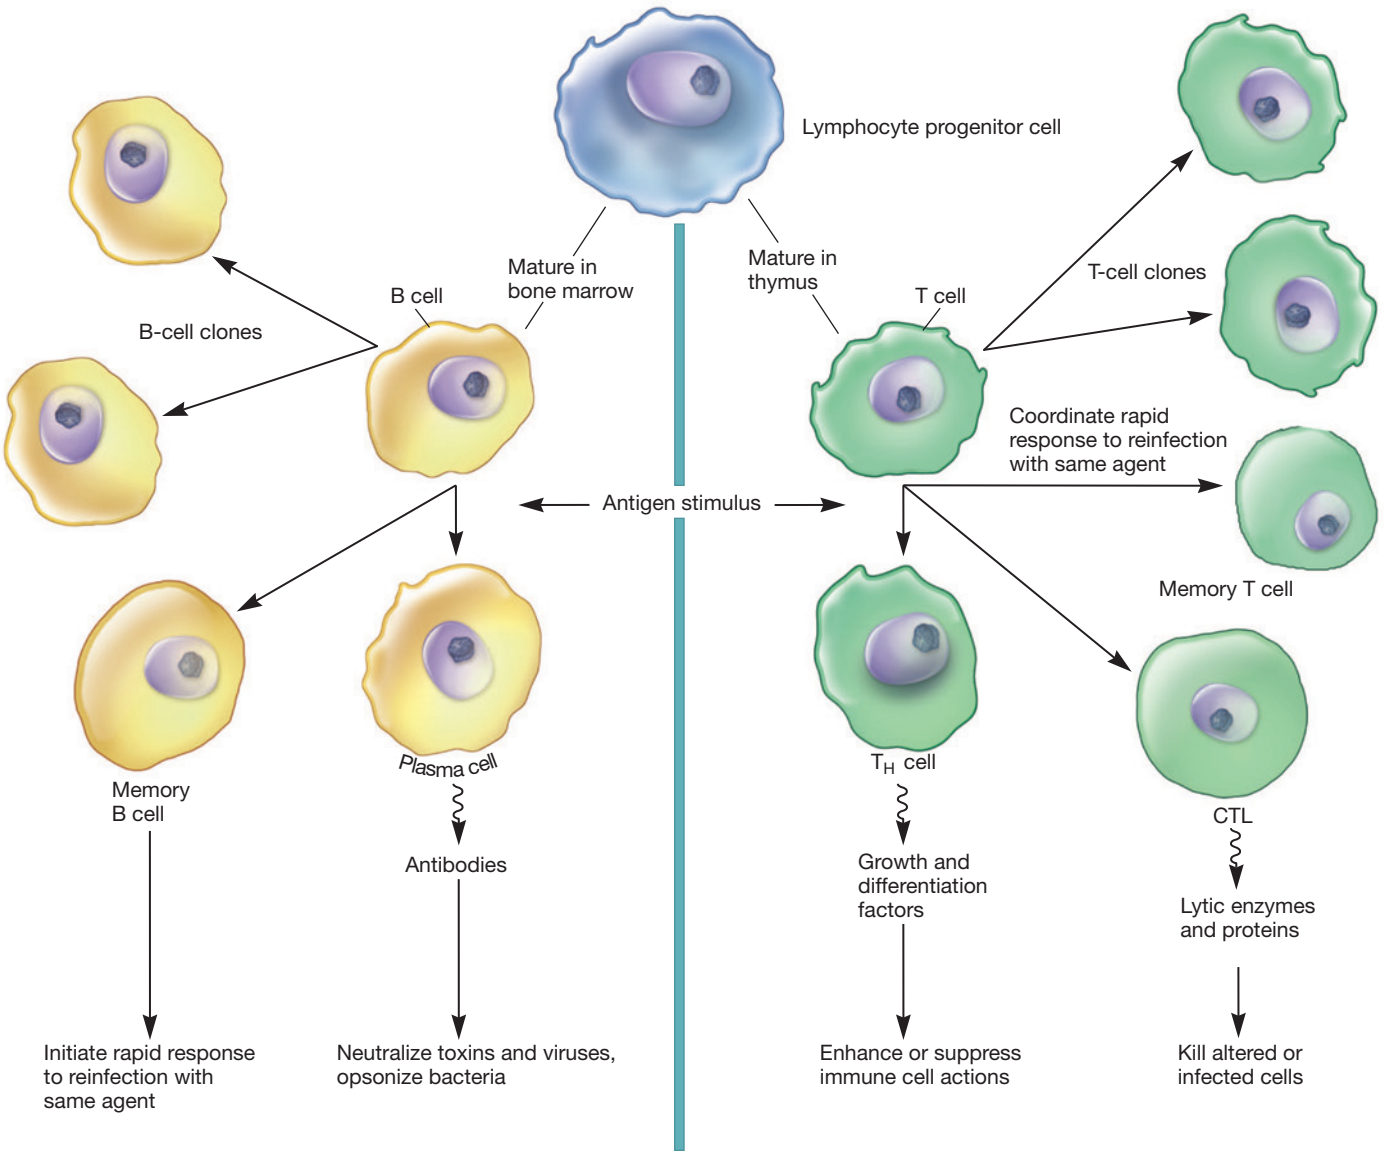

Figure 33.11 The Development and Function of B and T Lymphocytes. B cells and T cells arise from the same cell lineage but diverge into two different functional types. Immature B cells and T cells are indistinguishable by histological staining. However, they express different proteins on their surfaces that can be detected by immunohistochemistry. Additionally, the final secreted products of mature B and T cells can be used to identify the cell type.

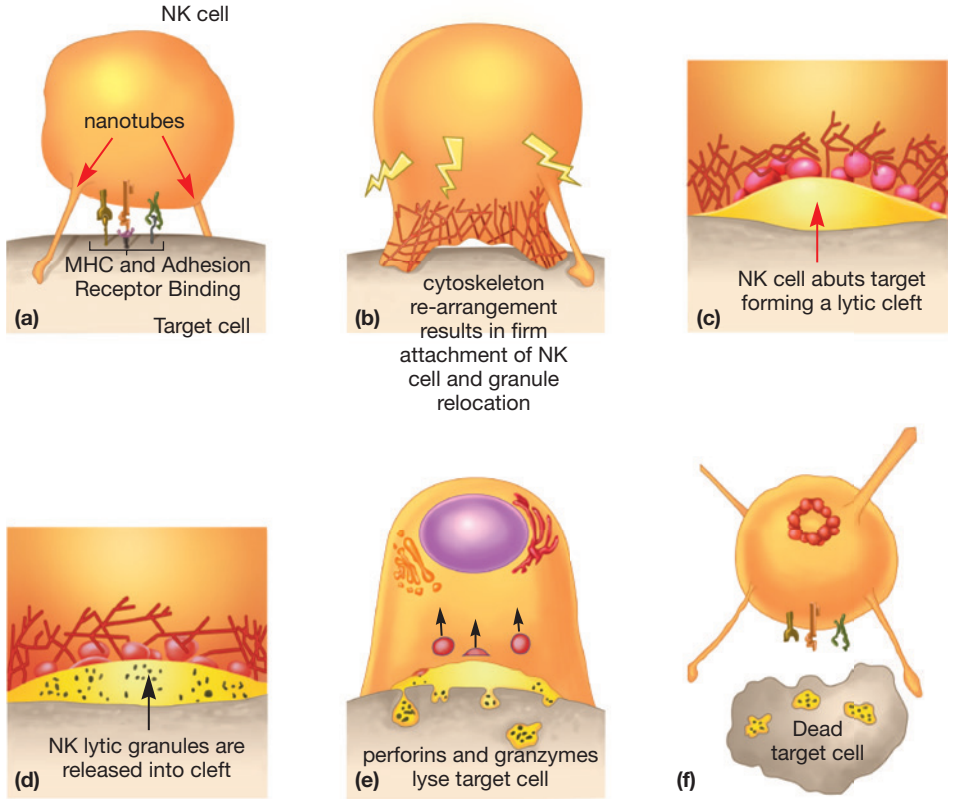

Figure 33.12 **The System Used by Natural Killer (NK) Cells to Recognize and Destroy Abnormal Cells.** (a) NK cell evaluates target cell using membrane nanotubes. (b) Microtubules organize lytic granules toward the target cell. (c) A lytic cleft forms and (d) granules exit the NK cell into the cleft. (e) Lytic perforins and granzymes lyse the target cell. (f) The NK cell releases the dead target cell and migrates toward another cell.

Cytotoxic (killer) ILCs are represented by natural killer cells. **Natural killer (NK) cells** are a small population of large, nonphagocytic granular lymphocytes. The major NK cell function is to detect and destroy stressed, malignant, or virally infected cells (**figure 33.12**). Although the exact mechanism by which NK cells recognize target cells is not known, it is clear that they survey adjacent cells by forming membrane nanotube connections, and by "kissing" targets via several surface receptors (figure 33.12*a*). These interactions provide both kill and don't kill signals to the NK cell. It is the balance of these signals that determines the fate of the target cell. If the target cell is found to be defective or infected, the NK cell kiss becomes deadly.

Once activated to kill the target cell, the NK cell mobilizes its cytoskeletal proteins to form an "immunological synapse," similar to the synapses cytotoxic lymphocytes form with their targets. When kill signals are activated, the NK cell closely adheres to the target cell and releases its cargo of deadly molecules (figure 33.12). These include the pore-forming protein perforin and enzymes called granzymes. Together, these proteins trigger the target cell to commit suicide (apoposis).

NK cells also have another killing mechanism. NK cells have receptors for antibodies, and therefore can attack cells that are opsonized by antibodies. This process is called **antibody-dependent cell-mediated cytotoxicity** (**ADCC**) (**figure 33.13**), and the

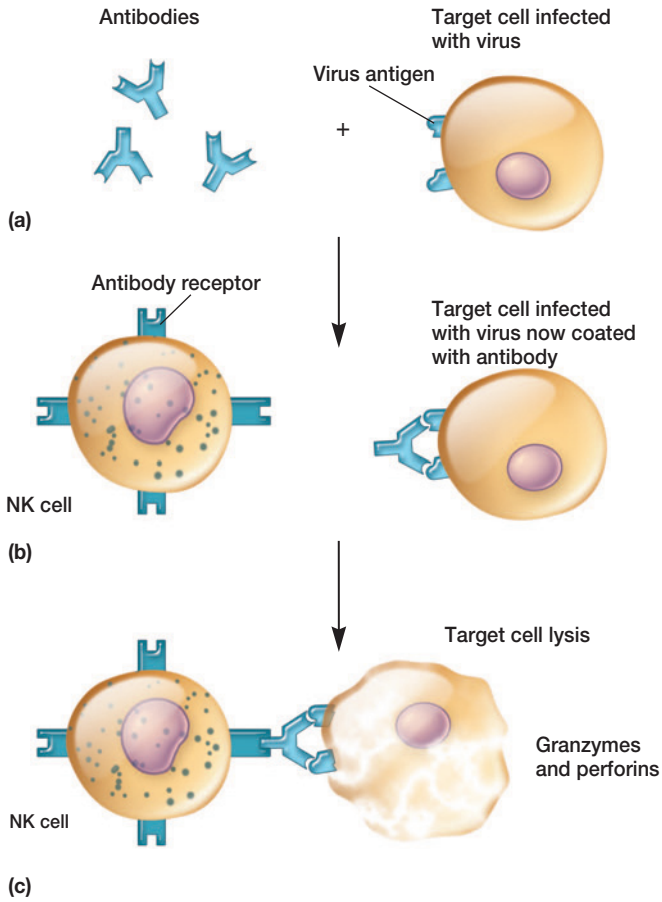

Figure 33.13 **Antibody-Dependent Cell-Mediated Cytotoxicity.** (a) In this mechanism, antibodies bind to a target cell infected with a virus. (b) NK cells have specific antibody receptors on their surface. (c) The antibody bridges the infected cell with the NK cell so that the target is close enough for enzymatic attack.

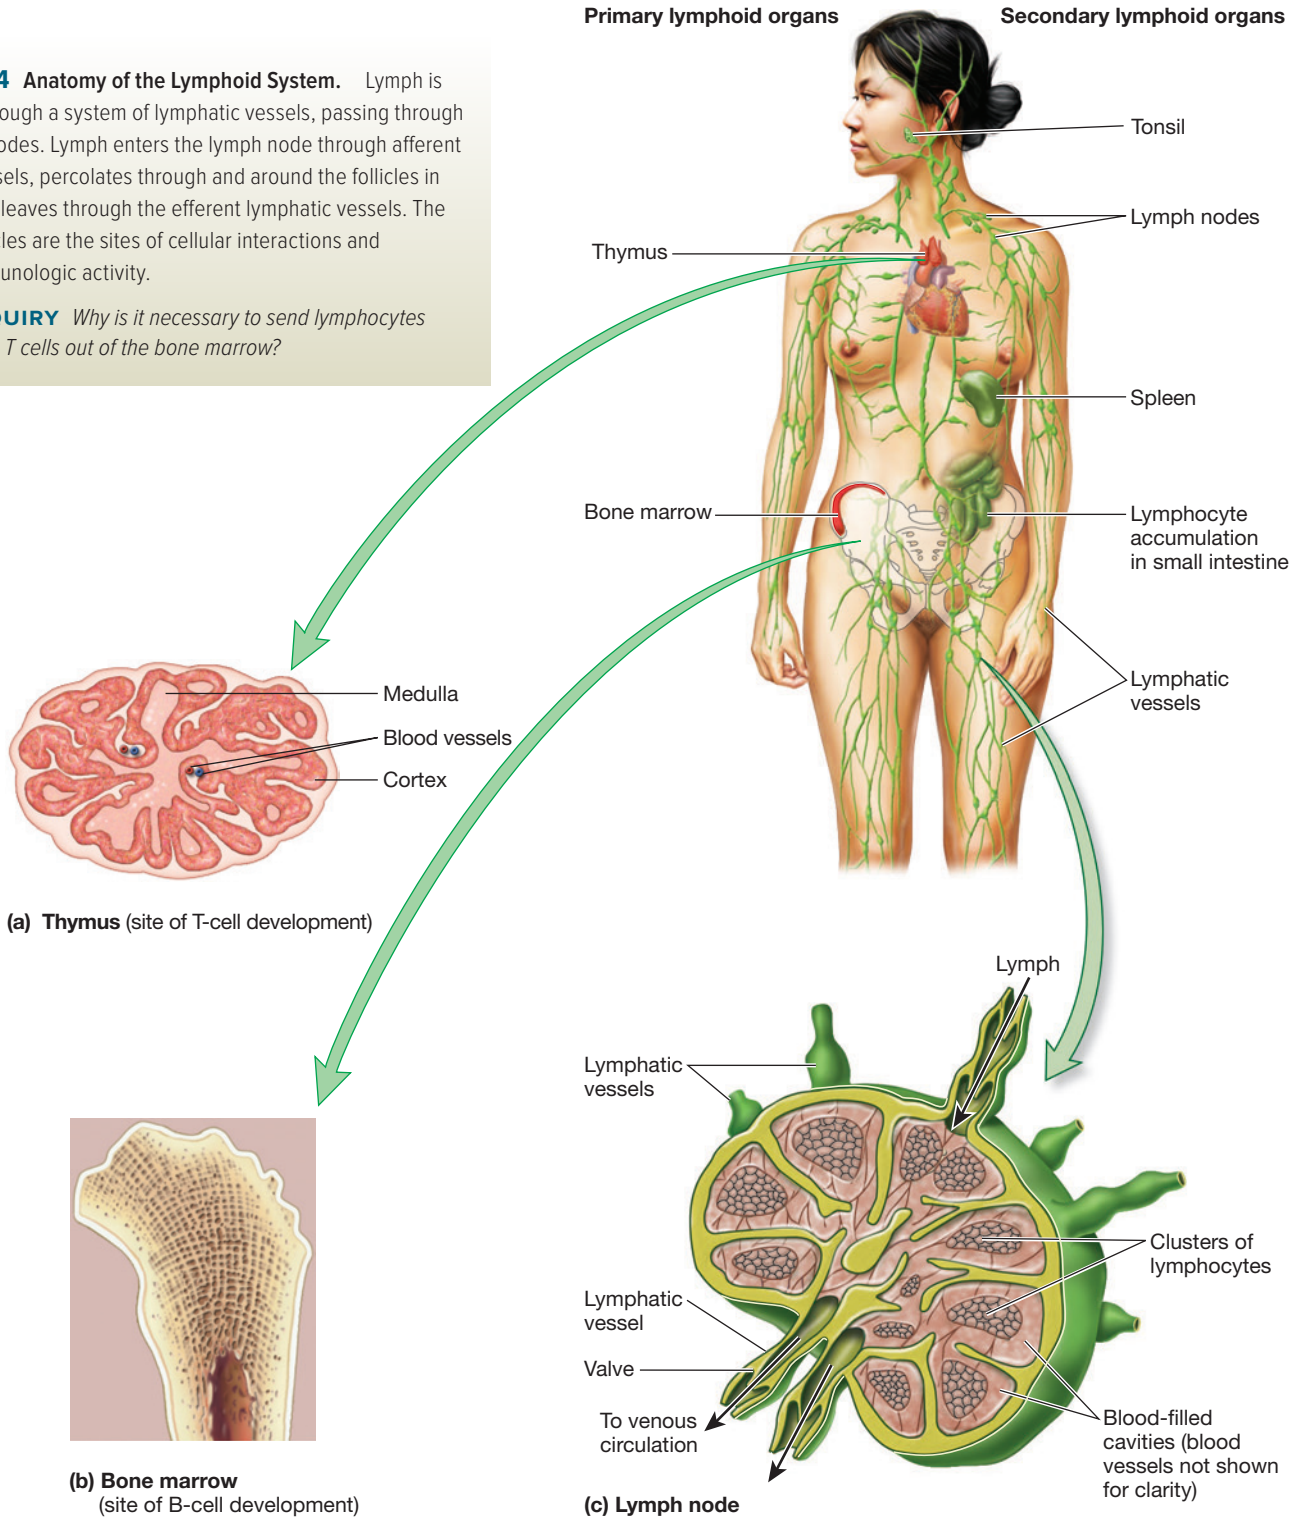
Figure 33.14 Anatomy of the Lymphoid System. Lymph is distributed through a system of lymphatic vessels, passing through many lymph nodes. Lymph enters the lymph node through afferent lymphatic vessels, percolates through and around the follicles in the node, and leaves through the efferent lymphatic vessels. The lymphoid follicles are the sites of cellular interactions and extensive immunologic activity.

MICRO INQUIRY *Why is it necessary to send lymphocytes destined to be T cells out of the bone marrow?*



bridging antibodies help facilitate the death of the target cell. Unlike T and B cells, NK cells do not exhibit memory responses to target cells, thus they are considered part of the innate immune response.

2. What is the purpose of T-cell secretion of cytokines?
3. Discuss the role of NK cells in protecting the host. What are the two mechanisms NK cells use to detect altered cells?

Organs and Tissues of the Immune System

Based on function, the organs and tissues of the immune system can be divided into primary or secondary lymphoid organs and tissues (**figure 33.14**). The primary organs and tissues are where immature lymphocytes mature and differentiate into antigen-sensitive B and T cells. The thymus is the primary lymphoid organ for T cells, and the bone marrow is the primary lymphoid tissue for B cells. The secondary organs and tissues are areas where lymphocytes may encounter and bind antigen, which triggers their proliferation and

differentiation into fully active, antigen-specific effector cells. The spleen is a secondary lymphoid organ, and lymph nodes and mucosal-associated tissues (GALT—gut-associated lymphoid tissue, and SALT—skin-associated lymphoid tissue) are secondary lymphoid tissues. These are now discussed in more detail.

Primary Lymphoid Organs and Tissues

The **thymus** is a highly organized lymphoid organ located above the heart. Precursor cells from the bone marrow migrate into the outer cortex of the thymus, where they proliferate. As they mature, about 98% die. This is due to a process known as **thymic selection** in which T cells that could recognize and respond to the host (self) are destroyed. The remaining 2% move into the medulla of the thymus (figure 33.14*a*), where they mature and subsequently enter the bloodstream. These T cells recognize and respond to the myriad of foreign nonhost substances, collectively referred to as "nonself."

In mammals, the bone marrow (figure 33.14*b*) is the site of B-cell maturation. Like thymic selection during T-cell maturation, a selection process within the bone marrow eliminates B cells that recognize self. Remaining B cells mature in the bone marrow and subsequently enter the bloodstream.

Secondary Lymphoid Organs and Tissues

The **spleen** is the most highly organized secondary lymphoid organ. It is a large organ located in the abdominal cavity that functions to filter the blood and trap blood-borne particles to be assessed for foreignness by phagocytes (figure 33.14). Macrophages and dendritic cells are present in abundance, and once trapped by splenic macrophages or dendritic cells, a pathogen is phagocytosed, killed, and digested. The resulting antigens are presented to lymphocytes, activating a specific immune response.

Lymph nodes lie at the junctions of lymphatic vessels, where macrophages and dendritic cells trap particles that enter the lymphatic system (figure 33.14*c*). If a particle is found to be foreign, it is then phagocytosed and degraded, and the resulting antigens are presented to lymphocytes.

Lymphoid tissues are found throughout the body either as highly organized or as loosely associated cellular complexes (figure 33.14). Some lymphoid cells are closely associated with specific tissues such as skin (skin-associated lymphoid tissue, or SALT) and mucous membranes (mucosal-associated lymphoid tissue, or MALT). SALT and MALT are good examples of highly organized lymphoid tissues that feature macrophages surrounded by specific areas of B and T lymphocytes and sometimes dendritic cells. Loosely associated lymphoid tissue is best represented by the bronchial-associated lymphoid tissue (BALT), because it lacks cellular partitioning. The primary role of these lymphoid tissues is to efficiently organize leukocytes to increase interaction between the innate and the adaptive arms of the immune response. Thus, the lymphoid tissues serve as the interface between the innate resistance mechanisms and adaptive immunity of a host. We now discuss these tissues in more detail.

Despite the skin's defenses, at times pathogenic microorganisms gain access to the tissue under the skin surface. Here they encounter a specialized set of cells called the ***s*kin-*a*ssociated *l*ymphoid *t*issue** (**SALT**) (figure 33.15). The major function of SALT is to confine microbial invaders to the area immediately underlying the epidermis and to prevent them from gaining access to the bloodstream. One type of SALT cell is the **Langerhans cell,** a dendritic cell that phagocytoses microorganisms that penetrate the skin. Once the Langerhans cell has internalized a foreign particle or microorganism, it migrates from the epidermis to nearby lymph nodes, where it presents antigen to activate nearby lymphocytes, inducing a specific immune response to that antigen. This dendritic cell–lymphocyte interaction illustrates another bridge between innate resistance and adaptive immunity.

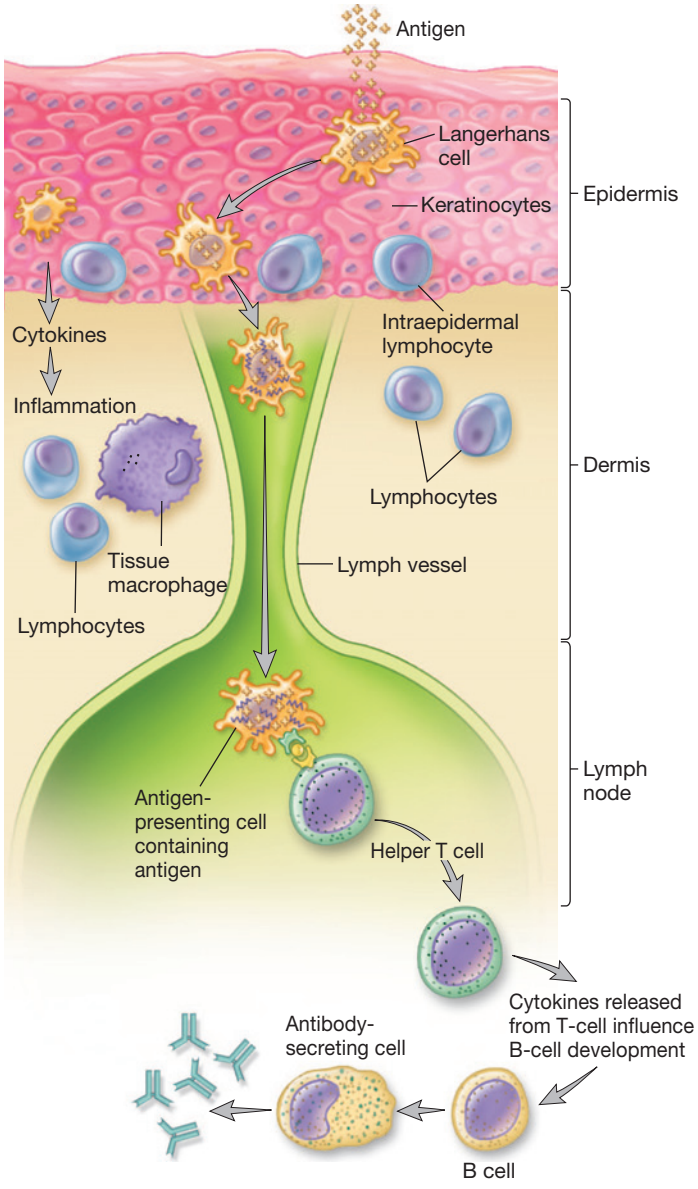

Figure 33.15 Skin-Associated Lymphoid Tissue (SALT). Keratinocytes make up 90% of the epidermis. They can secrete cytokines that cause an inflammatory response to invading pathogens. Langerhans cells internalize antigen and move to a lymph node, where they present antigen to helper T cells. The intraepidermal lymphocytes may function as T cells that can activate B cells to induce an antibody response.

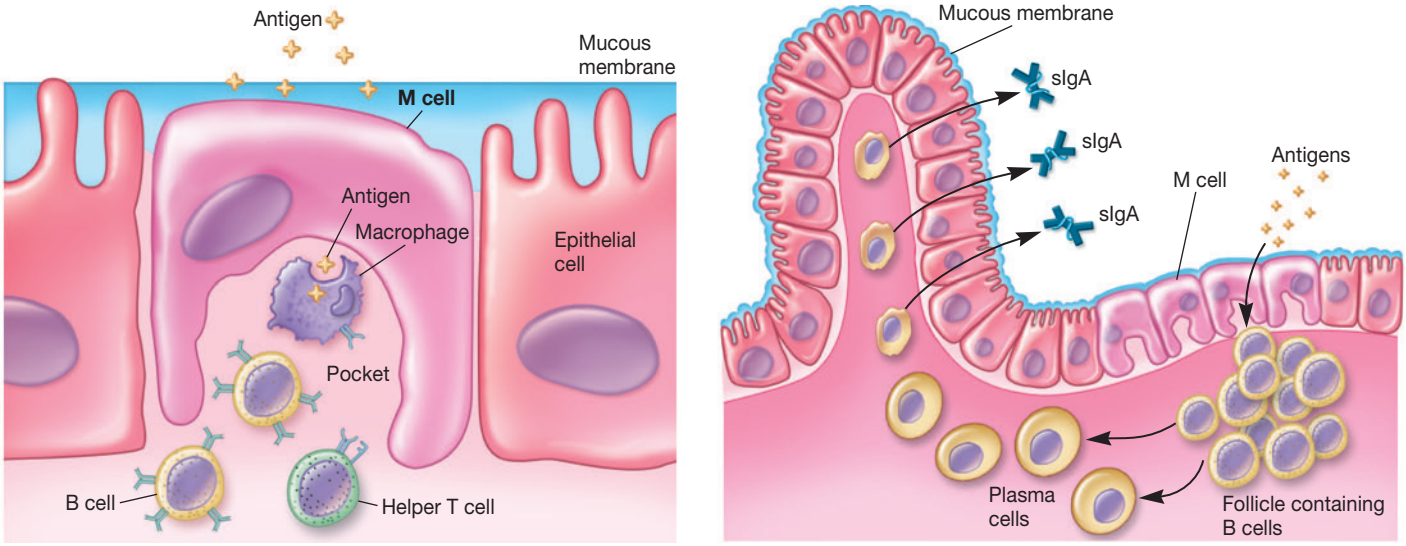

Figure 33.16 Function of M Cells in Mucosal-Associated Immunity. (a) Structure of an M cell located between two epithelial cells in a mucous membrane. The M cell endocytoses pathogens and releases them into the pocket containing helper T cells, B cells, and macrophages. It is within the pocket that pathogens often are destroyed. (b) Once in the M cell pocket, antigen enters an organized lymphoid follicle containing B cells. The activated B cells mature into plasma cells, which produce antibodies (sIgA; secretory **i**mmuno*g*lobulin *A*) that are released into the lumen, where they react with the antigen that caused their production.

The epidermis also contains another type of SALT cell called the **intraepidermal lymphocyte** (figure 33.15), a specialized T cell having potent cytolytic and immunoregulatory responses to antigen. These cells are strategically located in the skin so that they can intercept antigens that breach the first line of defense. Most of these specialized SALT cells have limited receptor diversity and have likely evolved to recognize common skin microbe patterns.

The specialized lymphoid tissue in mucous membranes is called ***m*ucosal-*a*ssociated *l*ymphoid *t*issue** (**MALT**). There are several types of MALT. The system most studied is the ***g*ut-*a*ssociated *l*ymphoid *t*issue** (**GALT**). GALT includes the tonsils, adenoids, diffuse lymphoid areas along the gut, and specialized regions in the intestine called Peyer's patches. Less well-organized MALT also occurs in the respiratory system and is called ***b*ronchial-*a*ssociated *l*ymphoid *t*issue** (**BALT**); the diffuse MALT in the genitourinary system does not have a specific name.

MALT operates by two basic mechanisms. First, when a foreign particle arrives at the mucosal surface, it contacts an **M cell** (**figure 33.16*a***). They reside above large epithelial pockets containing B cells, T cells, and macrophages. When a foreign particle contacts an M cell, it is endocytosed and released into the pocket. Macrophages engulf the particle or pathogen and degrade it. An M cell also can endocytose particles and release them to a cluster of cells called an organized lymphoid follicle (figure 33.16*b*). The B cells within this follicle react to the foreign particle and mature into antibody-producing plasma cells. The plasma cells leave the follicle and secrete mucous membrane–associated antibody. In the case of GALT, the antibody is transported into the lumen of the gut, where it interacts with the particles that caused its production. Similar to SALT, GALT intra- and interepithelial lymphocytes are strategically distributed so that the detection of foreign particles is increased, should the intestinal membrane be breached. ▶▶| *Antibodies are proteins that bind to specific 3-D molecules (section 34.7)*

As seen in our discussion thus far, a microbe attempting to invade a potential host encounters innate mechanisms including physical, chemical, and cellular barriers that are designed to kill the invader, digest the carcass into small antigens, and assist the lymphocytes in formulating long-term protection against the next invasion. We now examine the phagocytic processes in more detail and then consider how the host integrates many of the innate resistance activities into a substantial barrier to microbial invasion, known as the inflammatory response.

1. What is the function of the spleen? A lymph node? The thymus? What is the importance of thymic selection?
2. Injury to the spleen can lead to its removal. What impact would this have on host defenses?
3. Describe SALT and MALT functions in innate resistance.

33.5 Phagocytosis: Destroying Invaders and Recycling Their Parts

After reading this section, you should be able to:

- Explain the methods by which pathogens are recognized by phagocytes
- Describe the processes of autophagy and phagocytosis
- Forecast how biochemical activities within the phagocyte result in pathogen destruction

During their lifetimes, humans and other vertebrates encounter many microbial species, but only a few of these can grow and cause serious disease in otherwise healthy hosts. Phagocytic cells (macrophages, dendritic cells, and neutrophils) are an important early defense against invading microorganisms. These cells recognize, ingest, and kill cellular microbes by the process called **phagocytosis** (Greek *phagein*, to eat; *cyte*, cell; and *osis*, a process) and intracellular pathogens by the process of **autophagocytosis** (or autophagy). Phagocytic cells use two basic molecular mechanisms to recognize microorganisms: (1) opsonin-independent (nonopsonic) recognition and (2) opsonin-dependent (opsonic) recognition. They then encase the microorganisms within a "killing chamber." Recall that we discussed opsonic recognition in section 33.3, focusing on complement proteins and collectins. We now discuss nonopsonic recognition of foreignness and provide more detail regarding the result of pattern recognition by phagocytes.

Recognition of Foreignness Is Key for Survival

The ability to discriminate friend from foe affords a clear evolutionary advantage. This is no less true at the cellular level. Recognition of foreignness by mammals evolved in at least two ways. Both involve receptors that recognize molecules bearing microbial-associated molecular patterns (MAMPS). This ancient system is used by cells during innate immune responses. Detection of MAMPS begins with receptors that recognize molecules with repetitious patterns, and ends with common signal transduction mechanisms that produce antimicrobial responses (**figure 33.17**). PRMs are used by sentinel cells (macrophages, mast cells, and dendritic cells) in invader surveillance. They include C-type lectin receptors (CLRs), toll-like receptors (TLRs), nucleotide oligomerization domain (NOD)-like receptors (NLRs), and retinoic acid-inducible gene I (RIG-I)-like receptors (RLRs). We next examine the CLRs and TLRs that are membrane-bound. NLRs and RLRs are found in the cytosol, and are discussed later.

C-Type Lectin Receptors

CLRs are a large group of calcium-dependent membrane-bound proteins having one or more lectin-binding domains characterized by conserved amino acid residues specific for one type of carbohydrate (lectin). Thus a C-type lectin recognizes and binds to a specific carbohydrate found on MAMPs (section 33.4). They generally bind mannose, fucose, or glucan carbohydrates found on some bacteria (*Mycobacterium tuberculosis* and *Helicobacter pylori*), fungi (e.g., *Candida albicans* and *Aspergillus fumigatus*), helminths, and some viruses. CLRs also bind *N*-acetylglucosamine components of a number of different microorganisms, and the capsular polysaccharides of *Streptococcus pneumoniae* and *Klebsiella pneumoniae*. CLRs are concentrated on macrophages and dendritic cells. CLR-MAMP binding results in a signaling cascade that induces cytokine gene expression. This is mediated by the CLR cytoplasmic domain, which is called the immunoreceptor tyrosine-based activation motif (ITAM) in the CLR cytoplasmic domain. Binding also results in receptor-MAMP internalization, its degradation, and subsequent MAMP presentation to lymphocytes, as described later.

Toll-Like Receptors

Introduced in section 33.4, we now continue our discussion of **toll-like receptors** (**TLRs**). TLRs are transmembrane receptors expressed by a variety of cells that participate in innate immunity, especially macrophages and dendritic cells. They are also found on the intracellular organelles of those cells, mainly on membranes of endosomes, lysosomes, endolysosomes, and endoplasmic reticulum, where they detect cytoplasmic MAMPs. These transmembrane receptors have an extracellular (or extra-organelle) leucine-rich repeat domain that binds MAMPs, and a cytoplasmic Toll/interleukin-1 receptor (TIR) domain that activates downstream transcription signaling (figure 33.17). Binding of a MAMP to a TLR causes the TIR to recruit a specific adapter protein, either MyD88 or TRIF, which in turn facilitates transcription of distinct sets of immune response genes. Activation through the MyD88-dependent adapter causes NFκB to activate transcription of pro-inflammatory cytokine genes. All TLRs except TLR3 can use this pathway. Alternatively, activation through the TRIF-dependent adapter causes NFκB and IRF3 pathways to express type I interferon, chemokines, and inflammatory cytokines. TLRs 3 and 4 use TRIF. There are at least 10 distinct human TLRs that recognize and subsequently initiate an immune response.

NOD-Like Receptors

Unlike the transmembranous TLRs, **nucleotide-binding and oligomerization domain (NOD)-like receptors** are cytosolic. They too can bind to MAMPs. Once bound to MAMPs, they recruit and bundle additional proteins in a process known as oligomerization. NOD-like receptors (NLRs) sense intracellular MAMPs (e.g., viral RNA, anthrax toxin, group B streptococci, and *Listeria monocytogenes*), along with host molecules called "damage-associated molecular patterns" (DAMPs), such as uric acid and heat-shock proteins. DAMPs are a diverse group of molecules that arise from cell injury and stress.

NLRs are characterized by leucine-rich repeats (LRRs) within the C-terminus and nucleotide binding domain (NBD). LRRs bind the MAMP or DAMP, stimulating the NBD to bind ribonucleotides. This facilitates oligomerization of several NLRs and recruits co-factors and the enzyme caspase-1. This NLR-caspase complex is called the **inflammasome**, because it enhances inflammation when caspase-1 cleaves and activates pro-inflammatory cytokines, especially pro-IL-1, which is produced in response to signals transduced by other PRMs, such as a TLR. Thus NLRs and TLRs can work together to provide a stronger inflammatory response (**figure 33.18**). Different inflammasomes form in response to the various MAMP or DAMP activators.

RIG-I-Like Receptors

Retinoic-acid-inducible gene I (RIG-I)-like receptors (RLRs) are yet another receptor family that are cytoplasmic. Structurally, RLR proteins have two N-terminal caspase-recruitment domains (CARDS), an RNA helicase domain, and a C-terminal repressor domain (RD). Recognition and binding of viral RNAs are through the helicase and RD. Upon RLR binding of viral RNA,

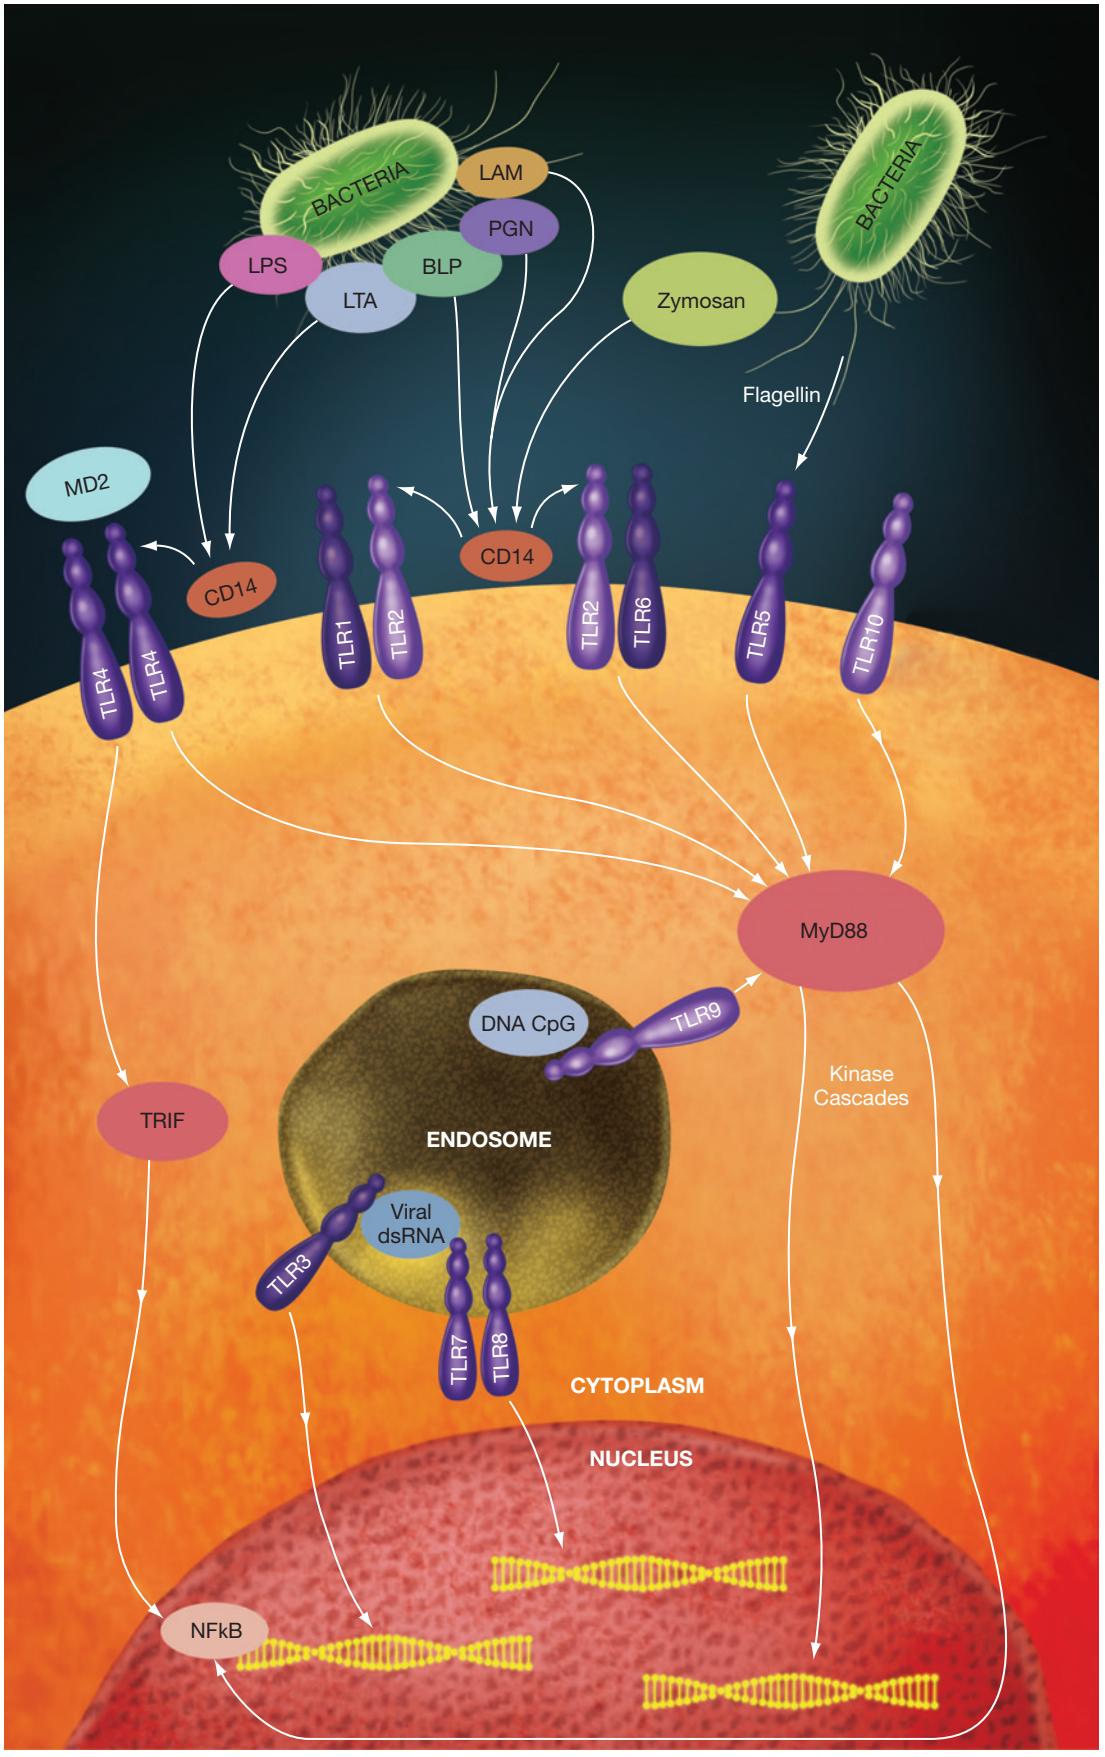

Figure 33.17 Recognition of Microbe-Associated Molecular Patterns (MAMPs) by Pattern Recognition Molecules (PRMs). MAMPs bind PRMs, especially toll-like receptors (TLRs), C-type lectin receptors (CLRs), and other pattern recognition receptors. PRM binding results in signaling that upregulates cytokine gene expression through common signal transduction pathways, like $NF_{\kappa}B$.

the CARDS domains trigger intracellular signal cascades leading to expression of interferon. Both dsRNA and ssRNA virus replication lead to dsRNA and triphosphate-capped ssRNA during the course of infection. RLRs recognize these forms of viral RNA and stimulate an antiviral cytokine response.

Intracellular Digestion

Ingestion and subsequent digestion of potential nutrient sources is a highly conserved process across species. Importantly, it has evolved into an intricate detection and removal process that extends beyond nutrient acquisition. Two parallel processes, phagocytosis and autophagy, accomplish ingestion and digestion, and are found to be widely distributed in nature. Phagocytosis imports extracellular particles via the extension of the cell membrane (as pseudopodia), to end up with an internal phagosome; this is often receptor-mediated (**figure 33.19*a,b***). Autophagy begins when intracellular microorganisms, or their products, are captured by intracellular membranes through PRMs, or are coated with ubiquitin, the tagging protein used for recycling by proteasomes (*see figure 5.8*). In this application, ubiquitin "labels" microorganisms for capture by a phagophore (free-floating, open membrane). The phagophore then encircles the microorganism, creating the double-membrane autophagosome (**figure 33.20**). Autophagy is widely recognized as an ancient means of homeostasis whereby cellular components are recycled. ◀◀ *There are several endocytic pathways (section 5.4)*

Once membrane-bound, microorganisms are delivered to and fused with lysosomes, fusion of phagosome and lysosome creates the phagolysosome (figure 33.19*c,d*). Fusion of the autophagosome and lysosome creates the autolysosome (figure 33.20). **Lysosomes** deliver a variety of hydrolases such as lysozyme, phospholipase A2, ribonuclease, deoxyribonuclease, and proteases. The activity of these degradative enzymes is enhanced by the acidic vacuolar pH. Collectively these enzymes participate in the destruction of the entrapped microorganisms. In addition, toxic **reactive oxygen species** (**ROS**) such as the superoxide radical ($O_2^{\cdot-}$), hydrogen peroxide (H_2O_2), singlet oxygen ($^1O_2$), and hydroxyl radical (·OH) are produced. Neutrophils also contain the heme-protein enzyme, myeloperoxidase, which catalyzes the production of hypochlorous acid. Some reactions that form ROS are shown in **table 33.4**. These reactions result in part from the respiratory, or oxidative, burst that accompanies the increased oxygen consumption and ATP generation needed for phagocytosis. The **oxidative burst** occurs within the phagosome or autophagosome as soon as it is formed. In this way, ROS are immediately effective in killing microorganisms. ◀◀ *Oxygen concentration (section 7.4)*

Macrophages, neutrophils, and mast cells have also been shown to form **reactive nitrogen species** (RNS). These molecules include nitric oxide (NO) and its oxidized forms, nitrite (NO_2^-) and nitrate (NO_3^-). RNS are very potent cytotoxic agents; nitric oxide is probably the most effective RNS. It can block cellular respiration by complexing with iron in electron transport proteins. Macrophages

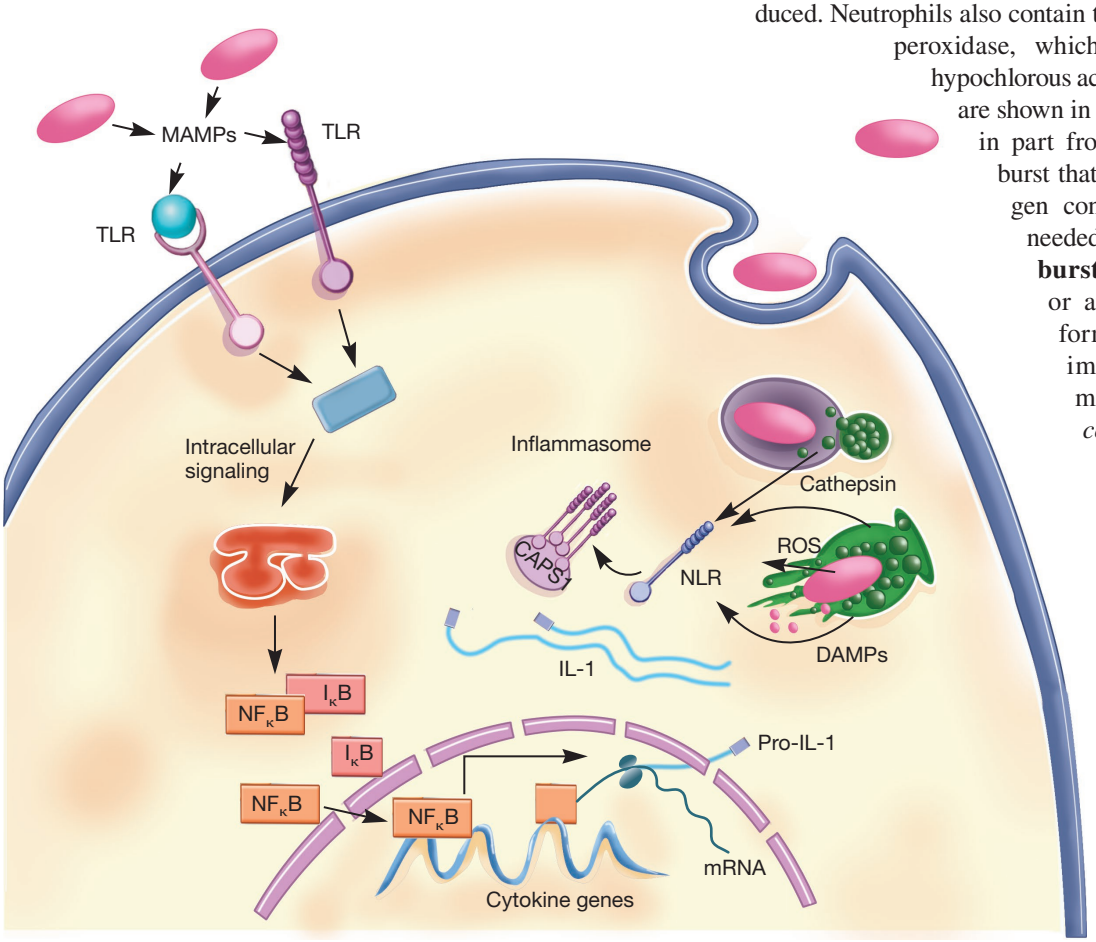

Figure 33.18 Cooperation Between Two Pattern Recognition Molecules (PRMs). Binding of toll-like and Nod-like receptors (TLR and NLR, respectively) by microbe-associated molecular patterns (MAMPs) activates two different response mechanisms that cooperate to produce a potent pro-inflammatory cytokine, interleukin (IL)-1. Binding of MAMPs to TLRs activates an ancient signal transduction system that releases the $NF_\kappa B$ transcription factor to upregulate gene expression of pro-IL-1. Importantly, binding of other MAMPs, cathepsin, or reactive oxygen species (from damaged phagolysosomes) to NLRs results in the oligomerization of several NRLs, which then assemble and activate the proteolytic enzyme, caspase (CAPS)-1. CAPS-1 cleaves pro-IL-1 into active IL-1 cytokine, upregulating numerous inflammatory cells and biochemical pathways.

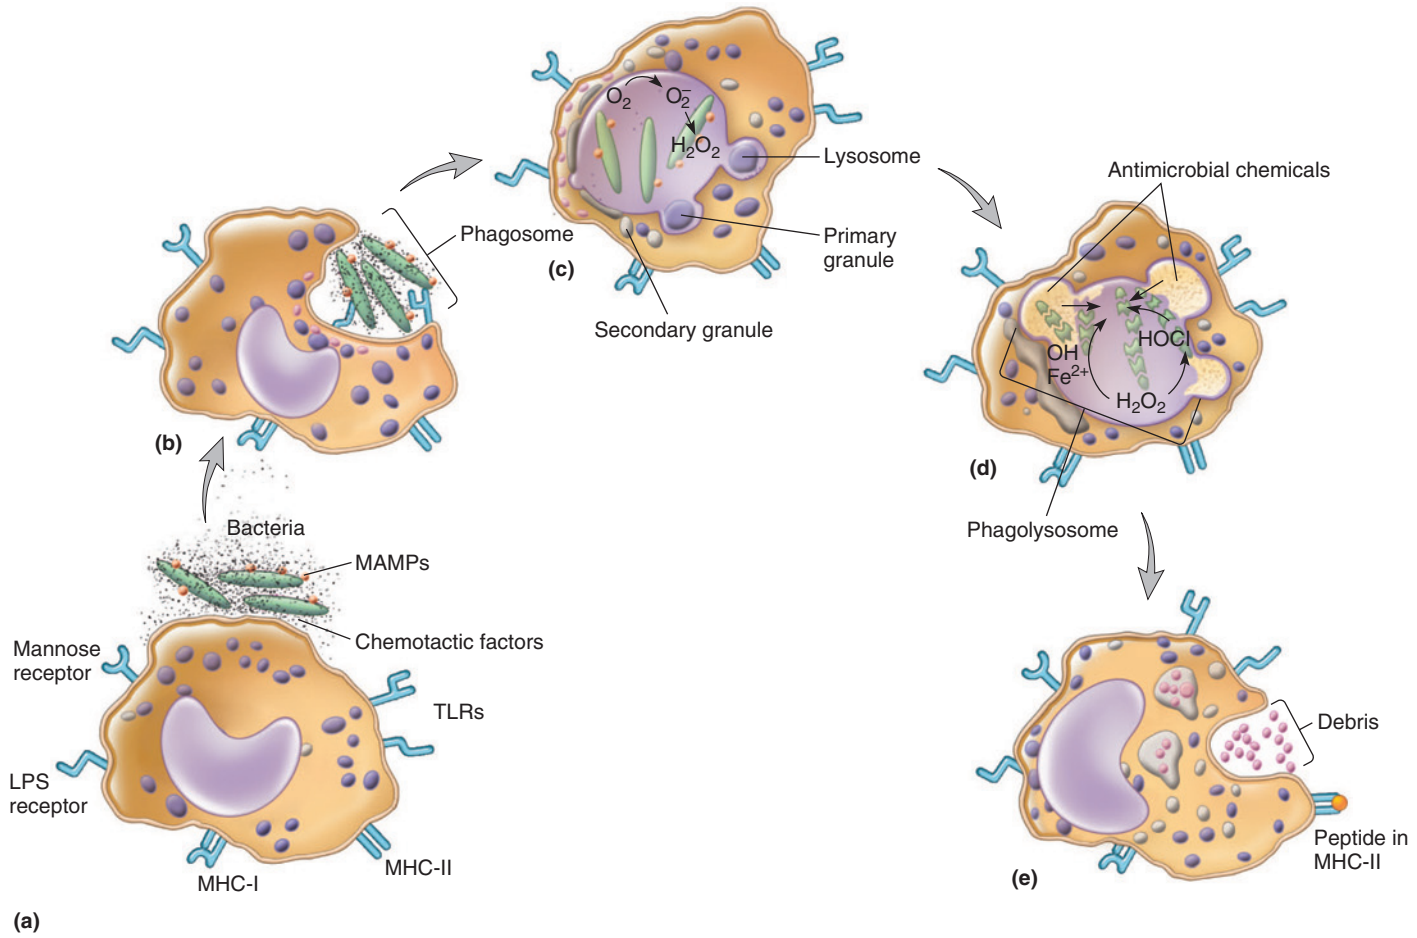

Figure 33.19 Phagocytosis. (a) Receptors on a phagocytic cell (e.g., a macrophage) and the corresponding MAMPs participating in phagocytosis. The process of phagocytosis includes (b) ingestion, (c) participation of granules, and O_2-dependent killing events, (d) intracellular digestion, and (e) exocytosis. As with autophagy, digested fragments can also enter the endoplasmic reticulum to be processed for antigen presentation. MHC proteins are discussed in chapter 34. LPS receptor: lipopolysaccharide receptor; TLRs: toll-like receptors; MHC-I: class I major histocompatibility protein; MHC-II: class II major histocompatibility protein; MAMPs: microbe-associated molecular patterns.

use RNS in the destruction of a variety of infectious agents as well as to kill tumor cells.

Neutrophil granules contain a variety of other microbicidal substances such as several cationic peptides, the bactericidal permeability-increasing protein (BPI), and broad-spectrum antimicrobial peptides, including defensins (section 33.3). These substances are compartmentalized for extracellular secretion or delivery to phagocytic vacuoles. Susceptible microbial targets include a variety of Gram-positive and Gram-negative bacteria, yeasts and molds, and some viruses. Defensins act against bacteria and fungi by permeabilizing cell membranes. This is accomplished by formation of voltage-dependent membrane channels that allow ionic efflux. Antiviral activity involves direct neutralization of enveloped viruses, so they can no longer bind host cell receptors; nonenveloped viruses are not affected by defensins.

Exocytosis

Once the microbial invaders have been killed and digested into small antigenic fragments, the phagocyte may do one of two things. The cell may expel the microbial fragments by the process of **exocytosis** (figure 33.19*e*). This is essentially a reverse of the phagocytic process whereby the phagolysosome unites with the cell membrane, resulting in the extracellular release of the microbial fragments. Neutrophils tend to do this. By contrast, macrophages and dendritic cells become **antigen-presenting cells** (*see figure 34.5*). This is accomplished by passing some of the microbial fragments from the phagolysosome to the endoplasmic reticulum (figure 33.19*e*). Here the peptide components of the fragments are united with glycoproteins, called histocompatibility proteins *(see figure 34.4)*, destined for the cell membrane. The glycoproteins bind the peptides so that they are presented outwardly from the cell once the glycoprotein is secured in the cell membrane. Antigen presentation is critical because it enables wandering lymphocytes to evaluate killed microbes (as antigens) and be activated. Thus antigen presentation links an innate immune response (phagocytosis and autophagy) to a specific immune response (lymphocyte activation). ▶▶| *Recognition of foreignness is critical for a strong defense (section 34.4)*

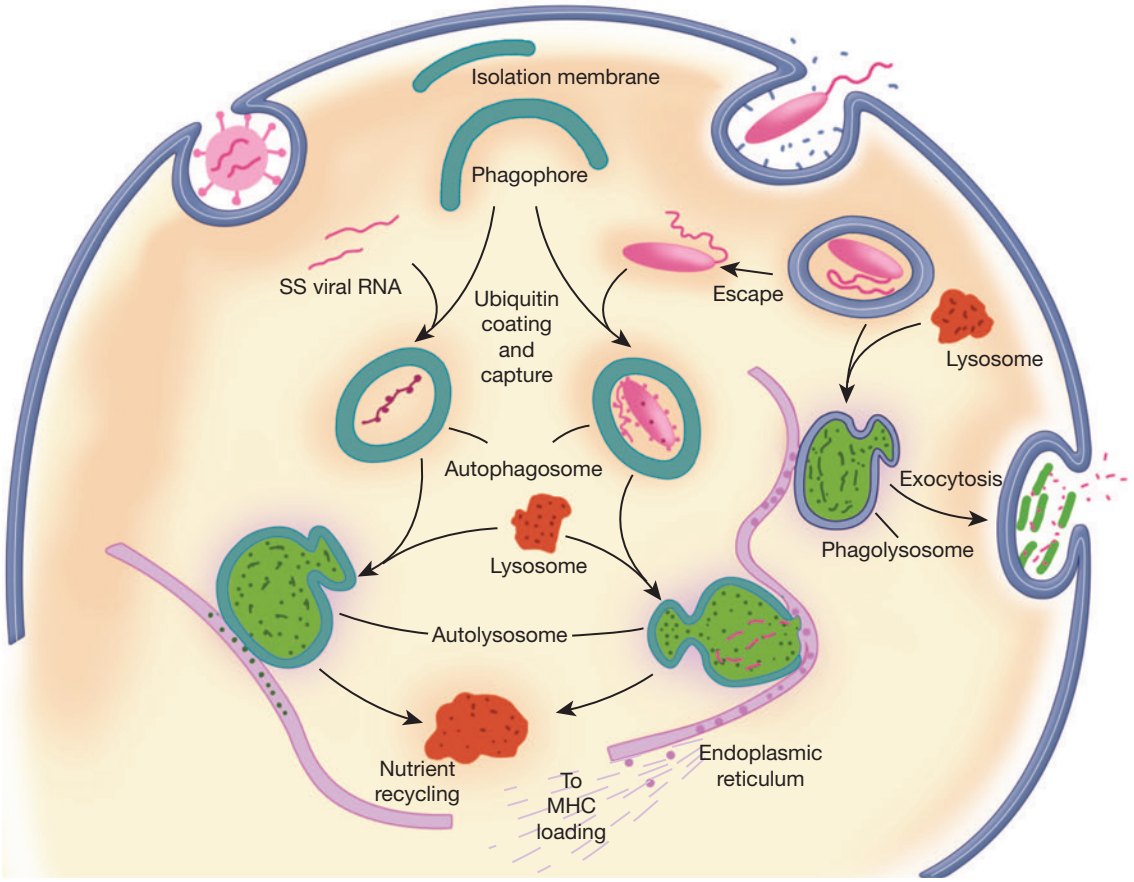

Figure 33.20 Autophagy Is Similar to Phagocytosis. Intracellular parasites such as viruses, and bacteria that escape the phagosome, are captured by free-floating membranes that form a phagophore, often through membrane-bound toll-like receptors. Cytosolic ubiquitin molecules coat the intracellular invaders and their macromolecules (such as viral RNA). The ubiquitinated particles are then surrounded by the phagophore to form an autophagosome. Like the phagosome that becomes the phagolysosome during phagocytosis, the autophagosome (autosome) fuses to lysosomes to digest its contents. Once the lysosome fuses with the autosome, it is called the autolysosome. Both phagolysosome and autolysosome can have some of their debris donated to the endoplasmic reticulum, where antigenic peptides are further processed to bind MHC molecules destined for the phagocyte's cell membrane. The remaining debris is recycled or released to the environment.

Table 33.4 Formation of Reactive Oxygen Intermediates

Oxygen Intermediate	Reaction
Superoxide ($O_2^{-}\bullet$)	$NADPH + 2O_2 \xrightarrow{\text{NADPH oxidase}} 2O_2^{-}\bullet + H^+ + NADP^+$
Hydrogen peroxide (H_2O_2)	$2O_2^{-}\bullet + 2H^+ \xrightarrow{\text{Superoxide dismutase}} H_2O_2 + O_2$
Hypochlorous acid (HOCl)	$H_2O_2 + Cl^- \xrightarrow{\text{Myeloperoxidase}} HOCl + OH^+$
Singlet oxygen ($^1O_2$)	$ClO^- + H_2O_2 \xrightarrow{\text{Peroxidase}} {}^1O_2 + Cl^- + H_2O$
Hydroxyl radical ($\bullet OH^-$)	$O_2^{-}\bullet + H_2O_2 \xrightarrow{\text{Peroxidase}} 2\bullet OH^- + O_2$

3. How do macrophages and dendritic cells become antigen-presenting cells?

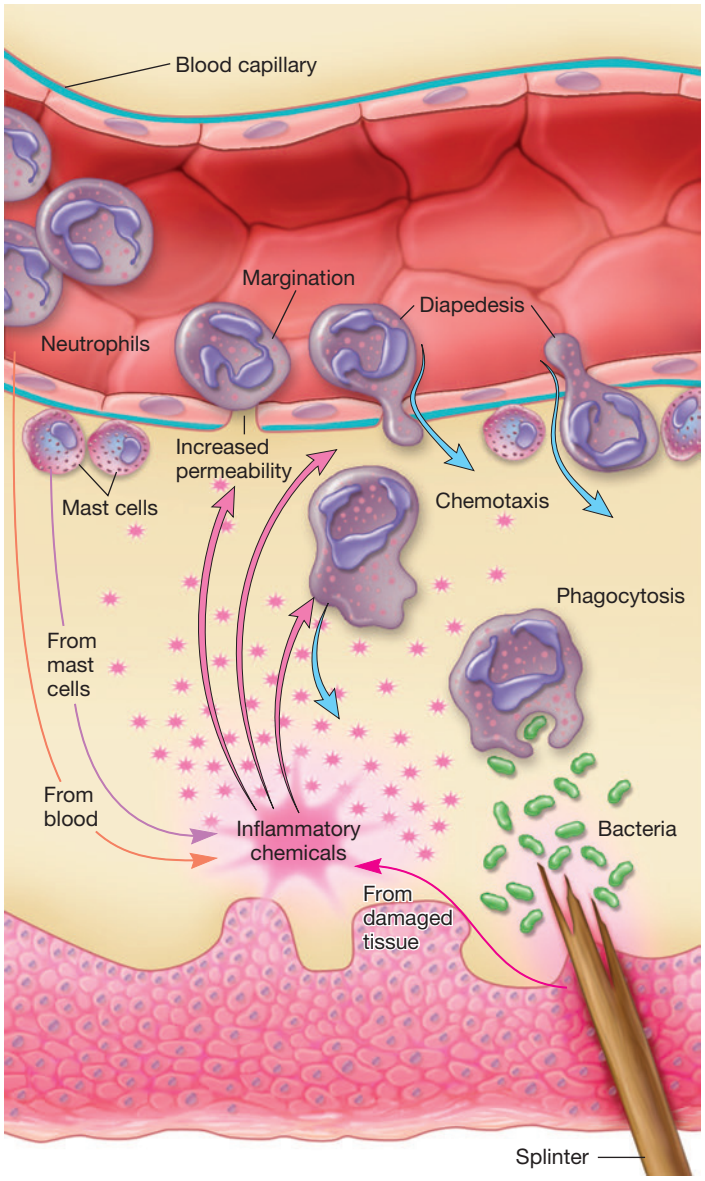
33.6 Inflammation Unites All the Components of Immunity

After reading this section, you should be able to:

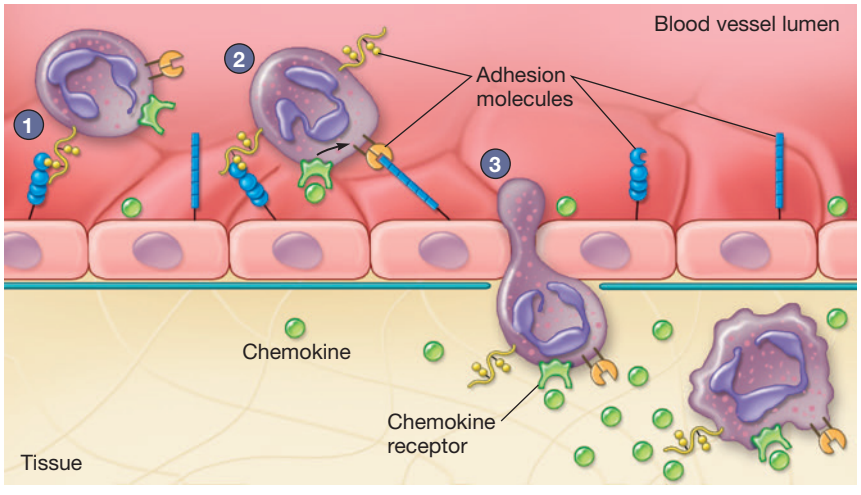
- Outline the sequence of innate host responses that result in inflammation
- Distinguish acute and chronic inflammation in terms of the host responses involved in each
- Construct a concept map relating host cells and processes that remove pathogens

The collective actions of the innate resistance response, combined with responses from adaptive defenses, culminate in a concentrated effort to remove foreign invaders. We now examine how the host responds on a larger scale and over longer time periods. Physiologically, the process is called inflammation, and its function is to bring all the host defenses together in response to injury or infection. **Inflammation** (Latin, *inflammatio,* to set on fire) is an important innate defense reaction to tissue injury, such as that caused by a pathogen or wound. Acute inflammation is the immediate response of the body to injury or cell death. The gross features were described over 2,000 years ago and are still known as the cardinal signs of inflammation: redness (*rubor*), warmth (*calor*), pain (*dolor*), swelling (*tumor*), and altered function (*functio laesa*). While often thought to be a negative event, wounds do not heal without inflammation. *Inflammatory Response*

The **acute inflammatory response** begins when injured tissue cells release chemical signals (chemokines) that activate the inner lining (endothelium) of nearby capillaries (**figure 33.21**). Within the capillaries, **selectins** (a family of cell adhesion molecules) are displayed on the activated endothelial cells. Selectins attract and attach wandering neutrophils to the endothelial cells. This slows the neutrophils and causes them to roll along the endothelium, where they encounter inflammatory chemicals that act as activating signals (figure 33.21*b*). These signals activate **integrins** (selectin receptors) on the neutrophils. The integrins then attach tightly to the selectins, causing the neutrophils to stick to the endothelium and stop rolling (margination). The neutrophils now undergo dramatic shape changes, squeeze through the endothelial wall (diapedesis) into the interstitial tissue fluid, migrate to the site of injury (extravasation), and attack the pathogen or other cause of the tissue damage. Neutrophils and other leukocytes are attracted to the infection site by chemotactic factors, which are also called **chemotaxins.** They include substances released by bacteria, endothelial cells, mast cells, and tissue breakdown products. Depending on the severity and nature of tissue damage, other types of leukocytes (e.g., lymphocytes, monocytes, and macrophages) may follow the neutrophils.



(a)



(b)

Figure 33.21 Physiological Events of the Acute Inflammatory Response. (a) At the site of injury (splinter), chemical messengers are released from the damaged tissue, mast cells, and the blood plasma. These inflammatory mediators stimulate neutrophil migration, diapedesis, chemotaxis, and phagocytosis. (b) Neutrophil integrins interact with endothelial selectins (1) to facilitate margination (2) and diapedesis (3).

MICRO INQUIRY *How does the movement of leukocytes in response to chemokines contribute to the cardinal signs of inflammation?*

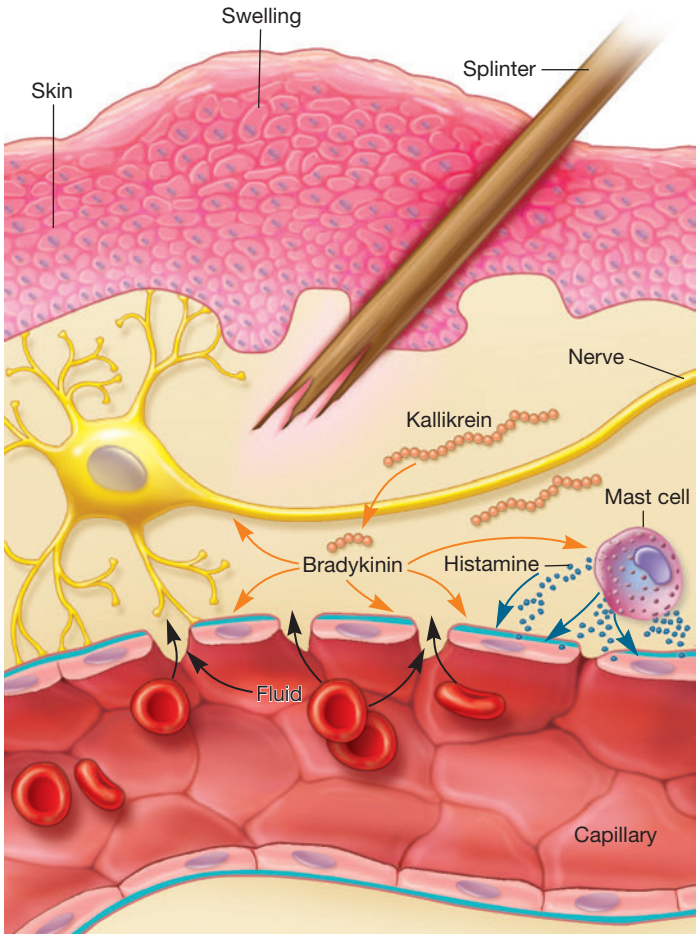


Figure 33.22 Tissue Injury Results in the Recruitment of Kallikrein, from Which Bradykinin Is Released. Bradykinin acts on endothelial and nerve cells, resulting in edema and pain, respectively. It also stimulates mast cells to release histamine. Histamine acts on endothelial cells, further increasing blood leakage into injured tissue sites.

The release of inflammatory mediators from injured tissue cells sets into motion a cascade of events that results in the development of the signs of inflammation. One response that ensues is the stimulation of local macrophages and distant liver cells to release antimicrobial and acute-phase proteins, respectively. In the local response, these mediators increase the acidity in the surrounding extracellular fluid, which activates the extracellular enzyme **kallikrein** (figure 33.22). Cleavage of kallikrein releases the smaller peptide bradykinin. Bradykinin then binds to receptors on the capillary wall, opening the junctions between cells and allowing fluid, red blood cells, and infection-fighting leukocytes to leave the capillary and enter the infected tissue. Simultaneously, bradykinin binds to mast cells in the connective tissue associated with most small blood vessels. This activates mast cells by causing an influx of calcium ions, which leads to degranulation and release of preformed mediators such as histamine. If nerves in the infected area are damaged, they release substance P, which also binds to mast cells, boosting preformed-mediator release. Histamine in turn makes intercellular junctions in the capillary wall wider so that more fluid, leukocytes, kallikrein, and bradykinin move out, causing swelling or edema. Bradykinin then binds to nearby capillary cells and stimulates the production of prostaglandins (PGE_2 and PGF_2) to promote tissue swelling in the infected area. Prostaglandins also bind free nerve endings, making them fire and start a pain impulse. At the same time, liver cells release additional complement proteins, the iron-binding glycoprotein lactoferrin, and various scavenging proteins called collectins (p. 717).

Activated mast cells also release a small molecule called arachidonic acid, the product of a reaction catalyzed by phospholipase A_2. Arachidonic acid is metabolized by mast cells to form potent mediators, including PGE_2 and PGF_2, thromboxane, slow-reacting substance (SRS), and leukotrienes (LTC_4 and LTD_4). These mediators play specific roles in the inflammatory response. During acute inflammation, the offending pathogen is neutralized and eliminated by a series of important events:

1. The increase in blood flow and capillary dilation bring into the area more antimicrobial factors and leukocytes that destroy the pathogen. Dead host cells also release antimicrobial factors.
2. Blood leakage into tissue spaces increases the temperature at that site and further stimulates the inflammatory response and may inhibit microbial growth.
3. A fibrin clot often forms and may limit the spread of the invaders.
4. Phagocytes collect in the inflamed area and phagocytose the pathogen. In addition, chemicals stimulate the bone marrow to release neutrophils and increase the rate of granulocyte production.

An acute inflammatory response resolves in days to a few weeks. Prolonged stimulation of the inflammatory pathways leads to progressive changes in cellular response and outcome, known as chronic inflammation. Recall that the end result of acute inflammation is tissue healing and repair. However, **chronic inflammation** is detrimental and is characterized by infiltration of lymphocytes and macrophages into the affected site and the formation of new connective tissue. This usually causes permanent tissue damage. As cycles of cellular infiltration and resolution continue, degradative enzymes from macrophages destroy more underlying tissue than is replaced. Furthermore, if innate responses are unable to protect the host from ongoing infection, chronic tissue injury, or the persistence of poorly degradable materials (sutures, implants, etc.), the body attempts to wall off and isolate the site by forming a **granuloma** (Latin, *granulum,* a small particle; Greek, *oma,* to form). A granuloma is a well-organized mass of neutrophils, epithelioid macrophages, eosinophils, multinucleated giant cells (two or more cells fused into one large cell), fibroblasts, and collagen (figure 33.23). Together, the cells and extracellular matrix proteins form a spherical mass that can bind calcium and form a recalcitrant

nodule, mineralizing the granuloma and making it harder to break down.

Importantly, chronic inflammation can occur as a distinct process without much acute inflammation, as evidenced by the chapter opening story about visceral fat causing chronic inflammation. The persistence of bacteria can also stimulate chronic inflammation. For example, mycobacteria, some of which cause tuberculosis and leprosy, have cell walls with a very high lipid content, making them relatively resistant to phagocytosis and intracellular killing. Granulomas formed around mycobacteria often calcify and appear on chest X rays, indicating potential tuberculosis. Of note is the fact that the mycobacterial granuloma keeps the bacteria from spreading throughout the body. However, if the immune system declines, granuloma integrity fails, releasing the bacteria into the alveoli, where they are coughed up and potentially transmitted to another host, having survived for many years within macrophages. ⏮ *Order* Corynebacteriales *includes important human pathogens (section 24.1)*

Retrieve, Infer, Apply

1. What major events occur during an inflammatory reaction, and how do they contribute to pathogen destruction?
2. How does chronic inflammation differ from acute inflammation?

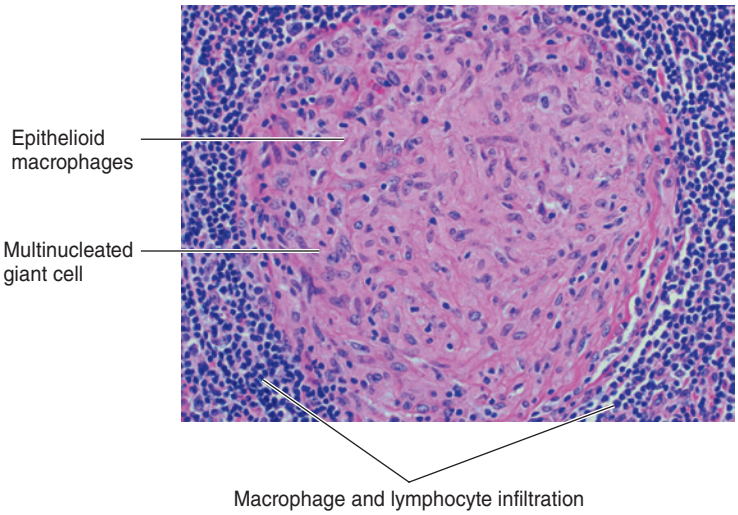

Figure 33.23 Photomicrograph of a Tuberculoid Granuloma. The granuloma is a well-organized mass of cells and proteins resulting from a chronic inflammatory response. Note the epithelioid macrophages in the granuloma as contrasted to the large number of normal macrophages surrounding it. Granuloma formation sequesters the mycobacteria, restricting access to its inflammatory products.

Key Concepts

33.1 Immunity Arises from Innate Resistance and Adaptive Defenses

- There are two interdependent components of the immune response to invading microorganisms and foreign material; innate resistance and adaptive immune responses.
- Innate resistance mechanisms offer substantial host defense against any microorganism or foreign material. They include general mechanisms that are a part of the animal's innate structure and function. The nonspecific system has no immunological memory; that is, nonspecific responses occur to the same extent each time.
- The adaptive immune response resists a particular foreign agent; moreover, adaptive immune responses improve on repeated exposure to the agent.
- Numerous cells and processes bridge the innate and adaptive immune responses (**figure 33.1**).

33.2 Innate Resistance Starts with Barriers

- Many direct factors (age, nutrition) or general barriers contribute in some degree to all host-microbe relationships. At times, they favor the establishment of the microorganism; at other times, they provide the host some measure of general defense (**figure 33.2**).
- Physical and mechanical barriers along with host secretions are the host's first line of defense against pathogens. Examples include the skin and mucous membranes and the epithelia of the respiratory, gastrointestinal, and genitourinary systems (**figures 33.3–33.5**).

33.3 Innate Resistance Relies on Chemical Mediators

- Mammalian hosts have specific chemical barriers that help combat the continuous onslaught of pathogens. Examples include cationic peptides, bacteriocins, cytokines, acute-phase proteins, and complement.
- The complement system is composed of a large number of serum proteins that play a major role in an animal's defensive immune response. There are three pathways of complement activation: the alternative, lectin, and classical pathways (**figure 33.7** and **table 33.1**).
- Cytokines are required for regulation of both the innate and adaptive immune responses. Cytokines have a broad range of actions on eukaryotic cells (**tables 33.2** and **33.3**).
- Acute-phase proteins are released from liver cells to bind microbial surfaces. They act as opsonins.

33.4 Cells, Tissues, and Organs Work Collectively to Form an Immune System

- The cells responsible for both nonspecific and adaptive immunity are white blood cells, which are also called leukocytes (**figure 33.9**). Examples include monocytes and macrophages, dendritic cells, granulocytes, and mast

cells. Phagocytic leukocytes use a receptor system (pattern recognition molecules; PRMs) to detect molecular patterns found on pathogens (microbe-associated molecular patterns; MAMPs).

- Immature undifferentiated lymphocytes are generated in the bone marrow and become committed to a particular antigenic specificity within the primary lymphoid organs and tissues. In mammals, T cells mature in the thymus and B cells in the bone marrow. The thymus is the primary lymphoid organ; the bone marrow is the primary lymphoid tissue (**figure 33.14**).
- Natural killer cells are a small population of large, nonphagocytic lymphocytes that destroy cancer cells and cells infected with microorganisms (**figures 33.12** and **33.13**).
- The secondary lymphoid organs and tissues serve as areas where lymphocytes may encounter and bind antigens, then proliferate and differentiate into fully mature, antigen-specific effector cells. The spleen is a secondary lymphoid organ, and the lymph nodes and mucosal-associated tissues (GALT and SALT) are the secondary lymphoid tissue (**figures 33.14–33.16**).

33.5 Phagocytosis: Destroying Invaders and Recycling Their Parts

- Phagocytic cells use two basic mechanisms for the recognition of extracellular microorganisms: opsonin-dependent and opsonin-independent. Detection of intracellular microorganisms is with opsonic-independent methods.
- Phagocytes use PRMs to detect MAMPs and damage- or danger-associated molecular patterns (DAMPs) on microorganisms and host cells. Membrane-bound and cytoplasmic PRMs transduce signals via the same molecular pathway to activate the inflammatory response. Toll-like receptors and NOD-like receptors are distinct classes of pathogen recognition receptors (**figures 33.17** and **33.18**).
- Phagocytosis involves the recognition, ingestion, and destruction of pathogens by lysosomal enzymes, reactive oxygen species, defensins, reactive nitrogen species, and metallic ions. A more conserved method of detection and digestion, called autophagy, uses intracellular membranes and lysosomes to kill and degrade intracellular pathogens (**figures 33.19** and **33.20**).

33.6 Inflammation Unites All the Components of Immunity

- Inflammation is one of the host's nonspecific defense mechanisms to tissue injury and infection.
- Inflammation can either be acute or chronic (**figures 33.21–33.23**).

Compare, Hypothesize, Invent

1. Some pathogens invade cells; others invade tissue spaces. Explain how innate responses differ for both types of pathogens.
2. How might the various antimicrobial chemical factors be developed into new methods to control infectious disease, such as for antibiotic resistant bacteria?
3. How might a scientist use selective gene "knockouts" in bacteria to test the role of the toll-like receptor proteins?
4. Conservation of resources is a common theme in biology. However, it is only recently that scientists are piecing together how human responses to intracellular damage, multicellular injury, invading microorganisms, and chronic toxin exposure share survival processes. It seems that mitochondria may have a prominent role in wide-scale sensing of cellular trouble and alerting ancient evolutionary processes to respond.

   Recalling what mitochondria do for the cell, what would you deduce mitochondria do to detect and announce danger to the cell?

   What types of experiments could you do to test your hypothesis?

   Why would an "ancient" signaling process be used for such an important function?

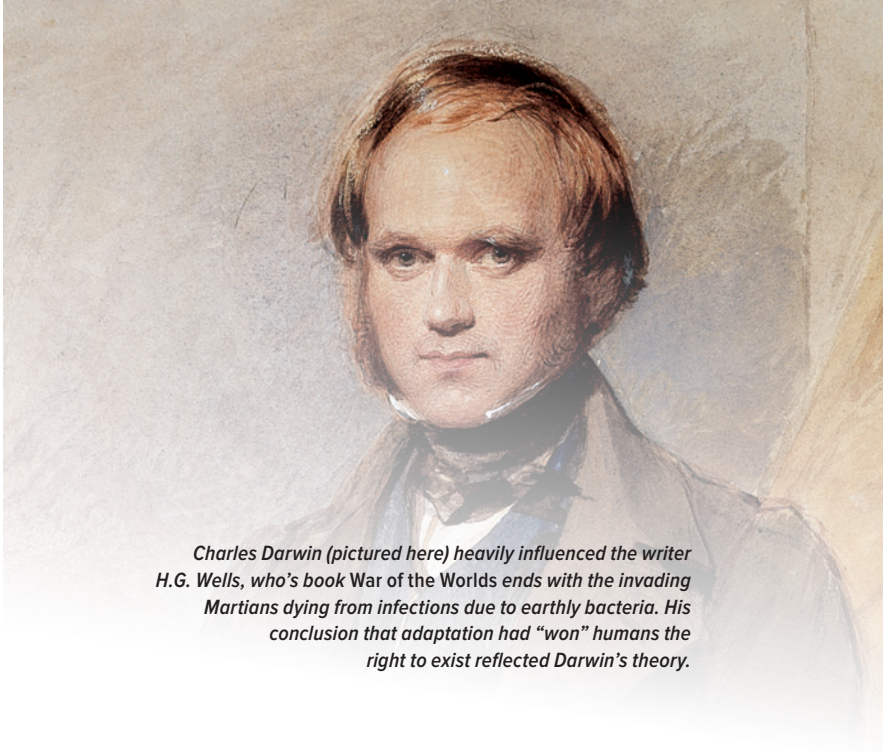
Adaptive Immunity



Charles Darwin (pictured here) heavily influenced the writer H.G. Wells, who's book War of the Worlds *ends with the invading Martians dying from infections due to earthly bacteria. His conclusion that adaptation had "won" humans the right to exist reflected Darwin's theory.*

It's in My Genes?

Next time someone wants to know why you never seem to get sick, you might say it's in your genes. A recent paper in *Science* magazine suggests that modern HLA DNA is rooted in an ancestral "family" tree that may include the infusion of DNA from primate relatives of *Homo sapiens*. HLA genes encode proteins important in immune function; these proteins identify "self" to the immune system as well as help activate an immune response when the host is threatened by an infectious agent. Scientists at Stanford University scanned the genomes of several thousand modern humans from around the globe and compared their HLA sequences to HLA sequences from the genomes of three Neanderthal and one Denisovan (the only one known to date) hominoids. They found that modern humans share several long stretches of HLA DNA with the ancient hominids and that these sequences were pervasive in modern genomes. The Stanford scientists believe that because HLA DNA diversifies quickly, the only possible explanation for the shared sequences is interbreeding between the common human ancestors and their archaic "cousins." Importantly, the data demonstrate that the HLA alleles from Neanderthals and Denisovans are more common in Europeans and Asians than Africans, pointing to the possibility that the archaic alleles entered the human gene pool after humans left Africa. All told, the modern HLA DNA has had hundreds of thousands of years to adapt to foreign antigens, and with the potential infusion of DNA from archaic cousins, it is exceedingly robust in protecting modern humans from foreign invasion.

Chapter 33 discusses nonspecific host resistance and the innate mechanisms by which the host is protected from invading microorganisms. Recall that the innate resistance system responds to a foreign substance in the same manner and to the same magnitude each time and that its activation can assist in the formation of adaptive immune responses. We now continue our discussion of the immune response by describing the adaptive responses used to protect the host. Although all vertebrates are born with adaptive immunity, it requires sufficient time to fully develop. Unlike innate immunity, upon subsequent exposure to a substance (antigen), activation of an adaptive immune response is significantly faster and stronger than the initial response. Additionally, a fully mature immune response involves cooperation between the host's ever-present innate resistance mechanisms and inducible adaptive responses.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Explain basic eukaryotic cell biology (sections 5.1–5.7)
- ✔ Diagram the flow of information in eukaryotes from DNA to protein and regulation of this flow (sections 15.2–15.4)
- ✔ Discuss the importance of the host complement response (section 33.3)
- ✔ Recall the structure and function of host leukocytes (section 33.4)
- ✔ Outline the events that occur during phagocytosis and inflammation (sections 33.5 and 33.6, respectively)

34.1 Adaptive Immunity Relies on Recognition and Memory

After reading this section, you should be able to:

- Contrast host innate resistance with adaptive immunity
- Outline the localization of B and T cells during development

Although the separation and discussion of innate and adaptive functions of immunity is artificial, it allows us to distinguish the preprogrammed, automatic responses of the innate side from the more diverse, developmental, and long-lasting aspects of the adaptive side. In reality the two sides of this coin we call immunity represent a single, elegant recognition and response system that is intimately integrated (**figure 34.1**).

The adaptive immune system of animals has three major functions: (1) to recognize anything that is foreign to the body ("nonself"); (2) to respond to this foreign material; and (3) to remember the foreign invader. The recognition response is highly specific. The immune system is able to distinguish one pathogen

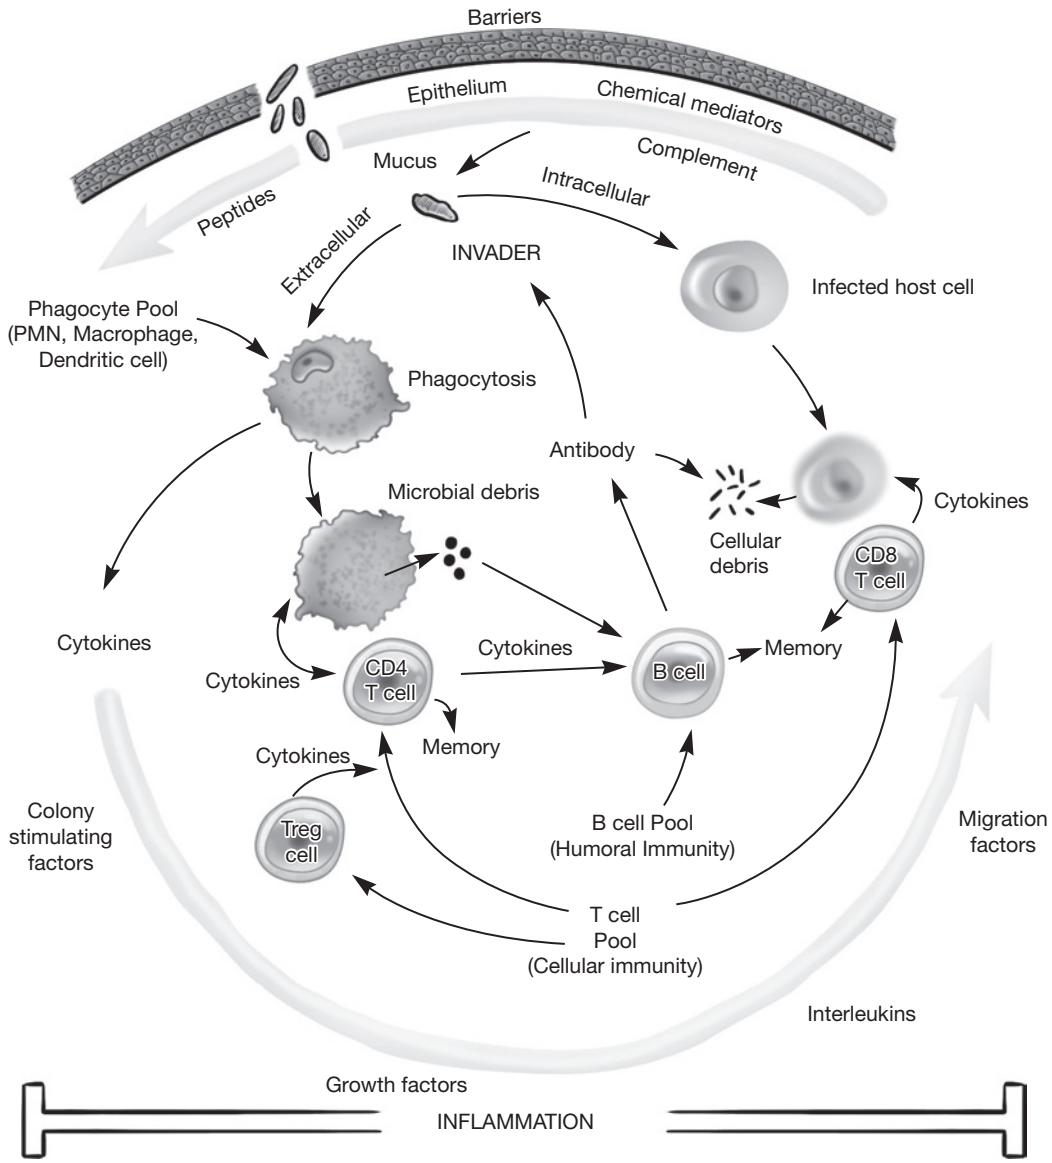


Figure 34.1 Innate and Acquired Components Integrate to Be an Elegant Immune System. Barriers, cells, chemical mediators, and inflammation of the innate arm of immunity respond maximally to every host insult. B-cell (humoral) and T-cell (cell-mediated) components of the adaptive arm of immunity respond selectively, specifically, and with memory to each insult. Together the two arms of immunity generate a highly effective immune protection system.

from another, to identify cancer cells, and to discriminate the body's own "self" molecules and cells as different from "nonself" molecules and cells. After recognition of nonself, the adaptive system responds by activating and amplifying specific **lymphocytes** to attack it. Recall that we defined lymphocytes in chapter 33 based on their physical appearance and generic duties within the host. In this chapter, we define them based on their specific biological functions.

The lymphocytes of concern are B cells and T cells. To begin, B- and T-cell progenitor cells develop in the embryonic bone marrow and relocate to specialized tissue sites for maturation. The B cells relocate to microenvironments within the bone marrow, leaving to seed secondary tissue sites when they are fully mature. The T-cell progenitors leave the bone marrow and migrate to the thymus, where they develop into at least four subsets of T cells. They also populate secondary lymphoid tissue sites once they mature (*see figure 33.14*). Mature B cells and T cells are induced to elicit an **effector response** when a foreign, nonself material is detected. A successful effector response either eliminates the foreign material or renders it harmless to the host. As a consequence of initial activation, some lymphocytes enter a state of limited activity and are referred to as **memory cells** because they will "remember" the foreign material that initially activated them. If the same substance is encountered at a later time, the B and T memory cells are already programmed to mount a response that is more intense and rapid to eliminate the nonself material to once again protect the host.

Four characteristics distinguish adaptive immunity from innate resistance:

1. **Discrimination between self and nonself.** The adaptive immune system almost always responds selectively to nonself and produces responses tailored to protecting against that type stimulus (e.g., virus vs. bacterium).
2. **Diversity.** The system is able to generate an enormous diversity of molecules such as cellular receptors and soluble proteins, including antibodies, that recognize trillions of different foreign substances.
3. **Specificity.** Immunity is highly selective in that it can be directed against one particular pathogen or foreign substance (among trillions); the immunity to one pathogen or substance usually does not confer immunity to others.
4. **Memory.** When reexposed to the same pathogen or substance, the host reacts so quickly that there is usually no noticeable illness. By contrast, the reaction time for innate defenses is just as long for later exposures to a given antigen as it was for the initial one.

Two branches or arms of adaptive immunity are recognized (figure 34.1): humoral immunity and cellular (cell-mediated) immunity. **Humoral (antibody-mediated) immunity,** named for the fluids or "humors" of the body, is based on the action of soluble glycoproteins called antibodies that occur in body fluids and on the plasma membranes of B lymphocytes. Circulating antibodies bind to microorganisms, toxins, and extracellular viruses, neutralizing them or "tagging" them for destruction by phagocytes and other mechanisms described in section 34.8. **Cellular (cell-mediated) immunity** is based on the action of specific kinds of T lymphocytes that directly attack target cells infected with viruses or parasites, transplanted cells or organs, and cancer cells. T cells release cytokines that can induce or assist with target cell suicide (apoptosis), target cell lysis, B-cell development, antibody production, or other functions that enhance adaptive immunity and innate defenses, such as phagocytosis and inflammation. Because the activity of the acquired immune response is so potent, it is imperative that T and B cells consistently discriminate between self and nonself with great accuracy. How they accomplish this is discussed next.

34.2 Molecules That Elicit Immunity Are Called Antigens

After reading this section, you should be able to:

- Predict the types of molecules that can serve as antigens
- Compare haptens and true antigens

While cells of the innate arm of immunity use a limited library of molecular patterns with which to identify nonself, the adaptive arm of immunity uses a more sophisticated database of biochemical and structural features to recognize foreignness. The term **antigen** refers to any self or nonself substance that elicits an immune response. Antigens include microbe-associated molecular patterns (MAMPS, described in chapter 33) as well as other molecules, including proteins, nucleoproteins, polysaccharides, and some glycolipids. While the term immunogen (*immun*ity *gen*erator) is a more precise term for a substance that elicits an immune response, antigen is used more frequently. Most antigens are large, complex molecules with a molecular mass generally greater than 10,000 daltons (Da). The ability of a molecule to function as an antigen depends on its size, structural complexity, chemical nature, and degree of foreignness to the host. ◀◀ *Lymphocytes (section 33.4)*

Each antigen can have several **antigenic determinant sites,** or **epitopes** (figure 34.2). Epitopes are the regions or sites of the antigen that bind to a specific antibody or T-cell receptor. Chemically, epitopes include sugars, organic acids and bases, amino acid side chains, hydrocarbons, and aromatic groups. The number of epitopes on the surface of an antigen is its **valence.** The valence determines the number of antibody molecules that can combine with the antigen at one time. If one determinant site is present, the antigen is monovalent. Most antigens, however, have more than one copy of the same epitope and so are multivalent. Multivalent

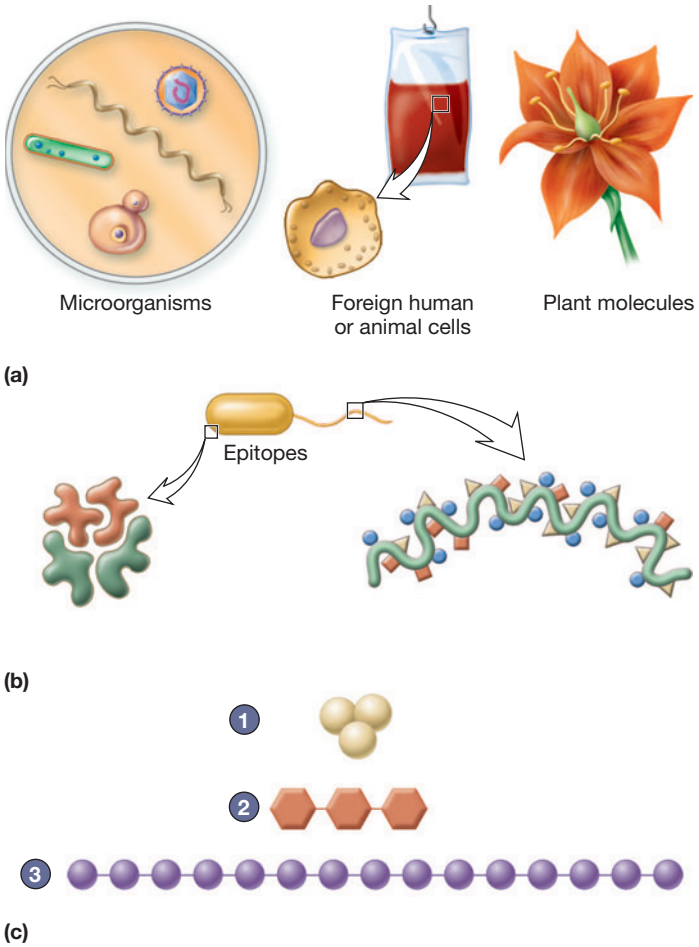

Figure 34.2 Antigen Characteristics Are Numerous and Diverse. (a) Whole cells, viruses, and some plant molecules are immunogenic, because they (b) have complex, three-dimensional configurations. (c) Molecules that are poorly immunogenic include (1) small molecules (haptens) not attached to a carrier molecule, (2) linear and conserved molecules, and (3) some large but repetitive molecules.

MICRO INQUIRY *What does the term valence mean and how does an antigen's valence influence an immune response?*

antigens generally elicit a stronger immune response than monovalent antigens. **Antibody affinity** relates to the strength with which an antibody binds to its antigen at a given antigen-binding site. Affinity tends to increase during the course of an immune response (section 34.7). The **avidity** of an antibody relates to its overall ability to bind antigen at all antigen-binding sites.

Haptens

Many small organic molecules are not antigenic by themselves but become antigenic if they bond to a larger carrier molecule such as a protein. These small molecules are called **haptens** (Latin *haptein,* to grasp). When lymphocytes are stimulated by combined hapten-carrier molecules, they can react to either the hapten or the larger carrier molecule. One example of a hapten is penicillin. By itself, penicillin is a small molecule that is not antigenic. However, when it

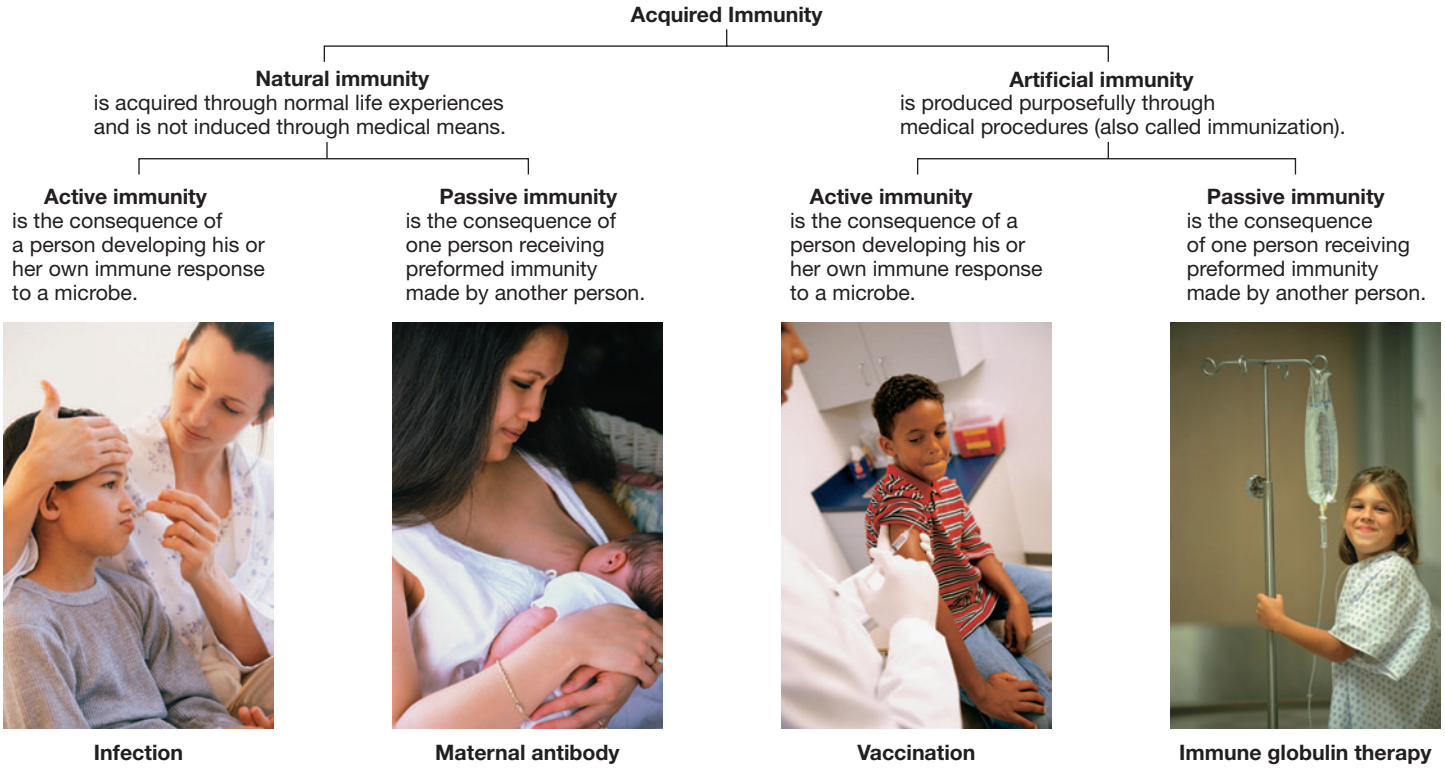

Figure 34.3 Immunity Can Be Acquired by Various Means.

is combined with certain serum proteins in sensitive individuals, it becomes immunogenic, activates lymphocytes, and initiates a severe and sometimes fatal allergic immune reaction. In these instances, the hapten is acting as an antigenic determinant or epitope.

Retrieve, Infer, Apply

1. Distinguish between self and nonself substances.
2. Define and give several examples of an antigen. What is an antigenic determinant site or epitope?
3. How does a hapten differ from an antigen?

34.3 Adaptive Immunity Can Be Earned or Borrowed

After reading this section, you should be able to:

- Report the methods by which immunity occurs by natural and artificial means
- Distinguish between the active and passive forms of natural and artificial immunity

Adaptive immunity refers to the type of acquired immunity a host develops after exposure to foreign substances or after transfer of antibodies or lymphocytes from an immune donor. Adaptive immunity results in a specific response to foreign substances and can be obtained actively or passively by natural or artificial means (**figure 34.3**).

Naturally Acquired Immunity

Naturally acquired active immunity occurs when an individual's immune system contacts an antigen such as a pathogen that causes an infection. The immune system responds by producing antibodies and activated lymphocytes that inactivate or destroy the pathogen. The immunity produced can be either lifelong, as with measles or chickenpox, or last for only a few years, as with influenza. **Naturally acquired passive immunity** involves the transfer of antibodies from one host to another. For example, some of a pregnant woman's antibodies pass across the placenta to her fetus. If the woman is immune to diseases such as polio or diphtheria, this placental transfer also gives her fetus and newborn temporary immunity to these diseases. Certain other antibodies can pass from a mother to her offspring when the child is fed breast milk. These maternal antibodies are essential for providing immunity to the newborn for the first few weeks or months of life, as the child's own immune system matures. Naturally acquired passive immunity generally lasts only a short time (weeks to months, at most).

Artificially Acquired Immunity

Artificially acquired active immunity results when an animal is vaccinated; that is, intentionally exposed to a foreign material and induced to form antibodies and activated lymphocytes. A **vaccine** may consist of a preparation of killed microorganisms; living, weakened (attenuated) microorganisms; genetically engineered organisms or their products; or inactivated bacterial toxins (toxoids) that are administered to induce immunity artificially. The

vaccine material induces production of antibodies and activated lymphocytes that bind to the whole bacterium, virus, toxin, and so forth to inactivate or help remove them from the host. Vaccines and immunizations are discussed in detail in chapter 37.

Artificially acquired passive immunity results when antibodies or lymphocytes produced by one host are introduced into another. Although this type of immunity is immediate, it is short-lived, lasting only a few weeks to a few months. An example of artificially acquired passive immunity would be botulinum antitoxin produced in a horse and given to a human suffering from botulism food poisoning.

Retrieve, Infer, Apply

1. What are the types of adaptive immunity?
2. What distinguishes natural from artificial immunity?
3. What are ways that active immunity is different from passive immunity?
4. Of the four types of acquired immunity, which do you think your immune system has undergone?

34.4 Recognition of Foreignness Is Critical for a Strong Defense

After reading this section, you should be able to:

- Define the method by which a host distinguishes itself from nonself (foreign) materials
- Diagram the host cell receptors that distinguish self from nonself
- Compare the processes by which MHC class I and class II receptors recognize foreignness
- Identify cells that can function as antigen-presenting cells (APCs)
- Explain the need to use "cluster of differentiation" (CD) molecules to name cells

Distinguishing between self and nonself is essential in maintaining host integrity. This distinction must be highly specific and selective so invading pathogens are eliminated but host tissue is not destroyed. An important extension of this exquisite survival mechanism, where self is distinguished from nonself, is seen in the modern use of tissue transplantation, where organs, tissues, and cells from unrelated persons are carefully matched to the self-recognition markers on the recipient's cells. While entire textbooks are devoted to this subject, we only discuss the aspects of foreignness recognition that assist us in understanding why and how lymphocytes respond.

Recall that each cell of a particular host needs to be identified as a member of that host so it can be distinguished from foreign invaders. To accomplish this, each cell must express proteins that mark it as a resident of that host. Furthermore, it is not enough to simply identify resident (self) cells; in addition, effective cooperation between cells must occur so that efficient information sharing and selective responses occur. Such a system has evolved in mammals and is encoded in the major histocompatibility gene complex.

The Major Histocompatibility Complex

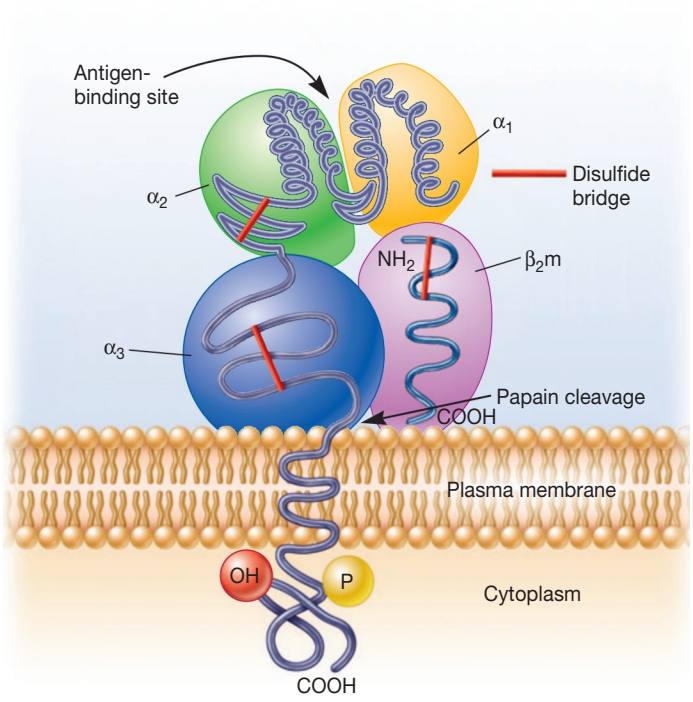
The ***m*ajor *h*istocompatibility *c*omplex** (**MHC**) is a collection of genes encoding proteins that enable the host to distinguish between self and nonself. The term histocompatibility is derived from the Greek word for tissue (*histo*) and the ability to get along (*compatibility*). Human MHC is located on chromosome 6 and is called the ***h*uman *l*eukocyte *a*ntigen** (**HLA**) complex. HLA proteins can be divided into three classes: class I are found on all types of nucleated body cells; class II appear only on cells that can process antigens and present them to other cells (i.e., macrophages, dendritic cells, and B cells); and class III molecules include various secreted proteins that have immune functions. Class III molecules are not required for the discrimination between self and nonself and will not be discussed further.

Class I MHC molecules include HLA types A, B, and C, and serve to identify almost all cells of the body as "self." They consist of a complex of two protein chains, one with a mass of 45,000 daltons, known as the alpha chain, and the other with a mass of 12,000 Da called β_2-microglobulin (**figure 34.4*a***). Only the alpha chain spans the plasma membrane, but both chains interact to form an antigen-binding pocket. Because MHC class I proteins are found on all nucleated cells (i.e., only red blood cells lack them), they stimulate an immune response when cells from one host are introduced into another host with different class I molecules. This is the basis for MHC typing when a patient is being prepared for an organ or bone marrow transplant.

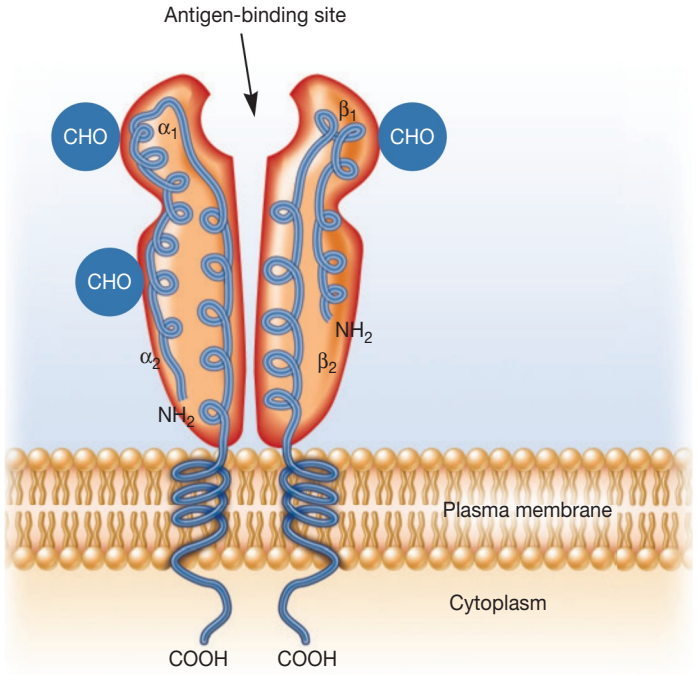
HLA proteins differ among individuals; the closer two people are related, the more similar are their HLA molecules. In addition, many forms of each HLA gene exist (i.e., HLA genes are polymorphic). This is because multiple alleles of each gene have arisen by gene mutation, recombination, and other mechanisms. Additionally, because HLA genes are codominant, each person expresses both alleles at each A, B, or C locus. Thus a person produces six different class I MHC proteins.

Class II MHC molecules are produced only by certain white blood cells, such as activated macrophages, dendritic cells, mature B cells, some T cells, and certain cells of other tissues. Importantly, class II molecules are required for T-cell communication with macrophages, dendritic cells, and B cells. Class II MHC molecules are also transmembrane proteins consisting of two distinct (heterodimeric) chains (figure 34.4*b*). Similar to MHC class I, the protein chains expressed from MHC class II genes combine to form a three-dimensional antigen-binding pocket into which a nonself peptide fragment can be captured for presentation to other cells of the immune system (immunocytes). Although MHC class I and class II molecules are structurally distinct, both fold into similar shapes. Each MHC molecule has a deep groove into which a short peptide derived from a foreign substance can bind (figure 34.4*c,d*). As discussed in section 34.5, antigen fragments in the MHC groove must be present to activate T cells, which in turn activate other immunocytes.

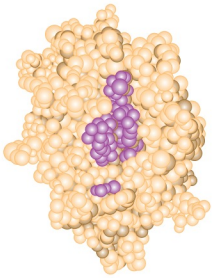
Class I and class II molecules inform the immune system of the presence of nonself by binding and presenting foreign peptides. These peptides arise in different places within cells as the result of **antigen processing** (**figure 34.5**). Class I molecules bind to peptides that originate in the cytoplasm. Foreign peptides within the cytoplasm of mammalian cells come from viruses or other intracellular pathogens, or are the result of cancerous transformation.



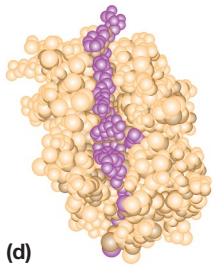
(a) Class I MHC



(b) Class II MHC



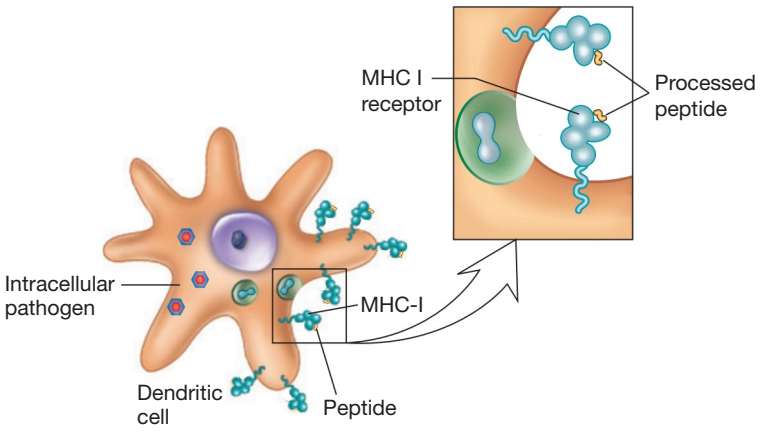
(c)



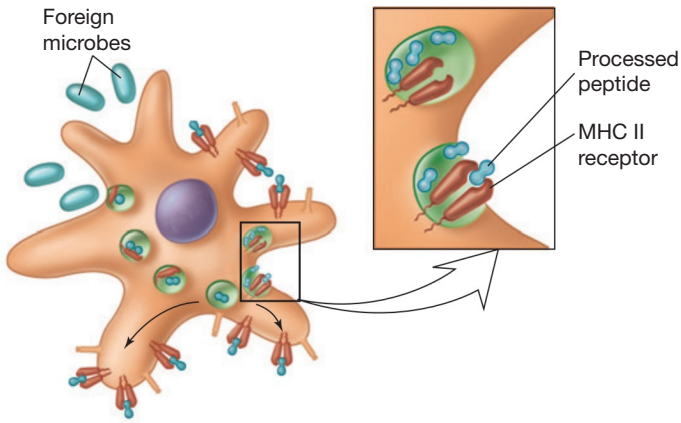
(d)

Figure 34.4 The Membrane-Bound Class I and Class II Major Histocompatibility Complex Molecules. (a) The class I molecule is a heterodimer composed of the alpha protein, which is divided into three domains: α_1, α_2, and α_3, and the protein β_2 microglobulin (β_2m). (b) The class II molecule is a heterodimer composed of two distinct proteins called alpha and beta. Each is divided into two domains α_1, α_2 and β_1, β_2, respectively. (c) This space-filling model of a class I MHC protein illustrates that it holds shorter peptide antigens (blue) than does a class II MHC. (d) The difference is because the peptide binding site of the class I molecule is closed off, whereas the binding site of the class II molecules is open on both ends.

MICRO INQUIRY *On what types of cells are MHC class I molecules found? MHC class II?*



(a)



(b)

Figure 34.5 Antigen Presentation. (a) Antigens arising from within a cell (including intracellular parasites) are degraded by a proteasome and integrated into the antigen-binding site of the MHC class I proteins for presentation on the cell surface. (b) Antigens arising from outside a phagocytic cell are captured by endocytosis and degraded by the lysosomal process and integrated into the antigen-binding site of MHC class II proteins for presentation on the cell surface.

MICRO INQUIRY *What cells recognize and bind to MHC class I molecules that carry antigens? What about MHC class II molecules with antigen?*

These intracellular antigenic proteins are digested by proteasomes (*see figure 5.8*) as part of the natural process by which a cell continually recycles its protein contents. Specific transport proteins are used to translocate the resulting short peptide fragments from the cytoplasm into the endoplasmic reticulum (ER). The class I MHC alpha chain and the β_2-microglobulin associate within the lumen of the ER. The class I MHC molecule and antigenic peptide are then carried to and anchored in the plasma membrane. This process, known as **endogenous antigen processing,** enables the host cell to present the antigen to a subset of T cells called $CD8^+$, or cytotoxic T lymphocytes (CTLs). $CD8^+$ T cells bear a receptor that is specific for class I MHC molecules presenting antigen; as will be discussed in section 34.5, these T cells bind and ultimately kill host cells presenting this foreign protein fragment.

Class II MHC molecules bind to fragments that initially come from antigens outside the cell, thus they undergo **exogenous antigen processing.** This pathway functions with particles (e.g., bacteria, viruses, toxins) that have been taken up by endocytosis. An **antigen-presenting cell** (**APC**), such as a macrophage, dendritic cell, or B cell, takes in the antigen or pathogen by receptor-mediated endocytosis or phagocytosis and produces antigen fragments by digestion in the phagolysosome. Fragments then combine with preformed class II MHC molecules and are delivered to the cell surface. The peptide within the MHC class II antigen-binding site can now be recognized by $CD4^+$ T-helper cells. Dendritic cells are particularly adept at presenting foreign peptides to T cells and stimulating them to become activated T cells. Unlike $CD8^+$ T cells, $CD4^+$ T cells do not directly kill target cells. Instead, they respond in two distinct ways. One is to proliferate, thereby increasing the number of $CD4^+$ cells that can react to the antigen. Some of these cells will become memory T cells that can respond to subsequent exposures to the same antigen. The second response is to secrete proteins that either directly inhibit the pathogen that produced the antigen or recruit and stimulate other cells to join in the immune response. ⏮ *Several cytoplasmic membranous organelles function in the secretory and endocytic pathways (section 5.4) Cytokines are chemical messages between cells (section 33.3); Phagocytosis (section 33.5)*

Cluster of Differentiation Molecules

As we note in the previous section, two important T cells are $CD4^+$ and $CD8^+$ T cells. These cells are so named because they bear cell-surface proteins that have specific roles in intercellular communication and are called ***c*luster of *d*ifferentiation (CDs) molecules** or **antigens** (also known as immunogens). Other cells also bear specific CD molecules. CDs are cell-surface proteins and many are receptors. CDs have both biological and diagnostic significance. They can be measured in situ and from peripheral blood, biopsy samples, or other body fluids. They often are used in a classification system to differentiate between leukocyte subpopulations. To date, over 300 CDs have been characterized. **Table 34.1** summarizes some of the functions of several CDs.

The presence of various CDs on the cell's surface can be used to determine the cell's identity. For example, the CD4 molecule is a cell-surface receptor for the human immunodeficiency virus (HIV; the virus that causes AIDS), and CD34 is found on the surface of stem cells. As we will see, using the CD antigen system to name cells is more efficient than describing all of a cell's functions. We also use this approach in naming specific cell types as we discuss their relative functions in immunity.

Retrieve, Infer, Apply

1. What are MHCs and HLAs? Describe the roles of the three MHC classes.
2. Define CD molecules.
3. Give some examples of the biological significance of cluster of differentiation molecules (CDs).
4. How are foreign peptides processed so as to activate $CD4^+$ T-helper cells and $CD8^+$ cytotoxic T cells, respectively?

Table 34.1 Functions of Some Cluster of Differentiation (CD) Molecules

Molecule	Function
CD1 a, b, c	MHC class I–like receptor used for lipid antigen presentation
CD3 δ, ε, γ	T-cell antigen receptor
CD4	MHC class II coreceptor on T cells, monocytes, and macrophages; HIV-1 and HIV-2 (gp120) receptor
CD8	MHC class I coreceptor on cytotoxic T cells
CD11 a, b, c, d	α-subunits of integrin found on various myeloid and lymphoid cells; used for binding to cell adhesion molecules
CD19	B-cell antigen coreceptor
CD34	Stem cell protein that binds to sialic acid residues
CD45	Tyrosine phosphatase common to all hematopoietic cells
CD56	NK cell and neural cell adhesion molecule

34.5 T Cells Oversee and Participate in Immune Functions

After reading this section, you should be able to:

- Categorize T cells based on their CD designation
- Contrast the biological functions of T-cell subsets
- Describe T-cell receptor structure and function
- Illustrate the T-cell developmental process
- Connect antigen presentation within MHC receptors and T-cell subset recognition
- Build a model of the molecular events resulting in T-cell activation

For adaptive immunity to develop, T cells and B cells must be activated. Activation results in proliferation and differentiation of progenitor cells into numerous T- and B-cell subsets, with environmental signals determining the final type of cell that forms. These include T cells ($CD8^+$ and $CD4^+$) cells that are major players in the cell-mediated immune response and have a major role in B-cell activation. They are immunologically adaptive, can carry a vast repertoire of immunologic memory, and can function in a variety of regulatory and effector ways. Because of their paramount importance, we discuss them first.

T-Cell Receptors

T cells respond to antigen fragments presented by MHC molecules through specific **T-cell receptor** (**TCR**) complexes on their plasma membrane surface. Each receptor complex is composed of two parts: a heterodimeric polypeptide receptor, and six accessory polypeptides, collectively referred to as CD3 (**figure 34.6*a***). The heterodimeric receptor can be one of two possible TCR dimers, the predominant α/β or the γ/δ; thus cells can be designated **α/β T cells** and **γ/δ T cells,** respectively. Each heterodimer forms a transmembrane receptor stabilized by disulfide bonds. The antigen recognition sites of the receptors form when the extracellular amino termini of the α and β or γ and δ; chains interact and create a three-dimensional pocket having terminal variable sections complementary to antigen fragments (similar to MHC antigen-binding sites). The cytoplasmic tails of the receptors associate with the CD3 accessory polypeptides, and transduce antigen-binding events into intracellular signals (figure 34.6*b*).

T-Cell Activation

During antigen presentation, the antigen held by the MHC of the antigen-presenting cell is bound by the TCR of the T cell, thus forming a bridge between the two (figure 34.6*b*). This causes a three-dimensional change in the TCR that stimulates the CD3 accessory proteins to send molecular signals to the T-cell nucleus. However, full T-cell activation occurs only when a second signal is communicated along with the antigen. A general discussion of this process in T cells now follows.

All naïve T cells require two signals to be activated into effector cells. **Signal 1** occurs when an antigen fragment, presented in

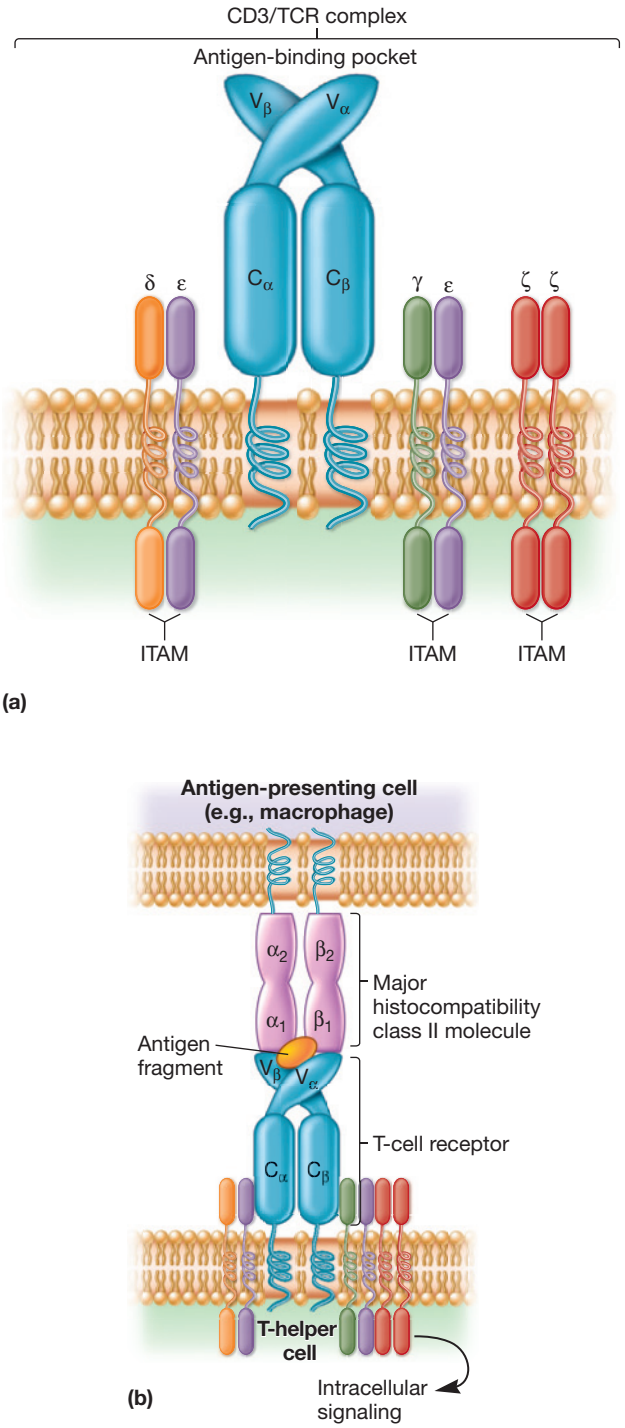


Figure 34.6 The T-Cell Receptor Protein Complex in T-Helper Cell Activation. (a) The overall structure of the antigen receptor complex on a T-cell plasma membrane. Notice the CD3 accessory proteins that convey the signal of antigen capture intracellularly. Extracellular antigen binding is communicated internally through the immunoreceptor tyrosine-based activation motifs (ITAMs) on the CD3 proteins. (b) An antigen-presenting cell begins the activation process by displaying an antigen fragment (e.g., peptide) within histocompatibility molecules. A T-helper cell is activated after the variable region of its receptor (designated V_α and V_β) reacts with the antigen fragment in a class II MHC molecule on the presenting cell surface.

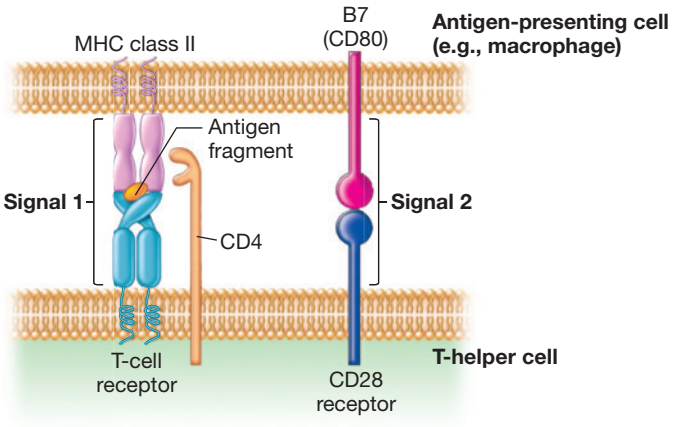
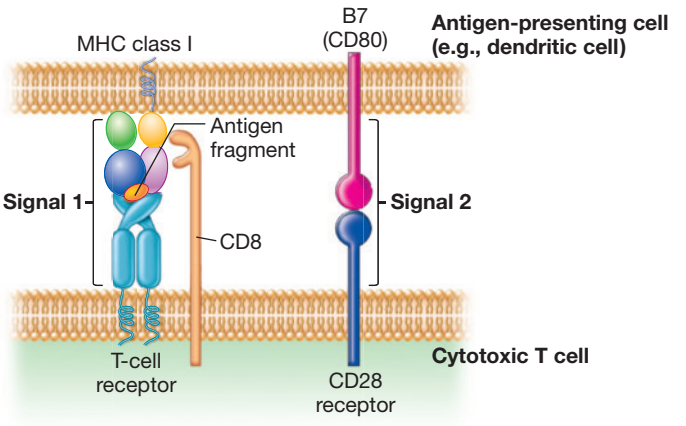
an MHC molecule of an antigen-presenting cell (APC), fills the appropriate T-cell receptor. In the case of T-helper (T_H) cells, antigen is presented by class II MHC molecules, which triggers CD4 coreceptors on the T_H cell to interact with the antigen-bound MHC molecule (**figure 34.7*a***). For $CD8^+$ cells to be activated, an endogenous (cytoplasmic) antigen is presented in class I MHC molecules on the APC, and the CD8 coreceptor on the T cell interacts with the antigen-bound MHC molecule on the APC to induce CTL function (figure 34.7*b*). In both cases, the T-cell coreceptor assists with signal 1 recognition.



(a)



(b)

Figure 34.7 Two Signals (Co-stimulation) Are Essential for T-Helper Cell Activation. The first signal is the presentation of the antigen fragment by a dendritic cell or other antigen-presenting cell (a) in the MHC class II molecule to activate the T-helper cell. (b) The first signal for T_C cells is presentation of the antigen fragment in the MHC class I molecule. The second signal occurs when the dendritic cell presents the B7 (CD80) protein to the T-helper or cytotoxic T cell with its CD28 protein receptor. Note that the CD3 complex is not shown.

MICRO INQUIRY *How can T-helper cells facilitate $CD8^+$ cell activation?*

In addition to signal 1, both naïve $CD4^+$ and $CD8^+$ cells require a second, co-stimulatory **signal 2** to become activated. More than one factor may contribute to signal 2, but the most important seems to be the **B7 (CD80) protein** on the surface of an APC, which binds to the CD28 receptor on the T cell (figure 34.7*b*). The activated T cell then synthesizes and secretes IL-2 to drive its own proliferation and differentiation. Overall, once T cells have been activated by two signals, they differentiate rapidly to respond to the antigen that activated them. T cells that receive only signal 1 often become **anergic,** or unresponsive.

One type of APC that is particularly good at stimulating naïve T cells is the dendritic cell. This is because it expresses high levels of B7 at all times. Other APCs may not produce sufficient B7 unless stimulated to do so. Poor B7 stimulation of $CD8^+$ cells requires activated $CD4^+$ (also known as T_H) cells to stimulate the APC to generate a different signal 2. This is one way in which T_H cells help $CD8^+$ T cells become activated. ◀◀ *Monocytes, macrophages, and dendritic cells (section 33.4)*

Types of T Cells

T cells originate from $CD34^+$ stem cells in the bone marrow, but T-cell precursors migrate to the thymus for further differentiation. This includes destruction or inactivation of cells that recognize self antigens (so-called self-reactive T cells). T-cell development in the thymus also results in its differentiation into one of four functional lineages. T cells differentiate into progenitor cells destined to become (1) natural T regulatory (nTreg) cells, (2) natural killer T (NKT) cells, (3) γ/δ T cells, and (4) α/β T cells (**figure 34.8**).

The α/β T cells make up the bulk of all T cells. They circulate in the blood in small numbers and are found in the secondary lymphoid tissues. Recall that the α/β designation describes the type of T-cell receptor (TCR) on these cells. In addition, α/β T cells also have either the CD4 or CD8 coreceptor to facilitate TCR recognition of the class II or class I MHC, respectively. Thus, an α/β T cell can be either a helper or cytotoxic T cell. Like all lymphocytes, T cells that have survived the process of development are called mature cells, but they are also considered to be "naïve" cells because they have not yet been activated by a specific MHC-antigen peptide combination. Activation of T cells involves specific molecular signaling events inside the cell, which is discussed in the section on T-cell activation. Antigen stimulation induces α/β T cells to assume their active roles as **effector cells,** as well as memory cells (figure 33.11). Effector T cells carry out specific functions to protect the host against foreign antigen. Effector $CD4^+$ T cells include the T-helper (T_H) cells, and the effector $CD8^+$ T cells mature into CTLs.

T-Helper Cells

Mature, naïve **T-helper (T_H) cells** are also known as **$CD4^+$ T cells.** The activation of specific transcription factors in response to cytokine stimulation drives naive T cells to differentiate into one the following types of $CD4^+$ T-helper cells: T_H type 1 (T_H1) cells, T_H type 2 (T_H2) cells, T_H type 9 (T_H9) cells, T_H type 17

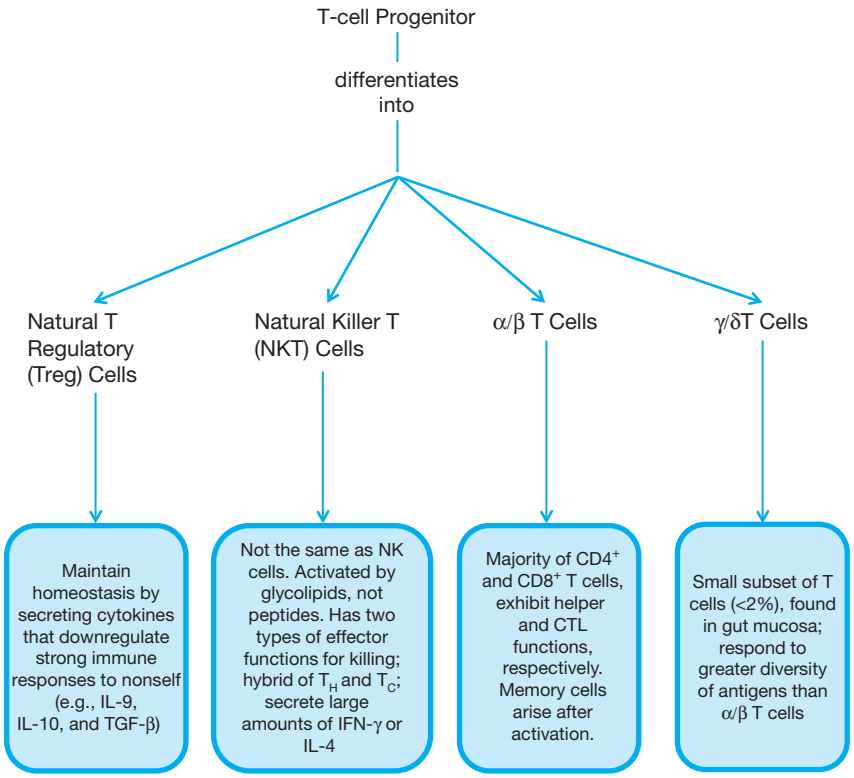


Figure 34.8 T-Cell Populations. T-cell subsets differentiate from their progenitor cells in the thymus. They leave the thymus upon maturation; however, they are still naïve in that they have not been activated by their specific antigen. At least four T-cell subsets leave the thymus and populate secondary lymphoid tissues where they await antigen activation.

(T_H17) cells, T_H type 22 (T_H22), T follicular helper type (T_{fh}) cells, $CD4^+$ induced regulatory T cells (iTreg), and T_H memory cells (**figure 34.9*a***). **T_H0** is often used to designate cells that are simply undifferentiated precursors of these cells.

T_H1 cells promote cytotoxic T lymphocyte activity, activate macrophages, and mediate inflammation by producing interleukins, interferon (IFN)-γ, and tumor necrosis factor-β (TNF-β) when the transcription factor T-bet is active. These cytokines are also responsible for delayed-type (type IV) hypersensitivity reactions, in which host cells and tissues are damaged nonspecifically by activated T cells (p. 763).

T_H2 cells tend to stimulate antibody responses in general and defend against helminth parasites by producing IL-4, IL-5, IL-6, IL-10, and IL-13. An overabundance of T_H2-type responses may also be involved in promoting allergic reactions.

T_H9 cells halt their characteristic T_H2 profile upon exposure to TGF-β and subsequently produce IL-9. IL-9 stimulates hematopoiesis and inhibits programmed cell death (apoptosis). T_H9 cells have been found in inflamed tissue and associated with autoimmune disease.

T_H17 cells result from exposure of naïve T_H cells to TGF-β and IL-6. These cells are found predominantly in the skin and intestinal epithelia, where they respond to bacterial invasion by secreting IL-17 and defensins, recruiting neutrophils, and inducing a strong inflammatory response. In addition, T_H17 cells have been implicated in several autoimmune diseases.

T_H22 cells differentiate from naïve $CD4^+$ T cells upon exposure to IL-6 and TNF-alpha. They primarily secrete pro-inflammatory cytokines IL-22, IL-13, and TNF-alpha. They are typically found at innate barriers (skin, intestine, lungs), where they act on various cell populations regulating wound healing and repair.

T_{fh} cells develop from antigen-stimulated $CD4^+$ T cells. They migrate through secondary lymphoid tissues, coaxing B cells to migrate into regions of lymphoid tissues where they secrete IL-21 and IL-4 to promote B-cell antibody production.

Regulatory T cells (**Tregs**) are derived from approximately 10% of $CD4^+$ T cells and 2% of $CD8^+$ T cells in response to exposure to IL-10. IL-10 activates a transcription factor that leads to production of a protein that binds to B7 (CD80), blocking the second signal required for lymphocyte activation (p. 744). Tregs also exert suppressor/regulatory functions through the secretion of IL-9, IL-10, and TGF-β. These cytokines inhibit T_H1 and T_H17 cells from upregulating inflammatory responses and T_H2 cells from assisting B cells in making antibody and upregulating allergic responses, in addition to a wider range of suppressor activities. The relatively recent reports of T_H9, T_H17, T_H22, and T_{fh} cells suggest that new technologies that assess genome and proteome expression of single cells may continue to reveal a growing list of T-cell subsets. ◀◀ *Single-cell genome sequencing (section 18.2); Proteomics (section 18.4)*

Cytotoxic T Lymphocytes

Naïve **$CD8^+$ T cells** that express antigen-specific T-cell receptors (TCRs) are historically designated as cytotoxic T cells (T_C). Activation by its specific antigen causes a T_C cell to mature into a **cytotoxic T lymphocyte** (**CTL**) that functions to destroy host cells that have been infected by intracellular pathogens, such as a virus, or have altered MHC surface proteins. Recall that to be activated, $CD8^+$ T cells interact with APCs through their class I MHCs (figure 34.9*b*). This is important because these cells mature into CTLs that must respond only to the same antigen presented in the class I MHC of host cells. Any host cell that presents the same antigen in its class I MHC receptors is thus targeted for destruction. Once activated, CTLs kill target cells in at least two ways: a cytolytic pathway, using **perforins** and granulysins, that is similar to complement-mediated lysis; and apoptotic (programmed cell death) pathways triggered by CD95-Fas-FasL (ligand) or by granzymes and perforins.

Superantigens

Several bacterial and viral proteins can provoke a drastic and harmful response when they are exposed to T cells. These protein antigens are known as **superantigens** because they "trick" a huge

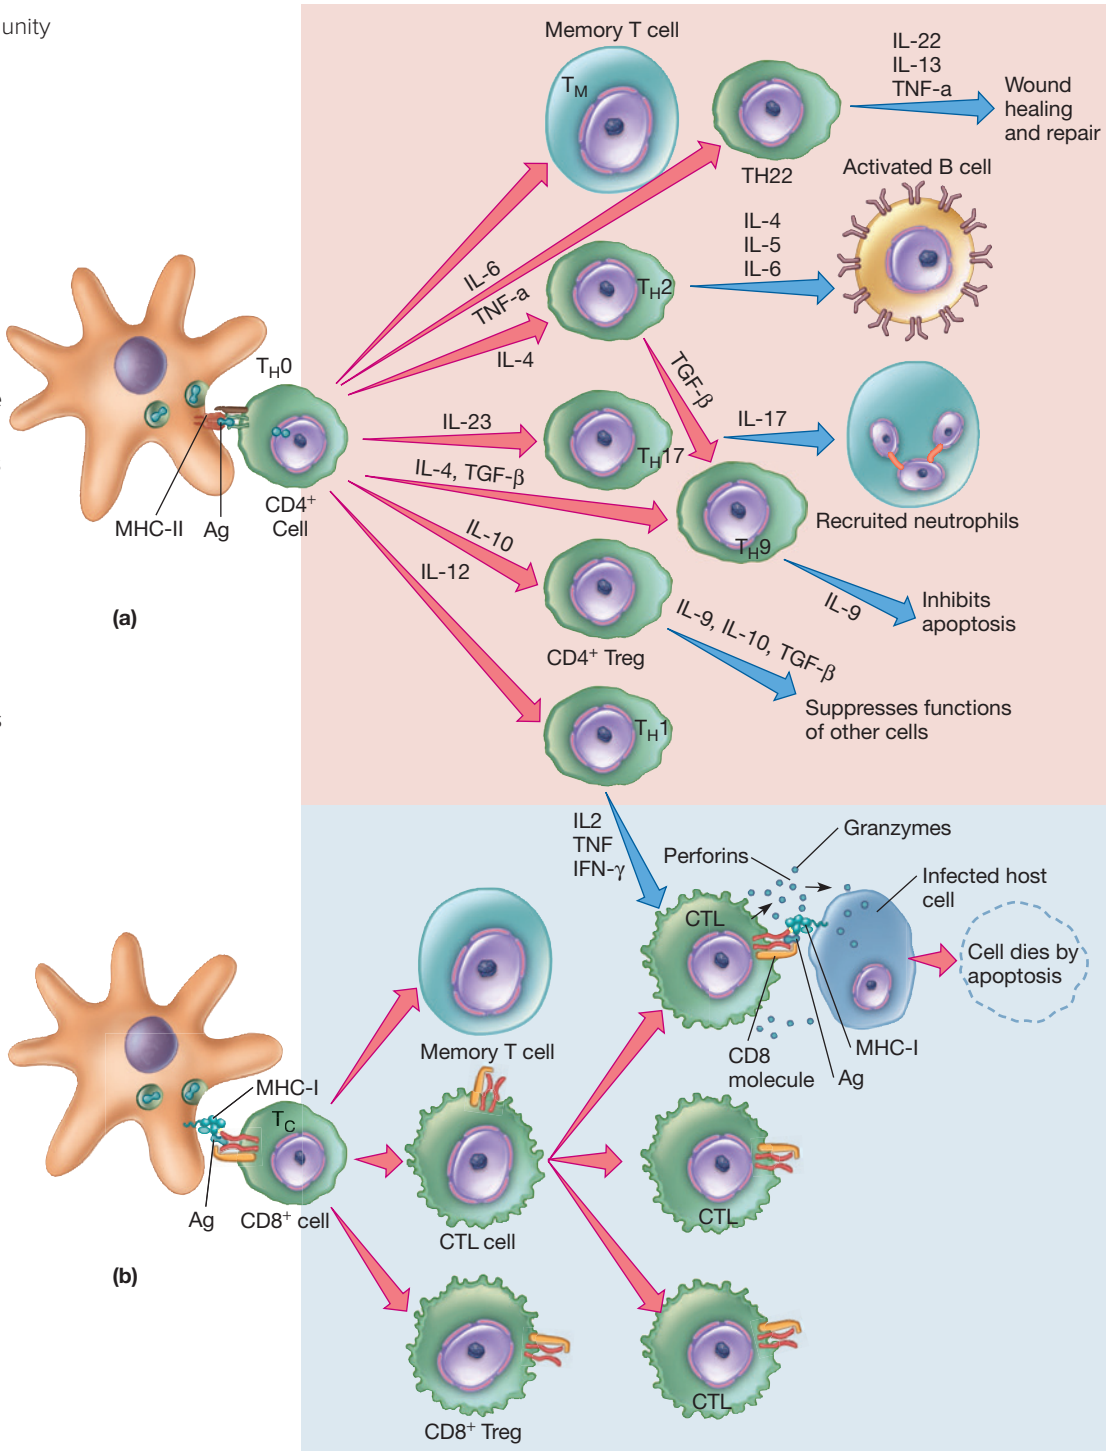

Figure 34.9 **T-Cell Development.** (a) Once activated, a $CD4^+$ T_H0 cell may differentiate into T_H1, T_H2, T_H9, T_H17, T_H22, or Treg cells. Cytokines near red arrows trigger differentiation of one cell to another while cytokines near blue arrows are produced by the associated cell. Memory T cells are also produced during expansion of the activated T-cell population. Each T_H phenotype secretes specific cytokines to effect the functions of other cells; some cytokines stimulate B-cell growth, replication, and antibody synthesis, others suppress migration and apoptosis, and still others enhance recruitment of phagocytes. (b) $CD8^+$ T_C cells differentiate into activated CTLs. CTLs induce apoptosis in target cells. (c) A cytotoxic T cell (left) contacts a target cell (right) (×5,700). (d) The CTL secretes perforin that forms pores in the target cell's plasma membrane. These pores allow the contents of the target cell to leak out and granzymes to enter and induce apoptosis.

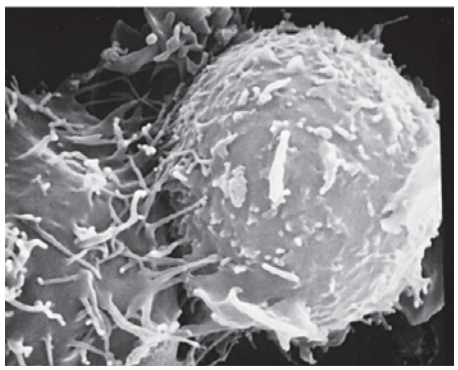
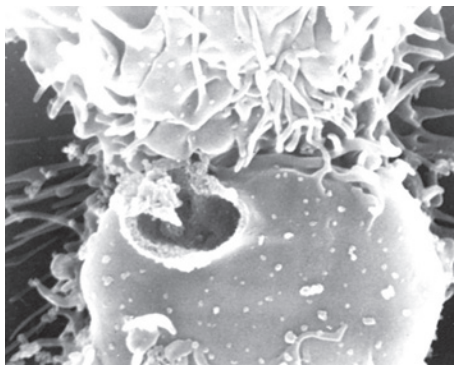


(c)



(d)

number of T cells into activation when no specific antigen has triggered them. Superantigens accomplish this by bridging class II MHC molecules on APCs to T-cell receptors in the absence of a specific antigen in the MHC-binding site. This interaction results in the activation of many different T cells with different antigen specificities. The consequence of this nonspecific activation is the release of massive quantities of cytokines from $CD4^+$ T cells. Indeed, nearly 30% of T cells can be activated by superantigen to overproduce pro-inflammatory cytokines such as TNF-α and interleukins 1 and 6, resulting in endothelial damage, circulatory shock, and multiorgan failure. Examples of superantigens include the staphylococcal enterotoxins (which can cause food poisoning) and the toxin that causes toxic shock syndrome. Because of these activities, staphylococcal enterotoxin B was originally added to the U.S. government's select agent list as a potential agent of terrorism. The devastating effects of superantigens serve to emphasize the importance of tightly regulating a normal immune response.

34.6 B Cells Make Antibodies and Do a Whole Lot More

After reading this section, you should be able to:

- Describe the B-cell receptor structure and function
- Illustrate the B-cell maturation process in response to antigen triggering
- Compare T-dependent- and T-independent B-cell activation
- Build a model of the molecular events resulting in B-cell activation

Stem cells in the bone marrow produce B-cell precursors *(see figure 33.11)*. Similar to T cells, it is becoming clear that unique subsets of B cells form along divergent developmental pathways and that these subsets may have unique functions. It appears that one subset acts more like cells of the innate resistance arm of immunity. Of note is that B cells also appear to express toll-like receptors (TLRs) throughout their developmental stages. Importantly, expression of TLRs on activated B cells may serve as additional (adjuvant-like) switches to regulate antibody production.

Until the science becomes clearer, we focus on the B-cell subset with a well-defined activation process. A specific antigen must activate these B cells so they can proliferate and differentiate into mature, antibody-secreting plasma cells. Prior to antigen stimulation, B cells produce a form of antibody (IgM or IgD) that is attached to their cell membrane and oriented so that the part of the antibody that binds to antigen is facing outward, away from the cell (**figure 34.10**). These cell-surface, transmembrane antibodies (also known as immunoglobulins) act as receptors for the

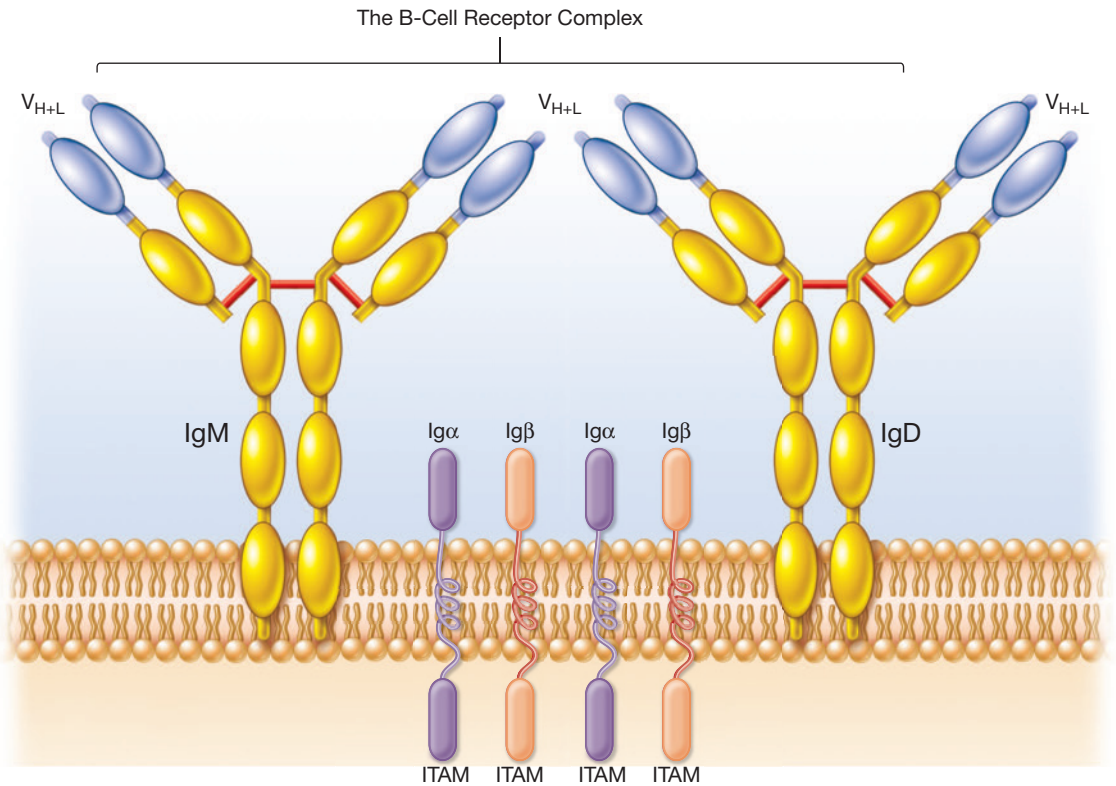

Figure 34.10 The Membrane-Bound B-Cell Receptor (BCR) Complex. The BCR is composed of monomeric IgM and IgD antibody, and the coreceptors Igα and Igβ. A B cell is activated after the variable region of one receptor (designated V_{H+L}) binds an antigen. The antigen is internalized, processed, and presented by the B cell's class II MHC molecule, so as to be recognized by a T_H2 cell (T-dependent activation). Activation can also occur after the variable regions of (two or more) receptors are bridged by an antigen (T-independent activation).

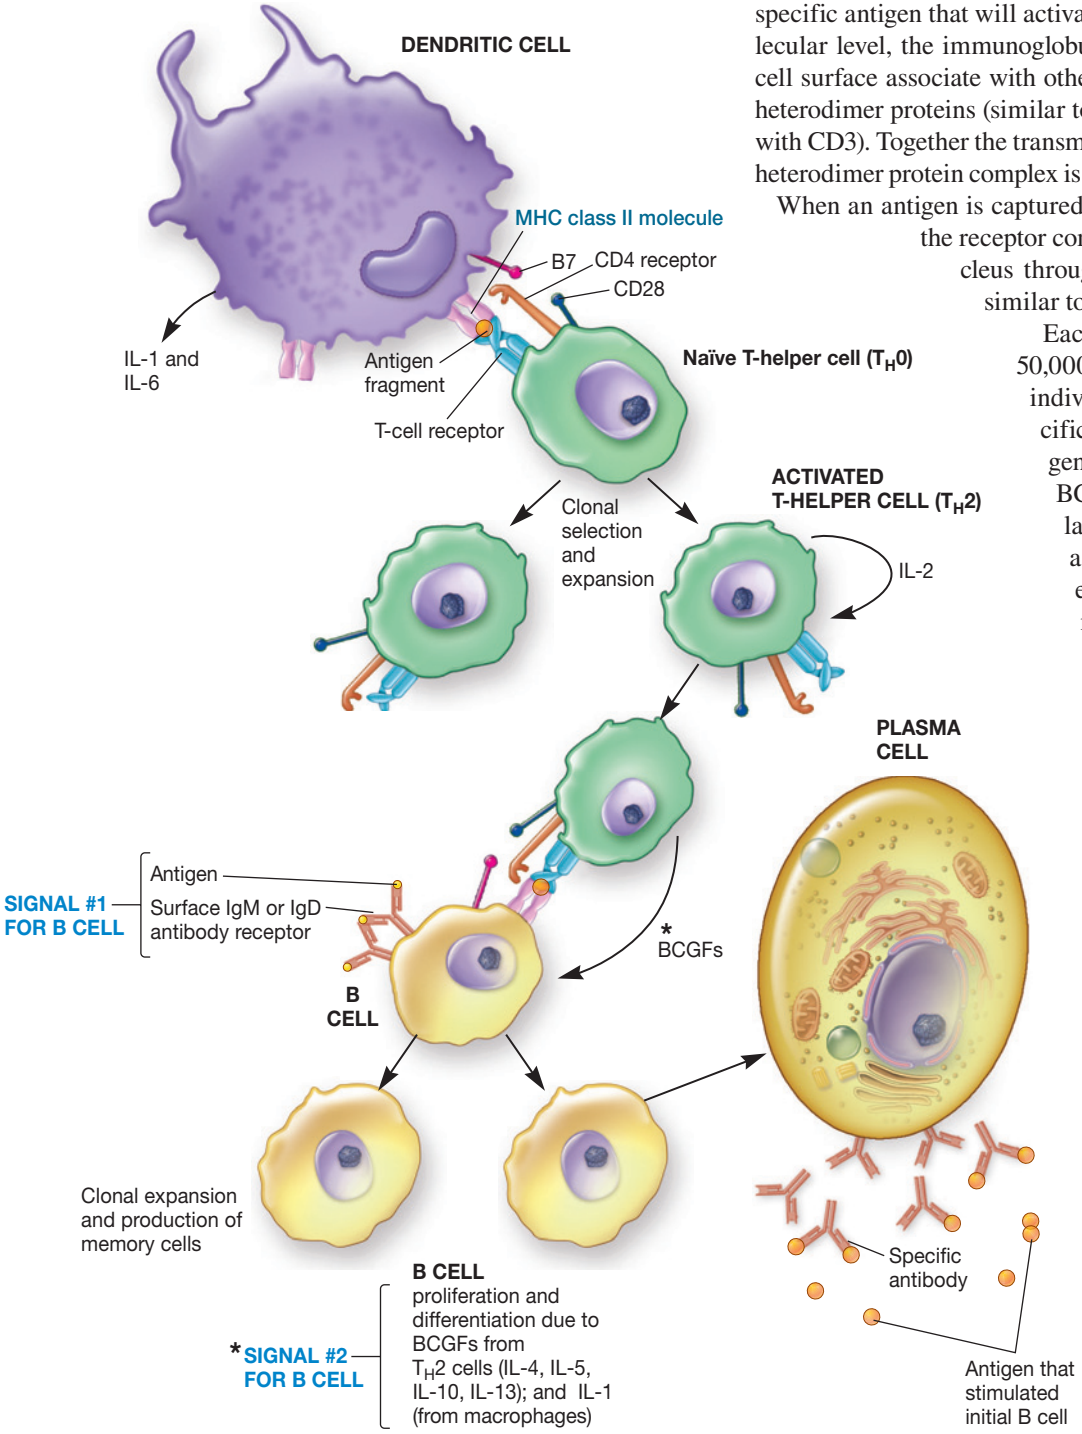

Figure 34.11 **T-Dependent Antigen Triggering of a B Cell.** Schematic diagram of the events occurring in the interactions between macrophages, T-helper cells, and B cells that produce humoral immunity. Many cytokines (e.g., IL-1, IL-4, IL-5, IL-6, IL-10, IL-13) act as B-cell growth factors (BCGFs) to stimulate B-cell proliferation. Cytokines such as IL-2, IL-4, IL-6, and IL-13 stimulate B-cell differentiation into plasma cells.

MICRO INQUIRY *Which cells are functioning as APCs in this figure?*

specific antigen that will activate that particular B cell. On a molecular level, the immunoglobulin receptor molecules on the B-cell surface associate with other proteins known as the Ig-a/Ig-b heterodimer proteins (similar to how the T-cell receptor interacts with CD3). Together the transmembrane immunoglobulin and the heterodimer protein complex is called the **B-cell receptor (BCR)**.

When an antigen is captured by the immunoglobulin receptor, the receptor communicates this capture to the nucleus through a signal transduction pathway similar to that described for T cells.

Each B cell may have as many as 50,000 BCRs on its surface. While each individual human carries BCRs specific for as many as 10^{13} different antigens, each individual B cell possesses BCRs specific for only one particular epitope on an antigen. Therefore a host produces at least 10^{13} different, undifferentiated B cells. These naïve B cells reside in the host awaiting activation by specific antigenic epitopes. Upon activation, B cells differentiate into antibody-producing **plasma cells** and memory cells (figure 34.1).

So far we have introduced the B-cell receptor and the fact that activated B cells secrete antibody. The fate of antigen bound to the BCR is critical for the transition from naïve B cell to antibody-secreting plasma cell. Once bound, B cells internalize the antigen-bound receptor by receptor-mediated endocytosis. Within the B cell, the antigen is transferred from the BCR to an MHC class II molecule, which then moves to the B-cell membrane to display the antigen on the B-cell surface. In this way, B cells become APCs, presenting antigen to T_H2 cells (**figure 34.11**). Upon formation of the immune synapse between the MHC class II on the B cell and TCR on the T_H2 cell, the B cell triggers the release of a specific suite of cytokines from the T_H2 cell. Thus the B and T_H2 cells activate each other. Interestingly, B cells are more effective antigen presenters than macrophages, especially at

low antigen concentrations. In summary, B cells have two immunological roles: (1) they proliferate and differentiate into memory cells and plasma cells, which respond to antigens by making antibodies, and at the same time (2) they can act as antigen-presenting cells, stimulating T cells to also respond.

B-Cell Activation

Similar to T cells, receptor binding is required to initially activate B cells, which may then also require growth and differentiation factors, supplied by other cells, to fully mature. T-helper cells are the primary source of cytokines that assist in this B-cell maturation process. This typical process is known as T-cell-dependent B-cell activation, because after stimulation by the antigen, the B-cell maturation process is dependent on the T_H2 cell for the cytokines to complete maturation. However, some antigens "force" the B cell into antibody production before T-cell growth and differentiation factors have influenced the maturation process. This other B-cell activation process is called T-cell-independent B-cell activation.

T-Dependent B-Cell Activation

In most cases, B cells specific for a given epitope on an antigen (e.g., epitope X) cannot develop into plasma cells that secrete antibody (anti-X) without the collaboration of T-helper cells; this is **T-dependent B-cell activation.** In other words, binding of epitope X to the B cell may be necessary, but it is not usually sufficient for B-cell activation. Antigens that elicit a response with the aid of T-helper cells are called **T-dependent antigens.** Examples include bacteria, foreign red blood cells, certain proteins, and hapten-carrier combinations.

T-dependent antigen triggering of a B cell occurs when an activated T_H2 cell directly associates with the B cell displaying the same antigen-MHC complex presented to the T_H2 on a dendritic cell. B-cell growth factors are then secreted by the activated T_H2 cell (figure 34.11). These interactions cause the B cell to proliferate and differentiate into a plasma cell, which starts producing antibodies. Thus B cells, like T cells, require two signals: antigen-BCR interaction (signal 1) and T-cell cytokines (signal 2). This is a very effective process: one plasma cell can synthesize more than 10 million antibody molecules per hour!

Interestingly, a subset of B cells has been identified that reins in T-cell–dependent inflammatory responses. These cells express the surface receptors CD1d and CD5, and also secrete the anti-inflammatory cytokine IL-10. They appear to be activated by a broad range of antigens and suppress T-dependent antibody responses elicited during inflammation.

T-Independent B-Cell Activation

As mentioned, a few specific antigens can trigger B cells into antibody production without T-cell cooperation. These are called **T-independent antigens,** and their stimulation of B cells is known as **T-independent B-cell activation.** Examples include bacterial lipopolysaccharides, certain tumor-promoting agents, antibodies against other antibodies, and antibodies to certain B-cell differentiation antigens. The T-independent antigens tend to be polymeric; that is, they are composed of repeating sugars or amino acids. The resulting antibody generally has a relatively low affinity for antigen.

The mechanism for activation by T-independent antigens probably depends on their polymeric structure. Large molecules present a wide array of identical epitopes to a B cell specific for that determinant. The repeating epitopes cross-link membrane-bound BCRs such that cell activation occurs and antibody is secreted. However, without T-cell help, the B cell cannot alter its antibody production, and no memory B cells are formed. Thus T-independent B-cell activation is less effective than T-dependent B-cell activation: The antibodies produced have a low affinity for antigen and no immunologic memory is formed.

Microbial Pattern Triggering

Identifying yet another crossover between innate and adaptive arms of the immune system, a unique subset of phenotypically distinct B cells, the innate response activator (IRA) B cells, not only make antibody but also produce granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-3. IRAs are typically found in the pleural and peritoneal cavities in a steady state of activation. In response to binding of bacterial lipopolysaccharide (LPS) by toll-like receptor-4 (TLR-4), they release large quantities of premade IgM antibody, and directly stimulate another subset of B cells to also release IgM. Additionally, IRAs then migrate to the spleen, where they secrete GM-CSF and IL-3, stimulating the production of phagocytes. Experimental models of sepsis suggest that the IRA B-cells are first-responders that direct emergency IgM release to abate bacteria invading through the lungs or intestines, while they sound an alarm to splenic stem cells, recruiting other defenders (*see figure 35.8*).

34.7 Antibodies Are Proteins That Bind to Specific 3-D Structures

After reading this section, you should be able to:

- Describe the structure of the B-cell receptor that is secreted as antibody
- Compare and contrast the five classes of antibody
- Diagram the antibody changes, induced by antigen binding, that facilitate antigen capture and removal from the host
- Integrate antibody secretion with antigen exposure
- Create a model of genetic diversity that results from recombination, alternative splicing, and somatic hypermutation
- Predict antibody specificity resulting from clonal selection

So far we have discussed antibody function and how B cells are activated to become antibody-secreting plasma cells. We now turn our attention to antibody structure and how a seemingly infinite diversity of antibodies can be synthesized by a single individual. An **antibody** or **immunoglobulin** (**Ig**) is a glycoprotein. There are five classes of human antibodies; all share a basic structure that varies in order to accomplish specific biological functions.

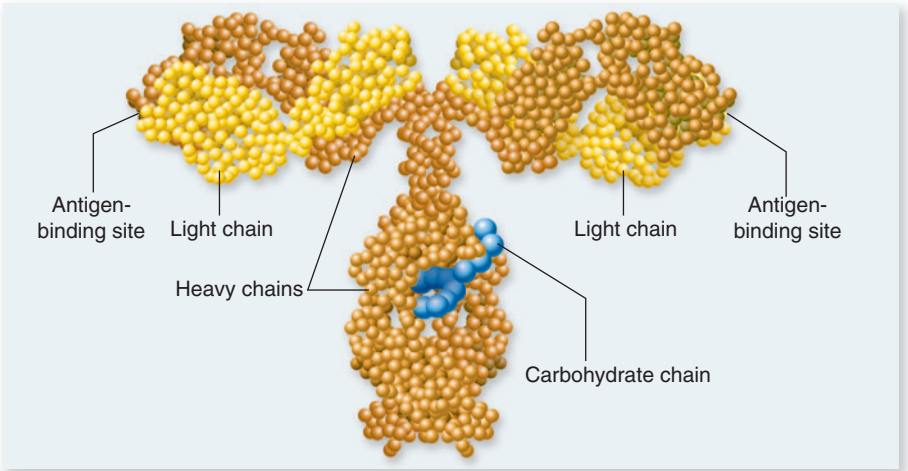
Immunoglobulin (Antibody) Structure

All immunoglobulin molecules have a basic structure composed of four polypeptide chains: two identical heavy and two identical light chains (**figure 34.12**). Each light-chain polypeptide usually consists of about 220 amino acids and has a mass of approximately 25,000 Da. Each heavy chain consists of about 440 amino acids and has a mass of about 50,000 to 70,000 Da. Heavy and light chains are connected to each other by disulfide bonds (figure 34.12*b*). The heavy chains are structurally distinct for each immunoglobulin class or subclass. Both light (L) and heavy (H) chains contain two different regions. The **constant** (**C**) **regions** ($\mathbf{C_L}$ and $\mathbf{C_H}$) have amino acid sequences that do not vary significantly between antibodies of the same class. The **variable** (**V**) **regions** (V_L and V_H) have different amino acid sequences, and these regions fold together to form the antigen-binding sites.

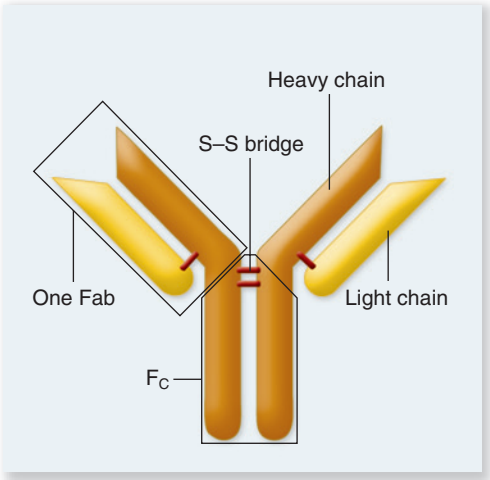
The four chains are arranged in the form of a flexible Y with a hinge region. This hinge allows the antibody molecule to be more flexible, adjusting to the different spatial arrangements of epitopes on antigens. The stalk of the Y is termed the **crystallizable fragment** (**Fc**) and can bind to a host cell by interacting with the cell-surface Fc receptor. The top of the Y consists of two **antigen-binding fragments** (**Fab**) that bind with compatible epitopes.

The light chain may be either of two distinct forms called kappa (κ) and lambda (λ). These can be distinguished by the amino acid sequence of the constant (C) portion of the chain. In humans, the constant regions of all light chains are identical. Each antibody molecule produced by a sole B cell will contain either κ or λ light chains but never both. The light-chain variable (V) domain contains hypervariable regions, or complementarity-determining regions (CDRs), that differ in amino acid sequence more frequently than the rest of the variable domain. These regions are essential in determining antigen specificity.

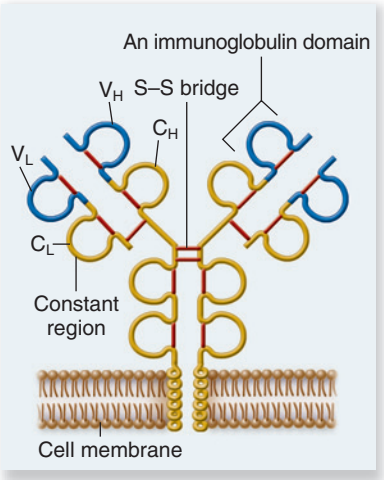
Like the light chain, the heavy chain also has a variable region (VH) at its amino terminal domain. The other domains of the heavy chains are termed constant (C) domains. The constant domains of the heavy chain form the constant (C_H) region. The amino acid sequence of this region determines the classes of heavy chains. In humans, there are five classes of heavy chains designated by lowercase Greek letters: gamma (γ), alpha (α), mu (μ), delta (δ), and epsilon (ε), and usually written as G, A, M, D, or E. The properties of these heavy chains determine,



(a)



(b)



(c)

Figure 34.12 Immunoglobulin (Antibody) Structure. (a) A computer generated model of immunoglobulin structure showing the arrangement of the four polypeptide chains. (b) Heavy and light chains are connected to each other by disulfide bridges (bonds). Each heavy and light chain pair form an antigen-binding fragment (Fab). The disulfide-linked heavy chains form the crystalizable fragment (Fc). The Fc fragments are composed only of constant regions, whereas the Fab fragments have both constant and variable regions. (c) Both the heavy and the light chains contain several homologous units of about 100 to 110 amino acids. Within each unit, called a domain, disulfide bonds form a loop of approximately 60 amino acids. Interchain disulfide bonds also link heavy and light chains together. All light chains contain a single variable domain (V_L) and a single constant domain (C_L). Heavy chains contain a variable domain (V_H) and either three or four constant domains (C_H1, C_H2, C_H3, and C_H4). The variable regions (V_H, V_L), when folded together in three-dimensions, form the antigen-binding sites.

2. What is the function of the Fc region of an antibody? The Fab region?
3. Name the two types of antibody light chains.
4. What determines the class of heavy chain of an antibody? Name the five immunoglobulin classes.

Immunoglobulin Function

Each end of the immunoglobulin molecule has a unique role. The Fab region is concerned with binding antigen, whereas the Fc region mediates binding to receptors (called Fc receptors) found on various immunocytes or the first component of the classical complement system. The binding of an antibody to an antigen usually does not destroy the antigen, even when the antigen is on a cell or other agent. Rather, the antibody serves to mark and identify the nonself agent as a target for immunological attack and to activate innate immune responses that can destroy the target. ⏮ *Complement is a cascading enzyme system (section 33.3)*

An antigen binds to an antibody at the antigen-binding site within the Fab region of the antibody. More specifically, a pocket is formed by the folding of the V_H and V_L regions (figure 34.12*c*). At this site, specific amino acids contact the antigen's epitope and form multiple noncovalent bonds between the antigen and amino acids of the binding site. Because binding is due to weak, noncovalent bonds such as hydrogen bonds and electrostatic attractions, the antigen's shape must exactly match that of the antigen-binding site. If the shapes of the epitope and binding site are not

truly complementary, the antibody will not effectively bind the antigen. Thus a lock-and-key mechanism operates; however, in at least one case, the antigen-binding site changes shape when it complexes with the antigen (an induced-fit mechanism; *see figure 10.16*). In either case, antibody specificity results from the nature of antibody-antigen binding.

Phagocytes have Fc receptors for immunoglobulin on their surface, so bacteria covered with antibodies are better targets for phagocytosis by neutrophils and macrophages. This is termed **opsonization.** Other cells, such as natural killer cells, destroy antibody-coated cells through a process called antibody-dependent cell-mediated cytotoxicity (*see figure 33.12*). Immune destruction also is promoted by antibody-induced activation of the classical complement system.

Immunoglobulin Classes

Immunoglobulin γ, or **IgG,** is the major immunoglobulin in human serum, accounting for 80% of the immunoglobulin pool (**figure 34.13*a***). IgG is present in blood plasma and tissue fluids. IgG acts against bacteria and viruses by opsonizing the invaders and neutralizing toxins and viruses (p. 759). It is also one of the two immunoglobulin classes that activate complement by the classical pathway. IgG is the only immunoglobulin molecule able to cross the placenta and provide natural immunity in utero and to the neonate at birth.

There are four human IgG isotypes (IgG1, IgG2, IgG3, and IgG4); these vary chemically in their heavy-chain composition and the number and arrangement of interchain disulfide bonds (figure 34.13*b*). Differences in biological function have been noted in these isotypes. For example, IgG2 antibodies are opsonic and develop in response to toxins. IgG1 and IgG3, upon recognition of their specific antigens, bind to Fc receptors expressed on neutrophils and macrophages. This increases phagocytosis by these cells. The IgG4 antibodies function as skin-sensitizing immunoglobulins.

Immunoglobulin μ, or **IgM,** accounts for about 5 to 10% of the serum immunoglobulin pool. It is usually a polymer of five monomeric units (pentamer), each composed of two heavy chains and two light chains (**figure 34.14*a***). The monomers are arranged in a pinwheel array with the Fc ends in the center, held together by disulfide bonds and a special J (joining) chain. Soluble, pentameric IgM is the immunoglobulin made during B-cell maturation, while individual IgM monomers are expressed on B cells, serving as the antibody component of the BCR (p. 748). Pentameric IgM tends to remain in the bloodstream, where it agglutinates (or clumps) bacteria, activates complement by the classical pathway, and enhances the ingestion of pathogens by phagocytic cells.

Although most IgM appears to be pentameric, around 5% or less of human serum IgM exists in a hexameric form. This molecule contains six monomeric units but seems to lack a J chain. Hexameric IgM activates complement up to 20 times more effectively than does the pentameric form. It has been suggested that bacterial cell-wall antigens such as lipopolysaccharides may directly stimulate B cells to form hexameric IgM without a J chain. If this is the case, the immunoglobulins formed during primary immune responses are less homogeneous than previously thought.

Immunoglobulin α, or **IgA,** accounts for about 12% of serum immunoglobulin. Some IgA is present in the serum as a monomer. However, IgA is most abundant in mucous secretions, where it is a dimer held together by a J chain (figure 34.14*b*). IgA, when transported from mucosal-associated lymphoid tissue (MALT) to mucosal surfaces, acquires a protein called the secretory component (*see figure 33.16*). **Secretory IgA** (**sIgA**), as the modified molecule is called, is the primary immunoglobulin of

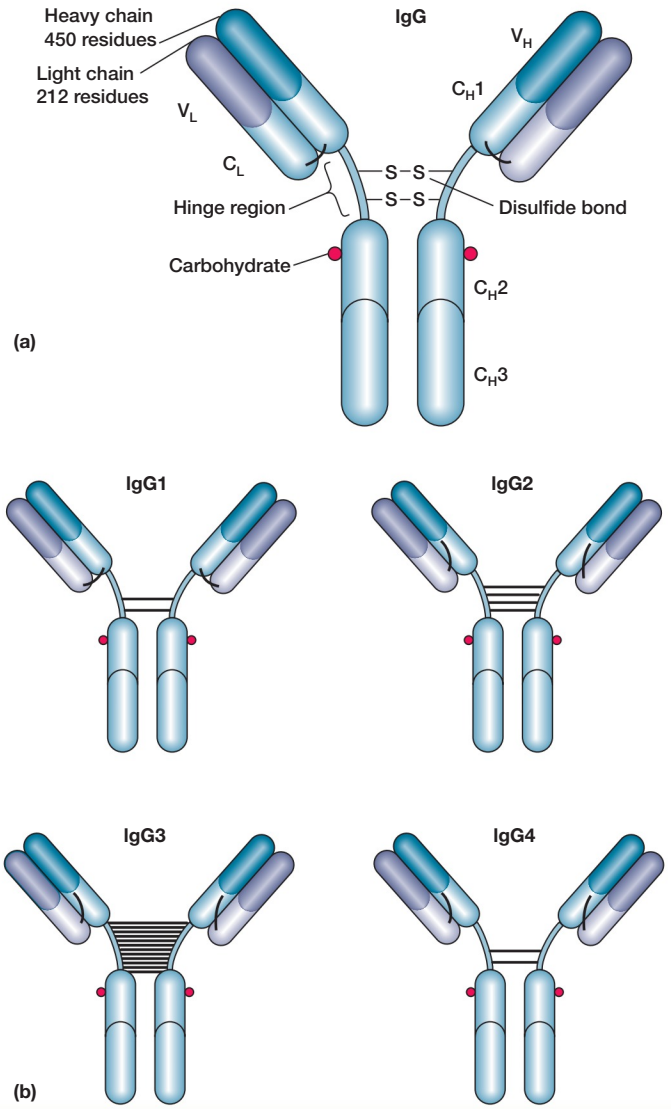

Figure 34.13 Immunoglobulin G. (a) The basic structure of human IgG. (b) The structure of the four human IgG subclasses. Note the arrangement and numbers of disulfide bonds (shown as thin black lines). Carbohydrate side chains are shown in red.

MICRO INQUIRY *What makes this class of immunoglobulin unique?*

(b) The dimeric structure of human secretory IgA. Notice the secretory component (tan) wound around the IgA dimer and attached to the constant domain of each IgA monomer. (c) The structure of human IgD showing the disulfide bonds that link protein chains (shown in black). (d) The structure of human IgE. Carbohydrate side chains are in red.

MICRO INQUIRY *Where is monomeric IgM commonly found?*

MALT. Secretory IgA is also found in saliva, tears, and breast milk. In these fluids and related body areas, sIgA plays a major role in protecting surface tissues against microorganisms by the formation of an immune barrier. For example, in the intestine, sIgA attaches to viruses, bacteria, and protozoa. This prevents pathogen adherence to mucosal surfaces and invasion of host tissues, a phenomenon known as immune exclusion. In addition, sIgA binds to antigens within the mucosal layer of the small intestine; subsequently the antigen-sIgA complexes are excreted through the adjacent epithelium into the gut lumen. This rids the body of locally formed immune complexes and decreases their access to the circulatory system. Secretory IgA also plays a role in the alternative complement pathway. ⏮ *Complement is a cascading enzyme system (section 33.3); Secondary lymphoid organs and tissues (section 33.4)*

Immunoglobulin δ, or **IgD,** has a monomeric structure (figure 34.14*c*) similar to that of IgG. IgD antibodies are abundant in combination with IgM on the surface of B cells and thus are part of the B-cell receptor complex. Therefore their function is to signal the B cell to start antibody production upon initial antigen binding.

Immunoglobulin ε, or **IgE** (figure 34.14*d*), makes up only a small percent of the total immunoglobulin pool. The skin-sensitizing and anaphylactic antibodies belong to this class. A number of different cell types, especially mast cells, eosinophils, and basophils, can become coated with IgE molecules because these cells have Fc receptors for IgE. When two cell-bound IgE molecules are cross-linked by binding to the same antigen, the cells degranulate. Degranulation releases preformed mediators of inflammation (e.g., histamine). It also stimulates production of an excessive number of eosinophils in the blood (eosinophilia) and increased rate of movement of the intestinal contents (gut hypermotility), which aid in the elimination of helminthic parasites. Thus although IgE is present in small amounts, this class of antibodies has potent biological capabilities, as is discussed in section 34.10.

4. Which immunoglobulin can cross the placenta?
5. Which immunoglobulin is most prevalent in the immunoglobulin pool? The least prevalent?

Antibody Kinetics

The synthesis and secretion of antibody can be evaluated with respect to time. Monomeric IgM serves as the B-cell receptor for antigen, and pentameric IgM is the first type of antibody secreted after B-cell activation. Later, under the influence of T-helper cells, IgM-secreting plasma cells may switch and produce another antibody class (e.g., IgG, IgA, or IgE). This is known as antibody class switching (p. 755).

The Primary Antibody Response

When an individual is exposed to an antigen (e.g., an infection or vaccine), there is an initial lag phase, or latent period (up to several weeks), before an antibody response is mounted. During this latent

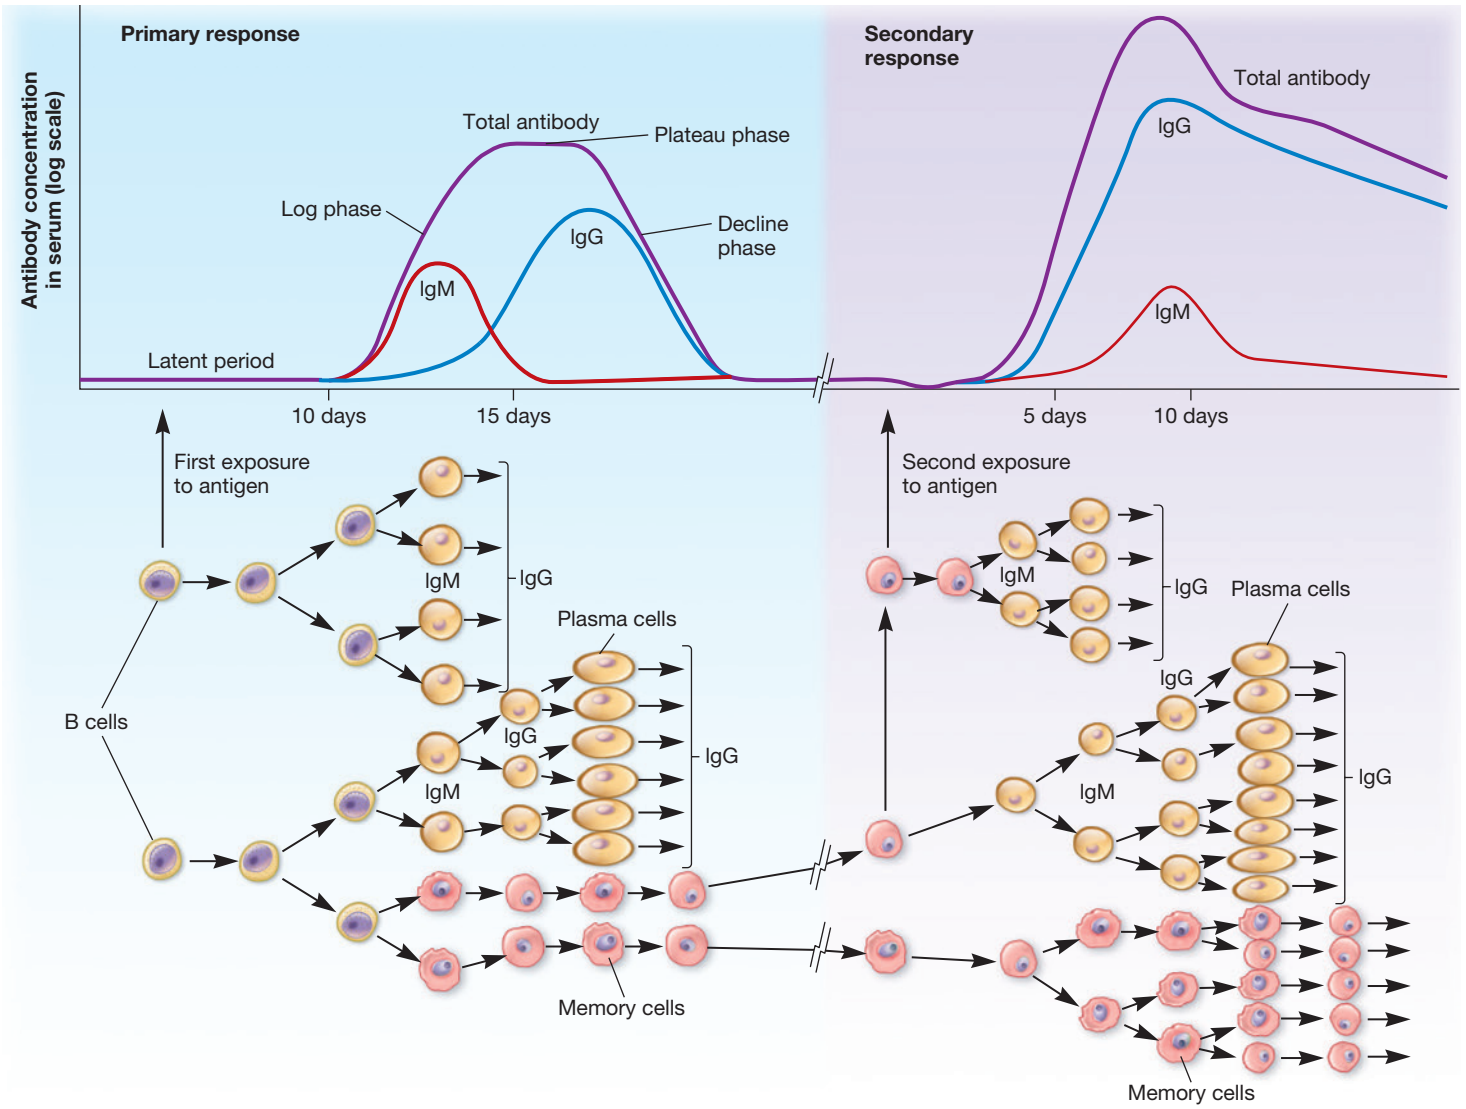

Figure 34.15 **Antibody Production and Kinetics.** The four phases of a primary antibody response correlate to the clonal expansion of the activated B cell, differentiation into plasma cells, and secretion of the antibody protein. The secondary response is much more rapid, and total antibody production is nearly 1,000 times greater than that of the primary response.

MICRO INQUIRY *How does the lag in IgM production compare during a primary and secondary response? Contrast this with the lag seen in IgG production during a primary and secondary response. What does this difference imply about the nature of the secondary response?*

period, no antigen-specific antibody can be detected in the blood (**figure 34.15**). This explains why antibody-based HIV tests, for example, are not accurate until weeks after exposure. Once B cells have differentiated into plasma cells, antibody is secreted and can be detected. During the primary antibody response, IgM appears first, then switches to another antibody class, usually IgG. The affinity of the antibodies for the antigen's determinants is low to moderate during the primary antibody response. The **antibody titer,** which is a measurement of serum antibody concentration (the reciprocal of the highest dilution of an antiserum that gives a positive reaction in the test being used), then rises logarithmically to a plateau during the second, or log, phase. In the plateau phase, the antibody titer stabilizes. This is followed by a decline phase, during which antibodies are naturally metabolized or bound to the antigen and cleared from circulation.

The Secondary Antibody Response

The primary antibody response primes the immune system so that it possesses specific immunological memory through its clones of memory B cells, each of which responds to different antigen. Upon secondary antigen challenge, as occurs when an individual is reexposed to a pathogen or receives a vaccine booster, B cells mount a heightened secondary response to the same antigen

(figure 34.15). Compared to the primary antibody response, the secondary antibody response has a much shorter lag phase and a more rapid log phase, persists for a longer plateau period, attains a higher IgG titer, and produces antibodies with a higher affinity for the antigen.

Diversity of Antibodies

One unique property of antibodies is their remarkable diversity. According to current estimates, each human can synthesize antibodies that can bind to more than 10^{13} (10 trillion) different epitopes. How is this diversity generated? The answer is threefold: (1) rearrangement of antibody gene segments, called combinatorial joining; (2) generation of different codons during antibody gene splicing; and (3) somatic mutations.

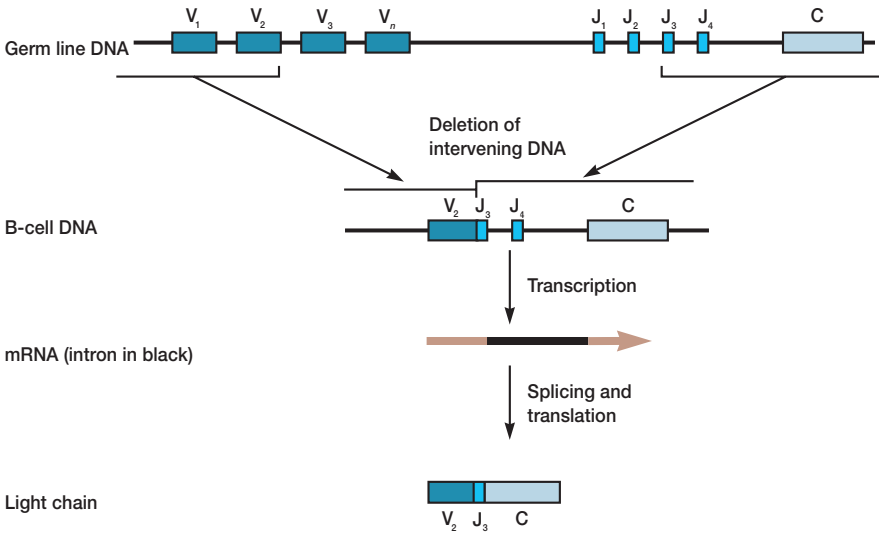

Figure 34.16 Light-Chain Production in a Mouse. One V segment is randomly joined with one J-C region by deletion of the intervening DNA. The remaining J segments are eliminated from the RNA transcript during RNA processing.

Combinatorial joining of immunoglobulin loci occurs because these genes are split into many gene segments. The genes that encode antibody proteins in precursor B cells contain a small number of exons, close together on the same chromosome, that determine the constant (C) region of the light chains. Separated from them but still on the same chromosome is a larger cluster of segments that determines the variable (V) region of the light chains. During B-cell differentiation, exons for the constant region are joined to one segment of the variable region. This occurs by recombination and is mediated by the enzymes called RAG-1 and RAG-2. This splicing process joins the coding regions for constant and variable regions of light chains to produce a gene encoding a complete light chain of an antibody. A similar splicing produces a complete heavy-chain antibody gene.

Because the light-chain genes actually consist of three parts and the heavy-chain genes consist of four, the formation of a finished antibody molecule is slightly more complicated than previously outlined. The germ-line DNA for the light-chain gene contains multiple coding sequences called V and J (joining) regions (**figure 34.16**). During the development of a B cell in the bone marrow, RAG enzymes join one V gene segment with one J segment. This DNA joining process is termed combinatorial joining because it can create many combinations of the V and J regions (**table 34.3**). In addition, an enzyme called *t*erminal *d*eoxynucleotidyl *t*ransferase (tdt) inserts nucleotides at the V-J junction, creating additional diversity. When the light-chain gene is transcribed, transcription continues through the DNA region that encodes the constant portion of the gene. RNA splicing subsequently joins the V, J, and C regions, creating mRNA.

Combinatorial joining in the formation of a heavy-chain gene occurs by means of DNA splicing of the heavy-chain counterparts of V and J along with a third set of D (diversity) sequences (**figure 34.17*a***). Initially, all heavy chains have the μ type of constant region. This corresponds to antibody class IgM (figure 34.17*b*). If a particular B cell is reexposed to its antigen, another DNA splice joins the VDJ region with a different constant region that can subsequently change the class of antibody produced by the B cell (figure 34.17*c*)—the phenomenon of **antibody class switching.** This process is regulated by antigen-activated helper T cells.

Antibody class switching solves a problem faced by an organism during the immune response. It must be able to bind lots of antigen, but it must also be able to clear the antigen-antibody complexes (immune clearance). Recall that the primary antibody response to antigen is IgM. Because secreted IgM is pentameric, its 10 antigen-binding sites allow it to bind strongly to foreign materials that have multiple repetitive epitopes. However, IgM is not the best antibody class for clearing the antigen from the host. In fact, depending on the

Table 34.3 Theoretical Antibody Diversity Resulting from Combinatorial Joining of Germ-Line Genes[1]

λ light chains	V regions = 2 J regions = 3 Combinations = $2 \times 3 = 6$
κ light chains	V_κ regions = 250 – 350 J_κ regions = 4 Combinations = $250 \times 4 = 1{,}000$ $= 350 \times 4 = 1{,}400$
Heavy chains	V_H = 250 – 1,000 D = 10–30 J_H = 4 Combinations = $250 \times 10 \times 4 = 10{,}000$ $= 1{,}000 \times 30 \times 4 = 120{,}000$

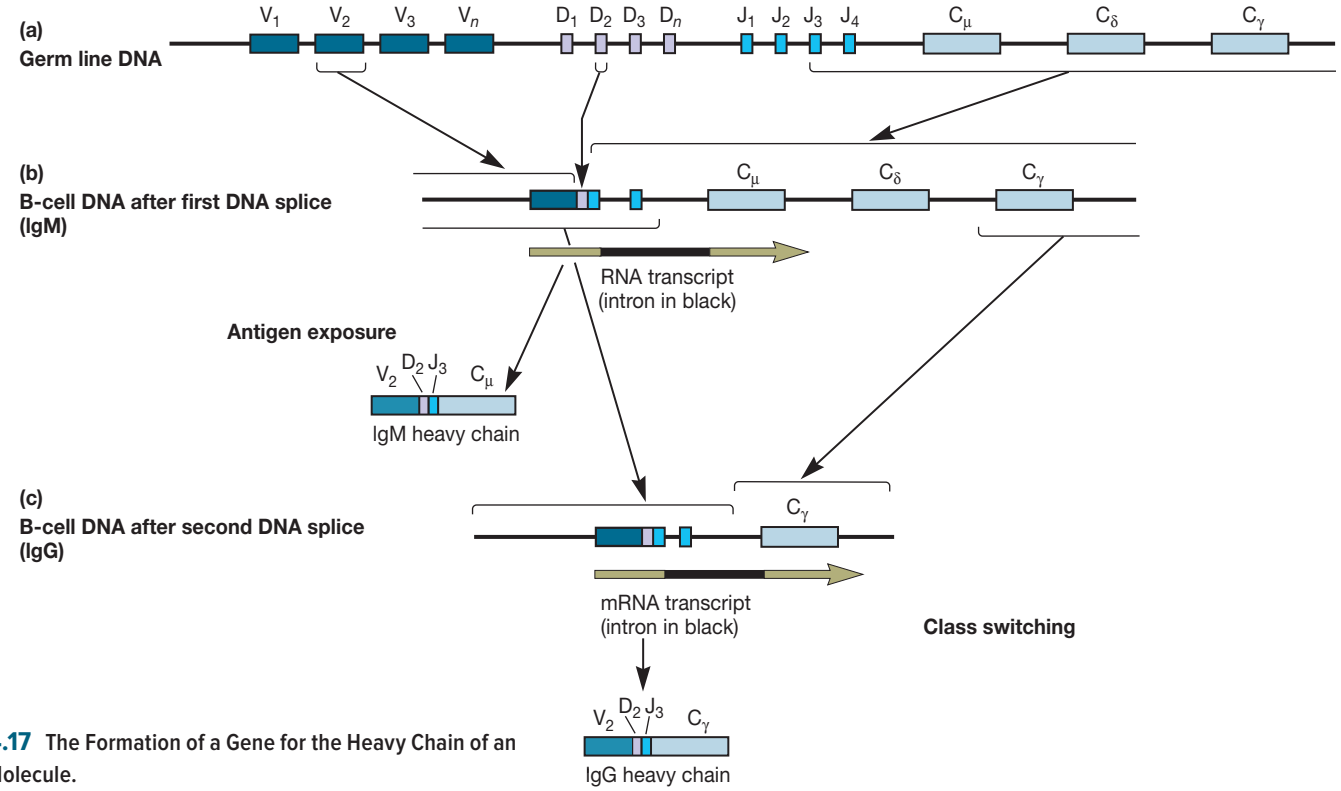

Figure 34.17 The Formation of a Gene for the Heavy Chain of an Antibody Molecule.

antigen and the body site, IgA or IgG provides better effector mechanisms for immune clearance. So how does an antigen-activated B cell change antibody class without altering antigen-binding affinity? Proliferating B cells are able to use combinatorial joining to attach the rearranged coding sequence for the variable region to another heavy-chain gene sequence (figure 34.17).

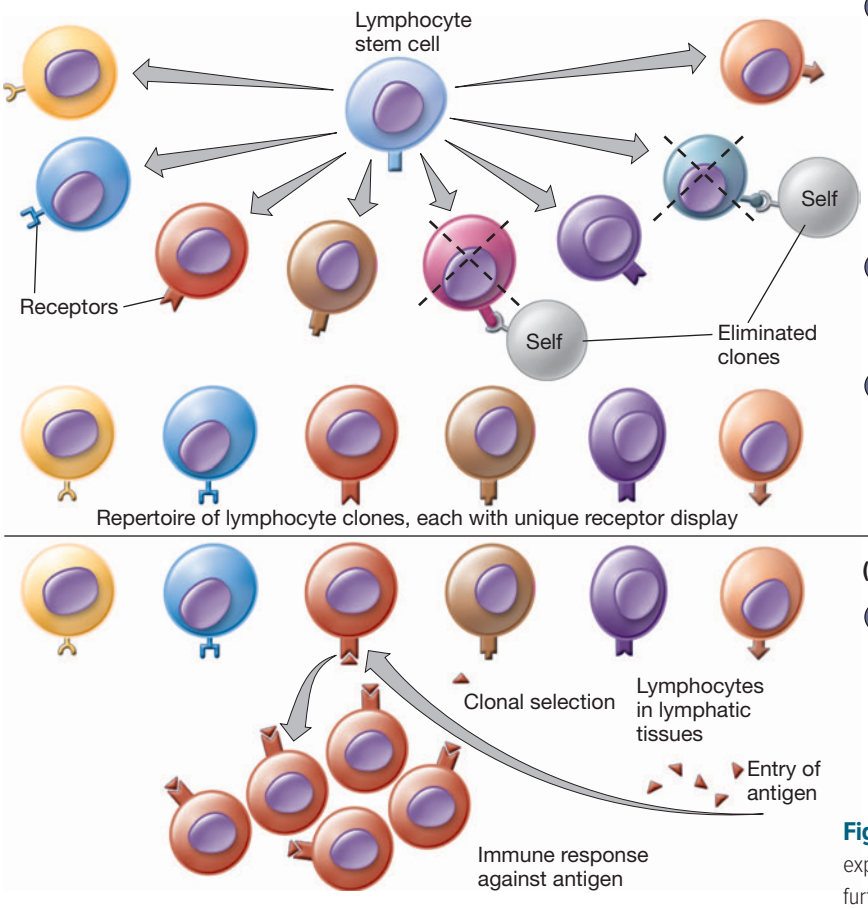
The switch from IgM to another antibody class results from a unique editing process that occurs when the proliferating B cell synthesizes the enzyme *a*ctivation-*i*nduced cytidine *d*eaminase (AID). AID replaces cytosine residues with uracil when the complementary DNA strands separate during transcription. This causes DNA repair enzymes to remove the inappropriate uracil (now on a DNA backbone). The abasic nucleotide is then excised, nicking one DNA strand. When nicking occurs in the respective μ and γ switch regions, recombination occurs; the μ constant region is excised, and the γ constant region is joined to the VDJ region.

Remember that combinatorial joining is only one of three mechanisms by which antibody diversity is generated. The other two processes are:

1. **Splice-site variability:** The junction for either VJ or VDJ splicing in combinatorial joining can occur between different nucleotides and thus generate different codons in the spliced gene. In addition, the activation of tdt can greatly increase the variability of the nucleotide sequence at the VJ or VDJ junctions during the splicing process. For example, one VJ splicing event can join the V sequence CCTCCC with the J sequence TGGTGG in two ways: CCTCCC + TGGTGG = CCGTGG, which codes for proline and tryptophan. Alternatively, the VJ splicing event can give rise to the sequence CCTCGG, which codes for proline and arginine. Thus the same VJ joining could produce polypeptides differing in a single amino acid.
2. **Somatic hypermutation of V regions:** The V regions of germ-line DNA are susceptible to a high rate of somatic mutation during B-cell development in response to an antigen challenge. The rearranged variable heavy and light genes encode "hotspots" of four to five nucleotides that are more likely to be altered by point mutation than other areas of the variable regions. The resulting point mutations are recognized by DNA repair enzymes that attempt to correct the altered bases. AID (the same enzyme that mediates antibody class switching) is one of the enzymes that is involved. AID deaminates DNA at cytosine, resulting in base pair mismatches and transition-type mutations. Additionally, repair of the base pair mismatch is error-prone and results in additional sequence diversity. Accumulation of the altered bases in the variable regions of B-cell immunoglobulin genes during antigen challenge promotes significant antibody diversity and thus appropriate antibody affinity. Adding the impact of antibody class switching to the above two processes should begin to explain how it is possible for unique antibodies to respond to the trillions of potential antigens in the environment.

Retrieve, Infer, Apply

1. What is the name of each part of the gene that encodes for the different regions of antibody chains?
2. Describe what is meant by combinatorial joining of V, D, and J gene segments.
3. In addition to combinatorial joining, what other two processes play a role in antibody diversity?



(a) Antigen-Independent Period

1. During development of early lymphocytes from stem cells, a given stem cell undergoes rapid cell division to form numerous progeny.

   During this period of cell differentiation, random rearrangements of the genes that code for the TCR or BCR occur. The result is a large array of genetically distinct cells, called clones, each clone bearing a different receptor that is specific to react with only a single type of foreign molecule or antigen.

2. At the same time, any lymphocyte clones that have a specificity for self molecules and could be harmful are eliminated from the pool of diversity. This is called immune tolerance.

3. The specificity for a single antigen molecule is programmed into the lymphocyte and is set for the life of a given clone. The end result is an enormous pool of mature but naïve lymphocytes ready to further differentiate under the influence of immune stimuli.

(b) Antigen-Dependent Period

4. Lymphocytes will then encounter antigens. These antigens will become the stimulus for the lymphocytes' final activation and immune function. Entry of a specific antigen selects only the lymphocyte clone or clones that carry matching TCR or BCR. This will trigger an immune response, which varies according to the type of lymphocyte involved.

Figure 34.18 Lymphocyte Clonal Expansion. (a) Cell populations expand and are restricted based on their MHC expression. (b) They are further expanded when activated by a specific antigen.

Clonal Selection

As noted, combinatorial joinings, somatic mutations, and variations in the splicing process generate the great variety of antibodies produced by mature B cells. From a large, diverse B-cell pool, specific cells are stimulated by antigens to reproduce and form B-cell clones containing the same genetic information. This is known as **clonal selection.** Both B and T cells undergo clonal selection. It is important because it accounts for immunological specificity and memory.

The clonal selection theory has four components or tenets. The first tenet is that there exists a pool of lymphocytes that can bind to a tremendous range of epitopes (**figure 34.18**). Because some the B and T cells in the pool react with self-epitopes, the second tenet is that these self-reactive cells are eliminated at an early stage of development. Indeed, this has been shown to be true for developing B cells (in the bone marrow) and self-reacting T cells (in the thymus). The third tenet is that once a lymphocyte has been released from its primary development site and is exposed to its specific antigen, it proliferates to form a **clone** (a population of identical cells derived from a single parent cell). Note that this clone has been "selected" by exposure to specific antigen, hence the name of the theory. The final tenet states that all clonal cells react with the same antigenic epitope that stimulated its formation. However, the cells may have somewhat different functions. For instance a B cell forms two different cell populations: antibody-producing plasma cells and memory cells.

Plasma cells are true protein factories that produce about 2,000 antibodies per second in their brief 5- to 7-day life-span. Memory cells circulate more actively from blood to lymph and live much longer (years or even decades) than do plasma cells. Memory cells are responsible for the immune system's rapid secondary antibody response (figure 34.15) to the same antigen. Finally, memory B cells and plasma cells are usually not produced unless the B cell has interacted with and received cytokine signals from activated T-helper cells (figure 34.11). Clonal selection theory has also led to the development of **monoclonal antibody** (**mAb**) technologies that have been exploited to treat disease (**Techniques & Applications 34.1**).

34.8 Antibody Binding Dooms the Target

After reading this section, you should be able to:

- Explain the consequences of antibody binding of antigen
- Assess the effectiveness of antigen removal by antibody
- Predict which antigens will be most susceptible to antibody action

As we have seen, the antigen-antibody interaction is a bimolecular association that exhibits exquisite specificity. The interactions that occur in animals are absolutely essential in protecting the animal against the continuous onslaught of microorganisms

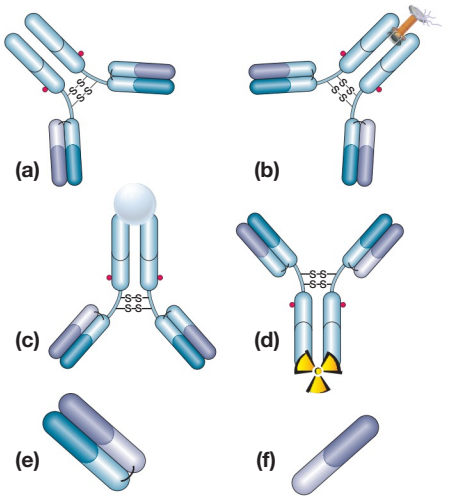
TECHNIQUES & APPLICATIONS

34.1 Monoclonal Antibody Therapy

The value of antibodies as tools for locating or identifying antigens is well established. For many years, antiserum extracted from human or animal blood was the main source of antibodies for tests and therapy, but most antiserum is problematic. It contains polyclonal antibodies, meaning it is a mixture of different antibodies because it reflects dozens of immune reactions from a wide variety of B-cell clones. This characteristic is to be expected, because several immune reactions may be occurring simultaneously, and even a single species of microbe can stimulate production of several different types of antibodies. With today's technology, a pure preparation of monoclonal antibodies (mAbs) that originate from a single clone and have a single specificity for the same epitope on a single antigen can be made. These monoclonal antibodies can be used therapeutically when they have been modified to deliver toxins, radionucleotides, drugs, and even cytokines directly to the antigen. Thus mAbs against specific antigens on cancer cells, infectious agents, and disease-associated proteins can be made to "target" those agents and facilitate their eradication without affecting other proteins, cells, or tissues.

The technology for producing monoclonal antibodies involves hybridizing human cancer cells and activated rabbit or mouse B cells in tissue culture systems. Over the years, methods for producing mouse-human chimeric mAbs (mouse variable chains on human constant chains) and humanized (mouse hypervariable amino acids in human antibodies) were developed. Today transgenic mice containing human antibody genes can be immunized with specific antigens to produce completely human B cells and mAbs. Furthermore, human mAbs are now made in *Escherichia coli* from bacteriophage containing human B cell DNA.

It is estimated that there are over 500 mAbs presently licensed or in development for the specific diagnosis or treatment of human disease. The mAbs target various types of cancer, autoimmune diseases, infection, sepsis, rheumatoid arthritis, Crohn's disease, and Alzheimer's disease, to name a few. Interestingly, immunologists have learned much about B-cell biology from the study of mAbs, including the function of antibody "orphan pieces" (single chain, single domain, Fab, $F(ab')_2$), previously thought to be nonfunctional products of proteolysis.



Monoclonal Antibody (mAb) Therapeutics. mAbs that retain their antigen binding specificity can be used (a) as the naked glycoprotein to stimulate antigen recognition and removal, or they can be altered to deliver, (b) cytokines, (c) drugs, or (d) radionucleotides to kill their targets. Additionally, antibody pieces such as the (e) single domain and the (f) single-chain fragments can also be used.

and their products, as well as cancer cells. This occurs partly because the antibody coats the invading foreign material, marking it for enhanced recognition by other components of the innate and adaptive immune systems. The mechanisms by which antibodies achieve this are now discussed.

Neutralization

Binding of antibody to biologically active materials (such as bacteria, toxins, or viruses) causes their inactivation or **neutralization** (figure 34.19). The capacity of bacteria to colonize the mucosal surfaces of mammalian hosts depends in part on their ability to adhere to mucosal epithelial cells. Secretory IgA (sIgA) antibodies block certain bacterial adherence factors from attaching to host cells. Thus sIgA can protect the host against infection by some pathogenic bacteria and perhaps other microorganisms on mucosal surfaces by neutralizing (preventing) their adherence to host cells, one form of immune exclusion.

Extracellular toxins made by pathogens attach to target host cells before exerting their bioactivity. Antibody binding of toxins prevents toxin-mediated injury to cells: The toxin-antibody complex either is unable to attach to receptor sites on host target cells and is unable to enter the cell, or it is ingested by macrophages. For example, diphtheria toxin inhibits protein synthesis after binding to the cell surface by its B subunit and subsequent passage of the A subunit toxin into the cytoplasm of the target cell. The antibody blocks the toxic effect by binding to the B fragment, thereby preventing the toxin from binding a target host cell. An antibody capable of neutralizing a toxin or

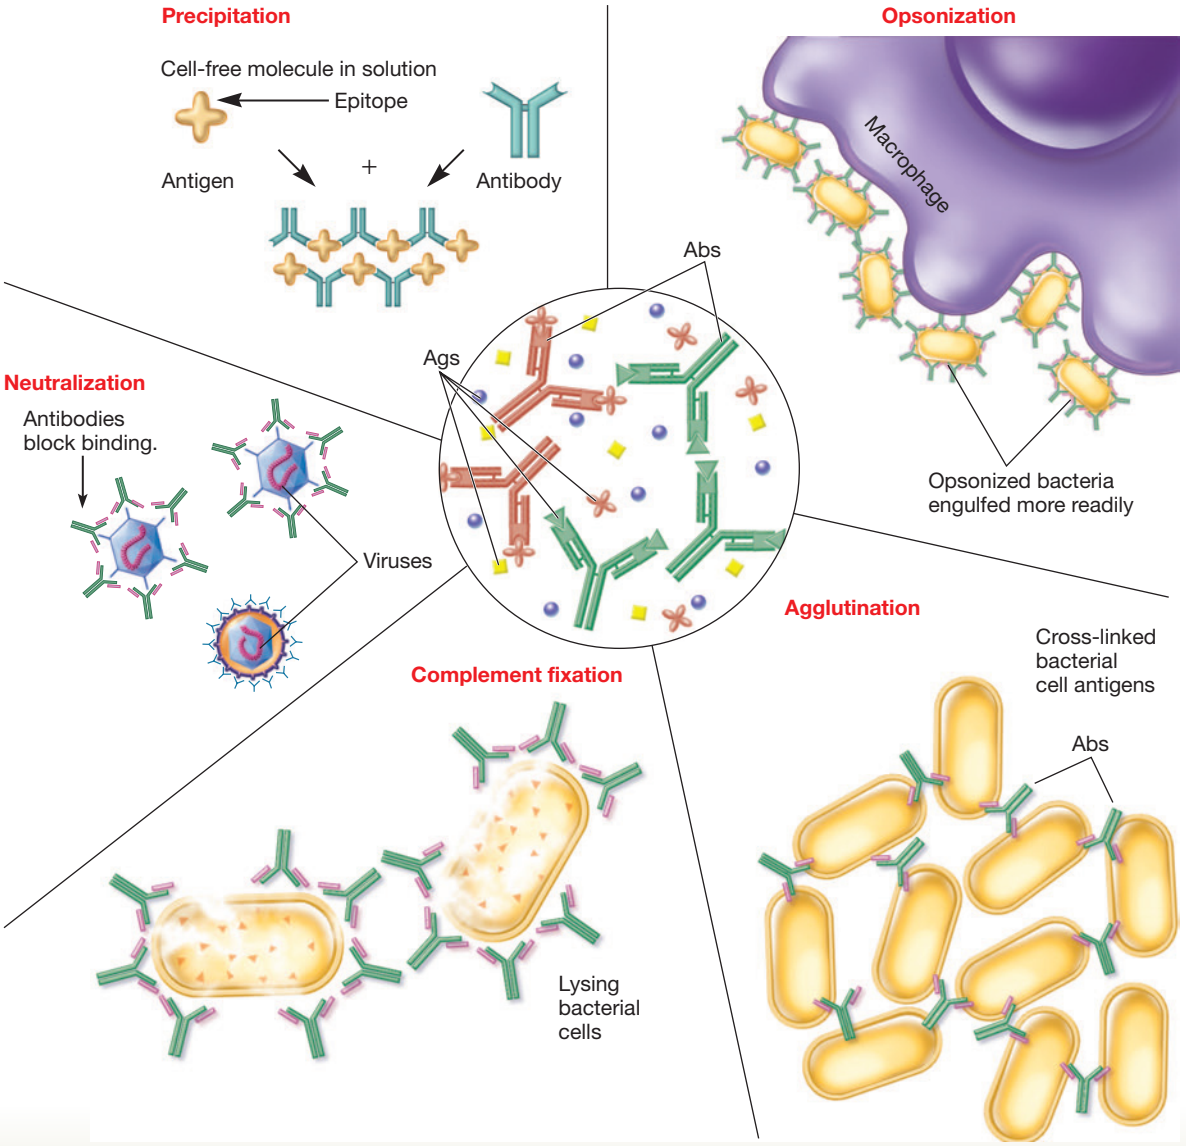


Figure 34.19 Consequences of Antigen-Antibody Binding. Immune complexes form when soluble antigens (Ag) bind soluble antibody (Ab), resulting in precipitation. Opsonization occurs when antibody binds to antigens on larger molecules or cells to be recognized by phagocytic cells. Agglutination results when insoluble antigens (such as viral or bacterial cells) are cross-linked by antibody. The classical complement cascade can be activated by immune complexes; this is called complement fixation. Neutralization results when antibody binds to antigens, preventing the antigen from binding to host cells.

MICRO INQUIRY *What is the difference between a precipitation and an agglutination reaction?*

antiserum containing neutralizing antibody against a toxin is called **antitoxin.** ▶▶| *Virulence defines a pathogen's success (section 35.2)*

In a similar fashion, IgG, IgM, and IgA antibodies can bind to some viruses during their extracellular phase and block their capacity to bind to host cells. This antibody-mediated viral inactivation is called **viral neutralization.**

Opsonization

The phagocytic process (see *figure 33.19*) can be greatly enhanced by opsonization. Phagocytes have an intrinsic ability to bind directly to microorganisms through pattern recognition by nonspecific cell-surface receptors, engulf the microorganisms, form phagosomes, and digest the microorganisms. As noted in *section 33.3,* opsonization is the process by which microorganisms or other foreign particles are coated with antibody or complement and thus prepared for "recognition" and ingestion by phagocytic cells. Opsonizing antibodies, especially IgG1 and IgG3, bind to Fc receptors on the surface of dendritic cells, macrophages, and neutrophils, after they bind to the target antigen. This process permits effective removal of antigens; the antibody forms a bridge between the phagocyte and the antigen, thereby increasing the likelihood of its phagocytosis (*see figure 33.6*).

Immune Complex Formation

Because antibodies have at least two antigen-binding sites and most antigens have at least two epitopes, cross-linking can occur, producing large aggregates termed **immune complexes** (figure 34.19). If the antigens are soluble molecules and the complex becomes large enough to settle out of solution, a **precipitation** (Latin *praecipitare,* to cast down) or **precipitin reaction** occurs. When the immune complex involves the cross-linking of cells or particles, an **agglutination reaction** occurs. These immune complexes are more rapidly phagocytosed than free antigens. However, immune complex formation can harm the host, as occurs in some types of kidney and vascular pathologies. Finally, formation of immune complexes is the basis of some diagnostic tests. ▶▶| *Immune responses can be measured or exploited to detect infections (section 36.4)*

34.9 Not Responding Is Also Part of Immunity

After reading this section, you should be able to:

- Evaluate the impact of improper B-cell activation
- Contrast the outcome of B-cell and T-cell exposure to self antigens

Acquired immune tolerance is the body's ability to produce T cells and antibodies against nonself antigens such as microbial antigens, while "tolerating" (not responding to) self antigens. Some of this tolerance arises early in embryonic life, when immunologic competence is being established. Three general tolerance mechanisms have been proposed: (1) negative selection by clonal deletion, (2) the induction of anergy, and (3) inhibition of the immune response by the action of Treg cells.

Negative selection by clonal deletion removes lymphocytes that recognize self antigens. These cells are eliminated during embryogenesis by apoptosis. T-cell tolerance induced in the thymus and B-cell tolerance in the bone marrow is called **central tolerance** (see figure 34.18*a*). Many autoreactive B cells undergo clonal deletion or become anergic as they mature in the bone marrow. However, another mechanism is needed to prevent immune reactions against self antigens, termed autoimmunity, because many antigens are tissue-specific and are not present in the thymus or bone marrow.

Mechanisms occurring elsewhere in the body are collectively referred to as **peripheral tolerance.** These supplement central tolerance. Peripheral tolerance is thought to be based largely on incomplete activation signals given to the lymphocyte when it encounters self antigens in the periphery of the body. This mechanism leads to a state of unresponsiveness called **anergy,** which is associated with impaired intracellular signaling and apoptosis. The deletion of self-reactive B cells takes place in secondary lymphoid tissue, such as the spleen and lymph nodes. Since B cells recognize unprocessed antigen, there is no need for the participation of MHC molecules in these processes. For those self antigens present at relatively low concentrations, immunologic tolerance is often maintained only within the T-cell population. This is sufficient to sustain tolerance because it denies the help essential for antibody production by self-reactive B cells. Regulatory T cells with suppressor activity can inhibit B- and other T-cell activation, as well as modify specific functions (p. 744).

Retrieve, Infer, Apply

1. Describe the three ways acquired immune tolerance develops in the vertebrate host.
2. How would you define anergy?

34.10 Sometimes the Immune System Doesn't Work the Way It Should

After reading this section, you should be able to:

- Illustrate differences between hypersensitivity, autoimmunity, tissue rejection, and immunodeficiency
- Relate types of hypersensitivity to the root biological cause
- Predict disease potential due to the presence in the body of "self-reactive" T and B cells
- Explain tissue rejection as a function of cells responding to the graft
- Propose the impact on immunity when T cells and B cells become deficient

As in any body system, disorders also occur in the immune system. Immune disorders can be categorized as hypersensitivities, autoimmune diseases, transplantation (tissue) rejection, and immunodeficiencies. Each of these is now discussed.

Hypersensitivities

Hypersensitivity is an exaggerated adaptive immune response that results in tissue damage and is manifested in the individual on a second or subsequent contact with an antigen. Hypersensitivity reactions can be classified from immediate to delayed. Obviously, immediate reactions appear faster than delayed ones, but the main difference between them is the nature of the immune response to the antigen. Realizing this fact in 1963, Peter Gell (1914–2001) and Robert Coombs (1921–2006) developed a classification system for reactions responsible for hypersensitivities. Their system correlates clinical symptoms with information about immunologic events that occur during hypersensitivity reactions. The **Gell-Coombs classification** system divides hypersensitivities into four types: I, II, III, and IV.

Type I Hypersensitivity

An **allergy** (Greek *allos,* other, and *ergon,* work) is one of the most common kinds of **type I hypersensitivity** reaction. Allergic

reactions occur when an individual who has produced IgE antibody in response to the initial exposure to an antigen (**allergen**) subsequently encounters the same allergen. Upon initial exposure to a soluble allergen, B cells are stimulated to differentiate into plasma cells and produce specific IgE antibodies with the help of T_H cells (**figure 34.20**). This IgE is sometimes called a **reagin,** and the individual has a hereditary predisposition for its production. Once synthesized, IgE binds to the Fc receptors of mast cells (basophils and eosinophils can also be bound) and sensitizes these cells, making the individual sensitized to the allergen. When a subsequent exposure to the allergen occurs, the allergen attaches to the surface-bound IgE on the sensitized mast cells, causing mast cell degranulation.

Degranulation releases physiological mediators such as histamine, leukotrienes, heparin, prostaglandins, PAF (*p*latelet-*a*ctivating *f*actor), ECF-A (*e*osinophil *c*hemotactic *f*actor of *a*naphylaxis), and proteolytic enzymes. These mediators trigger smooth muscle contractions, vasodilation, increased vascular permeability, and mucus secretion (figure 34.20). The inclusive term for these responses is **anaphylaxis** (Greek *ana,* up, back again, and *phylaxis,* protection). Anaphylaxis can be divided into systemic and localized reactions.

Systemic anaphylaxis is a generalized response that is immediate due to a sudden burst of mast cell mediators. Usually there is respiratory impairment caused by smooth muscle constriction in the bronchioles. The arterioles dilate, which greatly

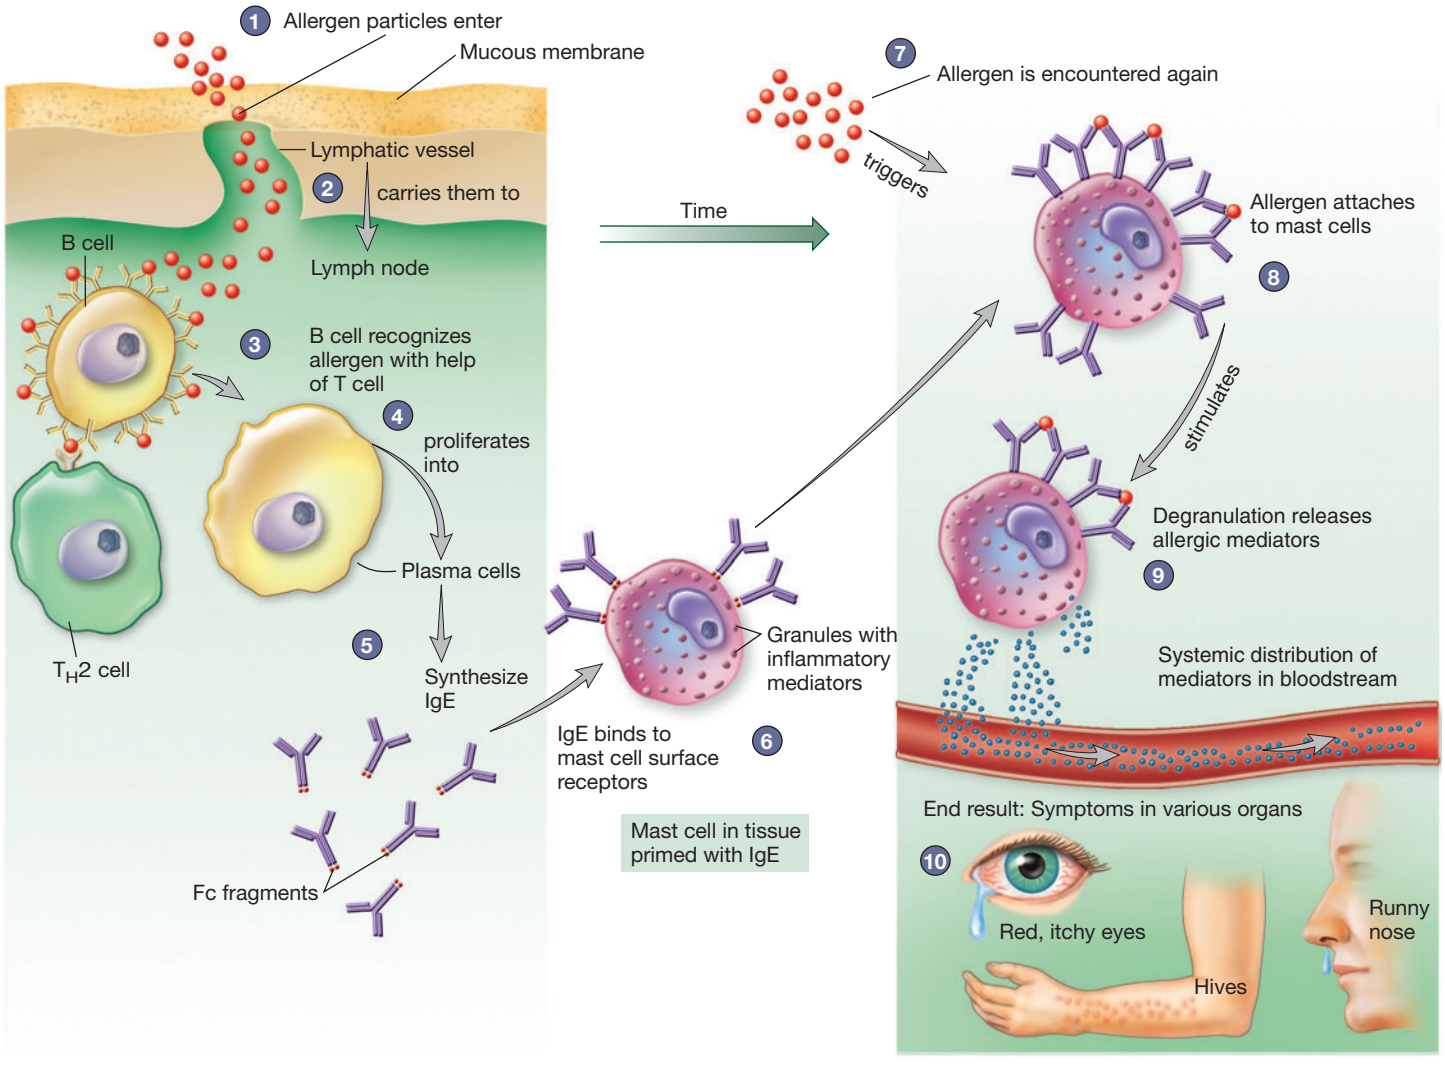

Figure 34.20 **Type I Hypersensitivity (Allergic Response).** (a) The initial contact (sensitization) of lymphocytes by small-protein allergens at mucous membranes results in T_H2 cell–assisted antibody class switching; plasma cells secrete IgE antibody. The IgE binds to its receptor on tissue mast cells (1–6). (b) Subsequent exposure to the same allergens results in their capture by the cell-bound IgE (7), triggering mast cell degranulation (8, 9). Characteristic signs and symptoms (hives, swelling, itching, etc.) of allergy ensue (10).

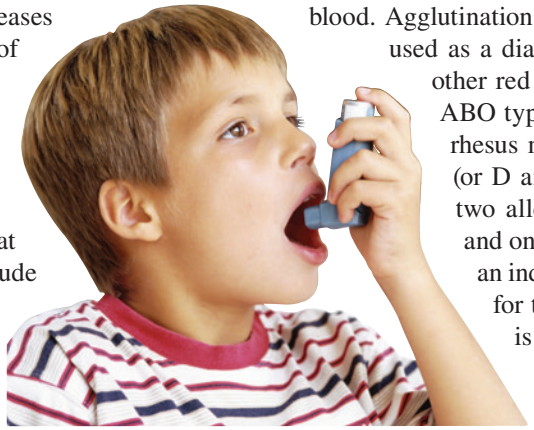
MICRO INQUIRY *What are some of the allergic mediators released during mast cell degranulation?*

reduces arterial blood pressure and increases capillary permeability with rapid loss of fluid into the tissue spaces. These physiological changes can be rapid and severe enough to be fatal within a few minutes from reduced blood flow, asphyxiation, reduced blood pressure, and circulatory shock. Common examples of allergens that can produce systemic anaphylaxis include drugs (penicillin), passively administered antisera, peanuts, and insect venom from wasps, hornets, or bees.



Localized anaphylaxis is called an **atopic** ("out of place") **reaction.** The symptoms that develop depend primarily on the route by which the allergen enters the body. Allergens that enter through the skin stimulate a localized reaction that results in a raised (wheal) and reddened (flare) lesion. Hay fever (allergic rhinitis) is a good example of atopy involving the upper respiratory tract. Initial exposure involves airborne allergens—such as plant pollen, fungal spores, animal hair and dander, and house dust mites—that sensitize mast cells located within the mucous membranes of the respiratory tract. Reexposure to the allergen causes a localized anaphylactic response: itchy and tearing eyes, congested nasal passages, coughing, and sneezing. Antihistamine drugs are used to help alleviate these symptoms.

Type II Hypersensitivity

Type II hypersensitivity is generally called a cytolytic or cytotoxic reaction because it results in the destruction of host cells, either by lysis or toxic mediators. In type II hypersensitivity, IgG or IgM antibodies are inappropriately directed against host cell-surface or tissue-associated antigens. They usually stimulate the classical complement pathway and a variety of effector cells (**figure 34.21**). The antibodies interact with complement (Clq) and the effector cells through their Fc regions. The cellular damage is similar to the lytic events that complement exerts on microbial membranes (*see figure 33.8*). Examples of type II hypersensitivity reactions include the response exhibited by a person who receives a transfusion with blood from a donor with a different blood group and erythroblastosis fetalis, which we now discuss.

Blood transfusion was often fatal prior to the discovery of distinct blood types by Karl Landsteiner in 1904. Landsteiner's observation that sera from one person could agglutinate the blood cells of another person led to his identification of four distinct types of human blood. The red blood cell types were subsequently determined to result from cell-surface glycoproteins, now called the **ABO blood groups** (**figure 34.22*a***). The type II hypersensitivity reaction seen in blood transfusion occurs as complement is activated by cross-linking antibodies (figure 34.22*b*).

Blood typing can be accomplished by a slightly more sophisticated method of Landsteiner's process whereby blood from one host is mixed with antibodies specific for type A or type B blood. Agglutination of red cells by antibody (figure 34.22*c*) is used as a diagnostic tool to determine blood type. Another red blood cell antigen often reported with the ABO type was discovered during experiments with rhesus monkeys. The so-called rhesus (Rh) factor (or D antigen) is determined by the expression of two alleles, one dominant (coding for the factor) and one recessive (not coding for the factor). Thus an individual who is homozygous or heterozygous for the dominant Rh allele has the antigen and is indicated as Rh^+. Expression of two recessive alleles results in the designation of Rh^- (no Rh factor). Incompatibility between Rh^- mothers and their Rh^+ fetus can result in maternal anti-Rh antibodies destroying fetal blood cells (**figure 34.23**). This type II hypersensitivity is called **erythroblastosis fetalis.** Control of this potentially fatal hemolytic disease of the newborn can be mitigated if the mother is passively immunized with anti-Rh factor antibodies (RhoGAM).

Type III Hypersensitivity

Type III hypersensitivity involves the formation of immune complexes (**figure 34.24**). Normally these complexes are phagocytosed effectively by dendritic cells and macrophages. In the presence of excess amounts of some soluble antigens, the antigen-antibody complexes may not be efficiently removed. Their accumulation can lead to a hypersensitivity reaction from complement that triggers a variety of inflammatory processes. The antibodies of type III reactions are primarily IgG. The inflammation caused by immune complexes and cells responding to such inflammation can result in

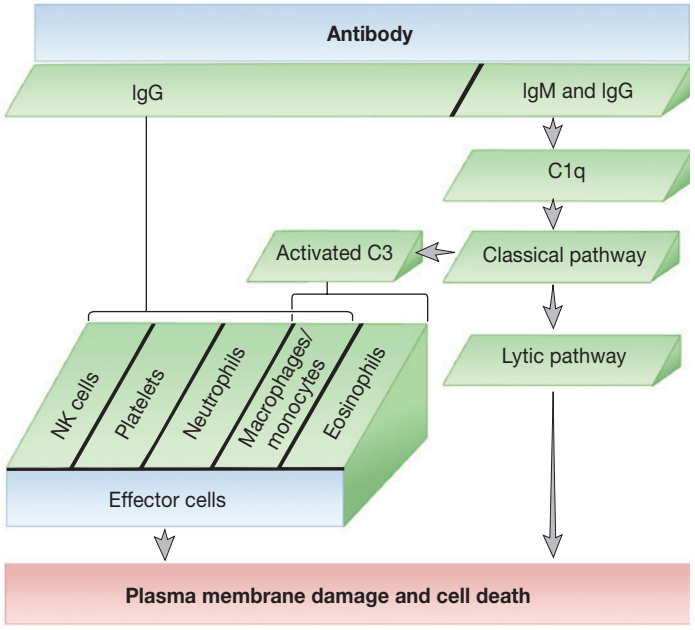


Figure 34.21 Type II Hypersensitivity. The action of antibody occurs through effector cells or the membrane attack complex, which damages target cell plasma membranes, causing cell destruction.

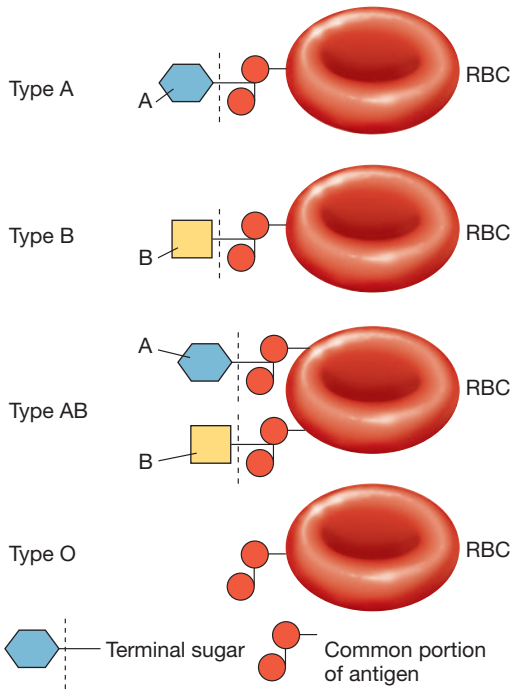
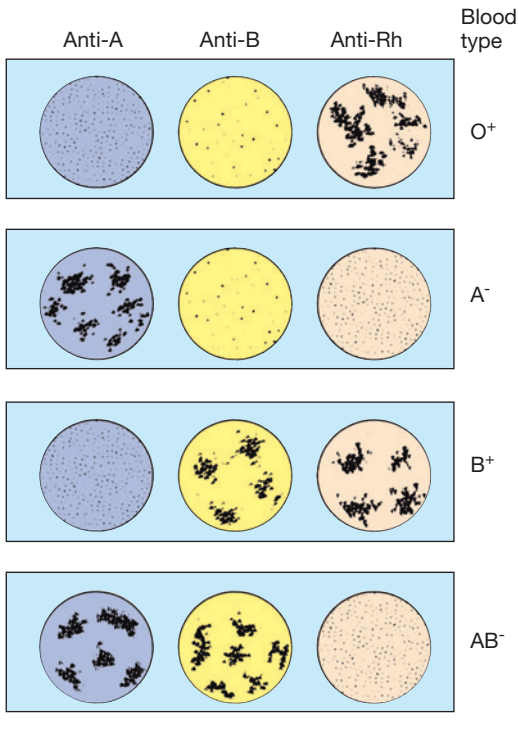
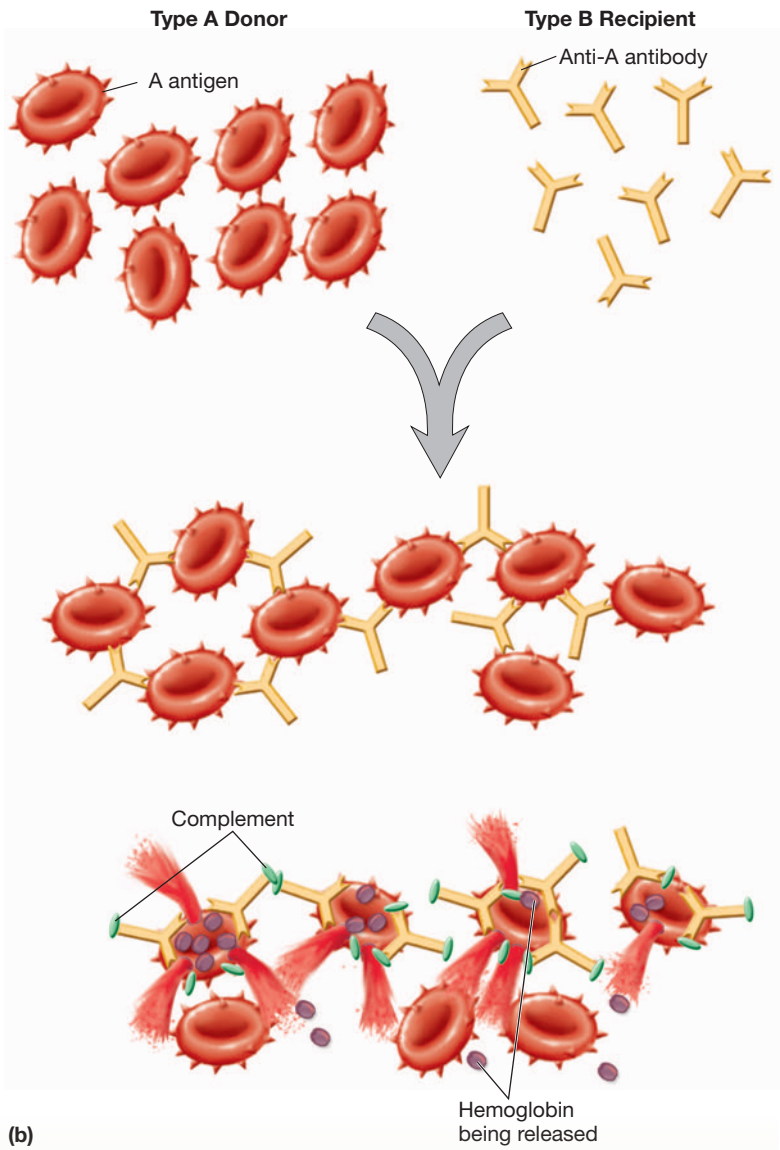


(a)



(c)



(b)

Figure 34.22 Immunohematology Is the Study of Immune Reactions Associated with Blood. (a) Red blood cells (RBCs) can have genetically inherited carbohydrate antigens (two possible sugar residues) on their surface. The presence of the antigen(s) determines the blood type. Some individuals may have one, both, or no antigen, resulting in the A or B, AB, or O blood types, respectively. (b) A host does not make antibodies to its own blood antigen(s); antibodies are made against blood antigens that are ubiquitous in nature, but not produced by the host making the antibody. Exposure of blood to antibody specific for its carbohydrate type results in RBC agglutination. RBC lysis can then occur if complement is activated by the antibody-agglutinated cells. (c) RBC agglutination with specific antibody is the basis for blood typing. Another molecule, the rhesus (Rh) factor, is another major RBC antigen that is typed to determine blood compatibility.

MICRO INQUIRY *What would be the genotype of an individual with type O, Rh^- blood?*

significant damage, especially of blood vessels (vasculitis), kidney glomerular basement membranes (glomerulonephritis), joints (arthritis), and skin (systemic lupus erythematosus).

Type IV Hypersensitivity

Type IV hypersensitivity involves delayed, cell-mediated immune reactions. A major factor in the type IV reaction is the time required for T cells to migrate to and accumulate near the antigens. Both T_H and CTL cells can elicit type IV hypersensitivity reactions, depending on the pathway in which the antigen is processed and presented. These events usually take a day or more to plateau. Two important type IV hypersensitivities are tuberculin hypersensitivity and allergic contact dermatitis. Other examples of type IV hypersensitivity reactions include the cell and tissue destruction caused by leprosy, tuberculosis, leishmaniasis, candidiasis, and herpes simplex lesions. These infectious diseases are discussed in chapters 38–40.

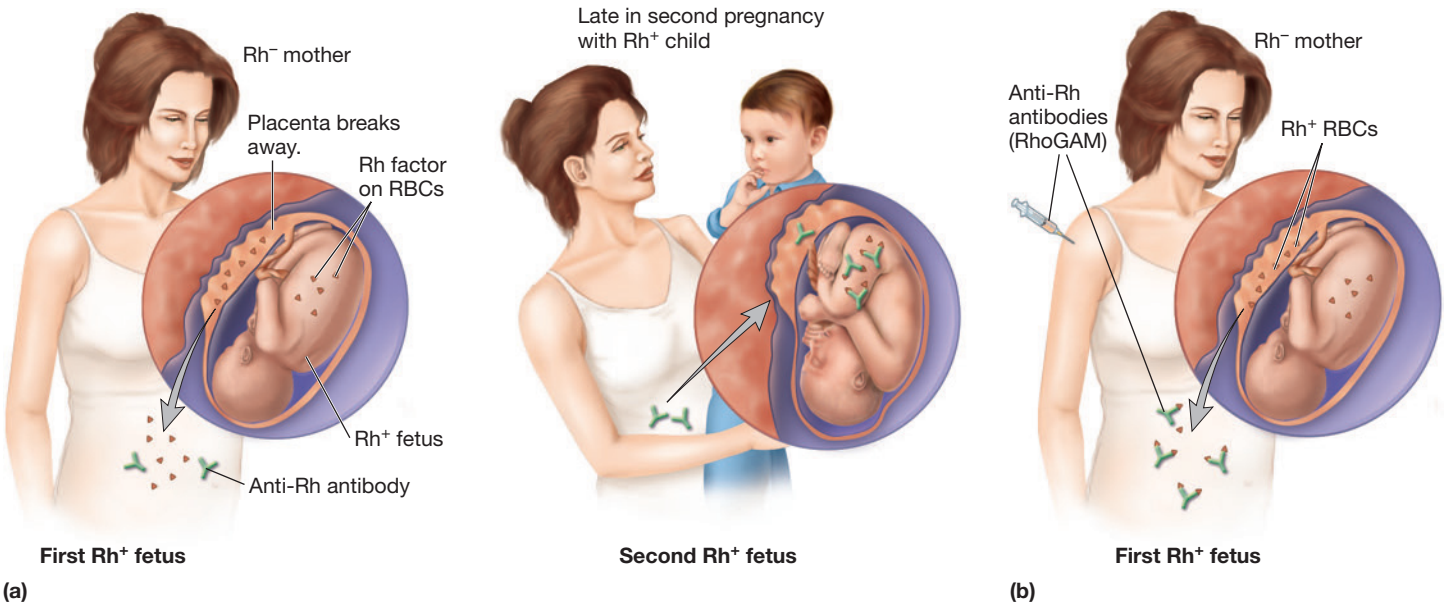


Figure 34.23 **Rh Factor Incompatibility Can Result in RBC Lysis.** (a) A naturally occurring blood cell incompatibility results when an Rh^+ fetus develops within an Rh^- mother. Initial sensitization of the maternal immune system occurs when fetal blood passes the placental barrier. In most cases, the fetus develops normally. However, a subsequent pregnancy with an Rh^+ fetus results in a severe, fetal hemolysis. (b) Anti-Rh antibody (RhoGAM) can be administered to Rh^- mothers during pregnancy to help bind, inactivate, and remove any Rh factor that may be transferred from the fetus. In some cases, RhoGAM is administered before sensitization occurs.

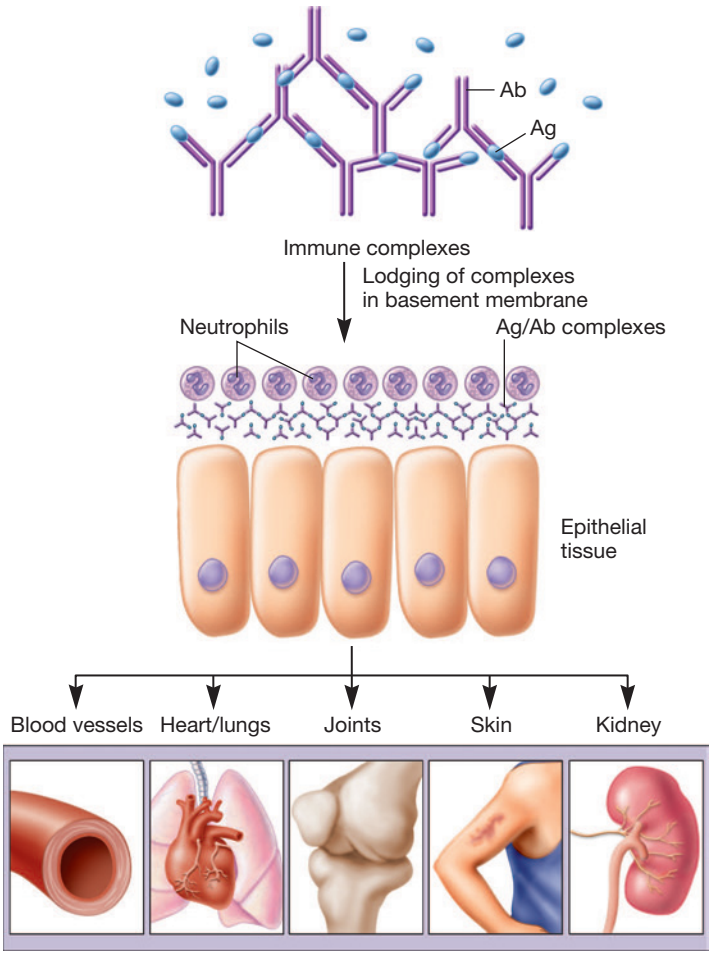

1. Antibody combines with excess soluble antigen, forming large quantities of Ab/Ag complexes.
2. Circulating immune complexes become lodged in the basement membrane of epithelia in sites such as kidney, lungs, joints, skin.
3. Fragments of complement cause release of histamine and other mediator substances.
4. Neutrophils migrate to the site of immune complex deposition and release enzymes that cause severe damage to the tissues and organs involved.

Figure 34.24 **Type III Hypersensitivity.** Circulating immune complexes may lodge at various tissue sites, where they activate complement and subsequently cause tissue cell lysis. Complement activation also results in granulocyte recruitment and release of their mediators, causing further injury to the tissue. Increased vascular permeability, resulting from granulocyte mediators, allows immune complexes to be deposited deeper into tissue sites, where platelet recruitment leads to microthrombi (blood clots), which impair blood flow, resulting in additional tissue damage.

In general, type IV reactions occur when antigens, especially those binding to serum proteins or tissue cells, are processed and presented to T cells. If the antigen is phagocytosed, it will be presented to T_H cells by the class II MHC molecules on the antigen presenting cell. This activates the T_H1 cell, causing it to proliferate and secrete cytokines such as IFN-γ and TNF-α. If the antigen is lipid soluble, it can cross the cell membrane to be processed within the cytosol and be presented to CTL cells by class I MHC molecules. CTLs induce apoptosis to kill the cell that is presenting the antigen. T_H-cell and CTL signals also stimulate the expression of adhesion molecules on the local endothelium to increase vascular permeability, allowing fluid and cells to enter the tissue space. The cytokines attract and recruit lymphocytes, macrophages, and basophils, exacerbating the inflammatory response. Extensive tissue damage may result.

In tuberculin hypersensitivity, partially purified proteins collectively called tuberculin are obtained from the bacterium that causes tuberculosis. After they are injected into the skin of the forearm, the response in a tuberculin-positive individual begins in about 8 hours, and a reddened area surrounding the injection site becomes indurated (firm and hard) within 12 to 24 hours. The T_H1 cells that migrate to the injection site are responsible for the induration. The reaction peaks in 48 hours and then subsides. The size of the induration is directly related to the amount of antigen that was introduced and to the degree of hypersensitivity of the tested individual.

Allergic contact dermatitis is a type IV reaction caused by haptens that combine with proteins in the skin to form the allergen that elicits the immune response (**figure 34.25**). The haptens are the antigenic determinants, and the skin proteins are the carrier molecules for the haptens. Examples of these haptens include cosmetics, plant materials (catechol molecules from poison ivy and poison oak), topical chemotherapeutic agents, metals, and jewelry (especially jewelry containing nickel).

Retrieve, Infer, Apply

1. Discuss the mechanism of type I hypersensitivity reactions and how these can lead to systemic and localized anaphylaxis.
2. What causes the typical raised and reddened skin reaction to antigen?
3. Why are type II hypersensitivity reactions called cytolytic or cytotoxic?
4. What characterizes a type III hypersensitivity reaction? Give an example.
5. Characterize a type IV hypersensitivity reaction.

Autoimmunity and Autoimmune Diseases

As we discuss in sections 34.1 and 34.9, the body is normally able to distinguish its own self antigens from foreign nonself antigens and usually does not mount an immunologic attack against itself. This phenomenon is called immune tolerance. At times the body loses tolerance and mounts an abnormal immune attack, either with antibodies or T cells, against its own self antigens.

It is important to distinguish between autoimmunity and autoimmune disease. Autoimmunity often is benign, whereas autoimmune disease often is fatal. **Autoimmunity** is characterized by the presence of serum antibodies that react with self antigens. These antibodies are called autoantibodies. The formation of autoantibodies is a normal consequence of aging; is readily inducible by infectious agents or drugs; and is potentially reversible (it disappears when the offending "agent" is removed or eradicated). **Autoimmune disease** results from the activation of self-reactive T and B cells that, following stimulation by genetic or environmental triggers, cause actual tissue damage (**table 34.4**). Examples include rheumatoid arthritis and type I diabetes mellitus.

Some investigators believe that the release of abnormally large quantities of self antigens may occur when an infectious agent causes host tissue damage. Others suggest that a change in the normal host-microbiota relationship (dysbiosis) results in

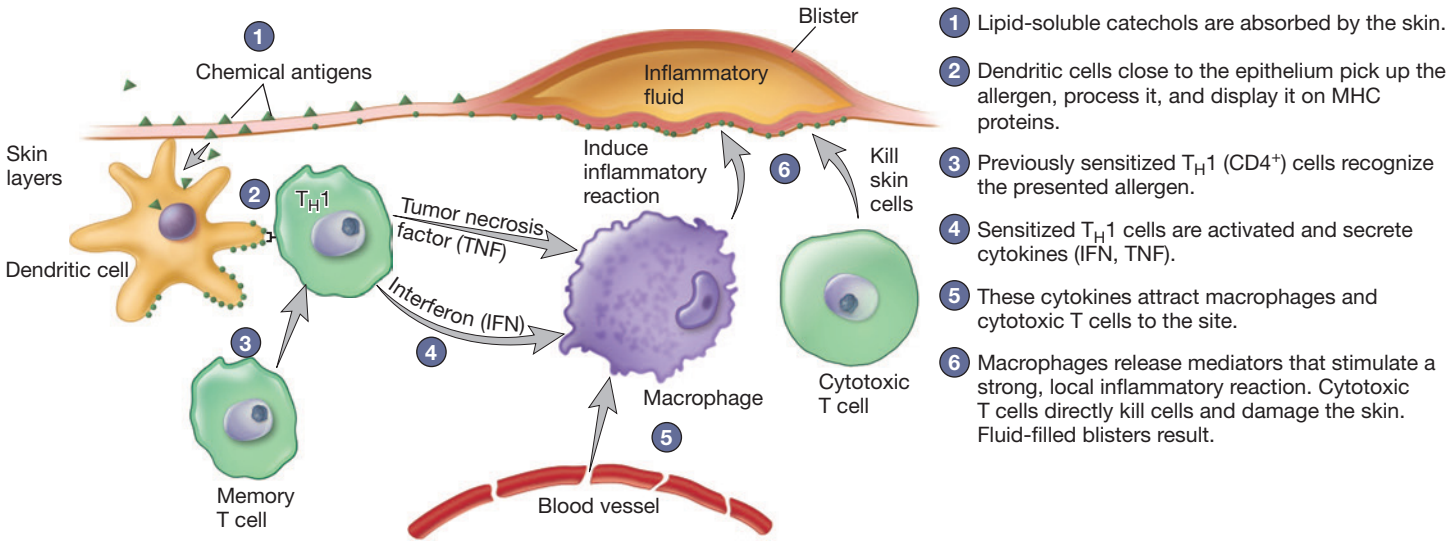

Figure 34.25 Contact Dermatitis. In contact dermatitis to poison ivy, a person initially becomes exposed to the allergen, predominantly 3-n-pentadecyl-catechol found in the resinous sap material urushiol, which is produced by the leaves, fruit, stems, and bark of the poison ivy plant. The catechol molecules, acting as haptens, combine with high molecular weight skin proteins. After 7 to 10 days, sensitized T cells are produced and give rise to memory T cells. Upon second contact, the catechols bind to the same skin proteins, and the memory T cells become activated in only 1 to 2 days, leading to an inflammatory reaction (contact dermatitis).

Table 34.4 Some Autoimmune Diseases in Humans

Disease	Autoantigen	Pathophysiology
Acute rheumatic fever	Streptococcal cell wall antigens mimic self antigens and induce antibodies that cross-react with antigens on cardiomyocytes and other cells.	Type II hypersensitivity leads to myocarditis, heart valve scarring, and arthritis.
Autoimmune hemolytic anemia	Rh blood group antigen induces antibody to Rh antigen on red blood cells.	Type II hypersensitivity leads to anemia when red blood cells are destroyed by complement and phagocytosis.
Goodpasture's syndrome	Damage to kidney basement membrane exposes cryptic collagen protein, inducing anti-collagen antibody.	Type II hypersensitivity results in glomerulonephritis and pulmonary hemorrhage.
Graves' disease	Antibody to thyroid-stimulating hormone (TSH) receptor mimics TSH.	Overstimulation of TSH receptor leads to hyperthyroidism.
Multiple sclerosis	Antibody and activated T cells to several nervous system antigens	Types II and IV hypersensitivities alter nerve communications, leading to numbness, weakness, spasm, and loss of motor and cognitive function.
Myasthenia gravis	Antibody to acetycholine receptor in skeletal muscle	Antibody blockade of neurotransmitter receptors results in progressive muscular weakness.
Rheumatoid arthritis	IgG antibody (to synovial joint cartilage antigen) recognized as foreign	Type III hypersensitivity from immune complexes of antibodies to antibodies results in joint inflammation and destruction.
Systemic lupus erythematosus	Antibodies to various cellular (DNA, nucleoprotein, cardiolipin) and blood clotting components	Type III hypersensitivity results in immune complex-induced arthritis, glomerulonephritis, vasculitis, and rash.
Insulin-dependent diabetes mellitus	Antibody and activated T cells to pancreatic beta cell antigens	Types II and IV hypersensitivities destroy beta cells, resulting in insulin deficiency.

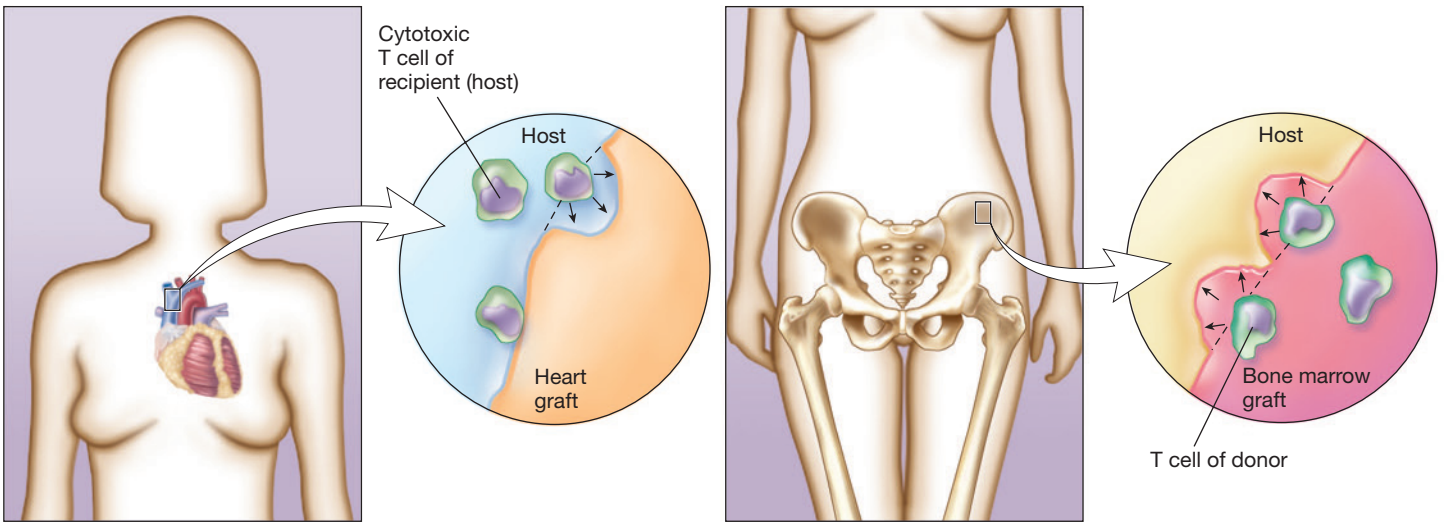
immune dysfunction. The same agents also may cause body proteins to change into forms that stimulate antibody production or T-cell activation. Simultaneously, the capacity of T cells to limit this type of reaction seems to be repressed.

Transplantation (Tissue) Rejection

Transplants between genetically different individuals within a species are termed **allografts** (Greek *allos,* other). Some transplanted tissues do not stimulate an immune response. For example, a transplanted cornea is rarely rejected because lymphocytes do not circulate into the anterior chamber of the eye. This site is considered an immunologically privileged site. Another example of a privileged tissue is the heart valve, which in fact can be transplanted from a pig to a human without stimulating an immune response. Such a graft between different species is termed a **xenograft** (Greek *xenos,* strayed).

Transplanting tissue that is not immunologically privileged generates the possibility that the recipient's cells will recognize the donor's tissues as foreign. This triggers the recipient's immune mechanisms, which may destroy the donor tissue. Such a response is called **host-versus-graft disease,** or tissue rejection. Tissue rejection can occur by two different mechanisms. First, foreign MHC molecules on transplanted tissue, or the "graft," are recognized by host T-helper cells, which aid cytotoxic T cells in graft destruction (**figure 34.26**). Cytotoxic T cells then recognize the graft because it bears foreign class I MHC molecules. This response is much like the activation of CTLs by virally infected host cells. A second mechanism involves T-helper cells reacting to the graft and releasing cytokines. The cytokines stimulate macrophages to enter, accumulate within the graft, and destroy it. MHC molecules play a dominant role in tissue rejection reactions because of their unique association with the recognition system of T cells. Unlike antibodies, T cells cannot recognize or react directly with non-MHC molecules (viruses, allergens). They recognize these molecules only when presented by an MHC molecule.

Because class I MHC molecules are present on every nucleated cell in the body, they are important targets of the rejection reaction. The greater the antigenic difference between class I molecules of the recipient and donor tissues, the more rapid and severe the rejection reaction is likely to be. Class II MHC molecule mismatch can also result in rejection and may be even more severe than class I mismatch reactions. However, the reaction can sometimes be minimized if recipient and donor tissues are matched as closely as possible. Most recipients are not 100% matched to their donors, so immunosuppressing drugs are used to prevent host-mediated rejection of the graft.



(a) host-versus-graft disease (b) graft-versus-host disease

Figure 34.26 Potential Transplantation Reactions. (a) Donated tissues that are not from an identical twin contain cellular MHC proteins that are recognized as foreign by the recipient host (host-versus-graft disease). The tissue is then attacked by host CTLs, resulting in its damage and rejection. (b) Donated tissue may also contain immune cells that react against host antigens. Recognition of a foreign host by donor CTLs results in graft-versus-host disease.

Organ transplant recipients also can develop **graft-versus-host disease.** This occurs when the transplanted tissue contains immune cells that recognize host antigens and attack the host. The immunosuppressed recipient cannot control the response of the grafted tissue. Graft-versus-host disease is a common problem in bone marrow transplants. The transplanted bone marrow contains many mature T cells. These cells recognize the host MHC antigens and attack the immunosuppressed recipient's normal tissue cells.

Immunodeficiencies

Defects in one or more components of the immune system can result in its failing to recognize and respond properly to antigens. Such **immunodeficiencies** can make a person more prone to infection than those people capable of a complete and active immune response. Despite the increase in knowledge of functional derangements and cellular abnormalities in the various immunodeficiency disorders, the fundamental biological errors responsible for them remain largely unknown. To date, most genetic errors associated with these immunodeficiencies are located on the X chromosome and produce primary or congenital immunodeficiencies (**table 34.5**). Other immunodeficiencies can be acquired because of infections by immunosuppressive microorganisms, such as HIV.

Retrieve, Infer, Apply

1. What is an autoimmune disease and how might it develop?
2. What is an immunologically privileged site and how is it related to transplantation success?
3. How does a tissue rejection reaction occur? How might a patient about to receive a bone marrow transplant be prepared? Explain why this is necessary.
4. Describe an immunodeficiency. How might immunodeficiencies arise?

Table 34.5 Some Congenital Immune Deficiencies in Humans

Condition	Symptoms	Cause
Chronic granulomatous disease	Defective monocytes and neutrophils leading to recurrent bacterial and fungal infections	Failure to produce reactive oxygen intermediates due to defective NADPH oxidase
X-linked agammaglobulinemia	Plasma cell or B-cell deficiency and inability to produce adequate specific antibodies	Defective B-cell differentiation due to loss of tyrosine kinase
DiGeorge syndrome	T-cell deficiency and very poor cell-mediated immunity	Lack of thymus or a poorly developed thymus
Severe combined immunodeficiency disease (SCID)	Both antibody production and cell-mediated immunity impaired due to a great reduction of B- and T-cell levels	Various mechanisms (e.g., defective B- and T-cell maturation because of X-linked gene mutation; absence of adenosine deaminase in lymphocytes)

Key Concepts

34.1 Adaptive Immunity Relies of Recognition and Memory

- The adaptive immune response system consists of lymphocytes that recognize foreign molecules (antigens) and respond to them. Two branches or arms of immunity are recognized: humoral (antibody-mediated) immunity and cellular (cell-mediated) immunity (**figure 34.1**).
- Acquired immunity refers to the type of specific (adaptive) immunity that a host develops after exposure to a suitable antigen.

34.2 Molecules That Elicit Immunity Are Called Antigens

- An antigen is a substance that stimulates an immune response. Each antigen can have several antigenic determinant sites called epitopes that stimulate production of and combine with specific antibodies (**figure 34.2**).
- Haptens are small organic molecules that are not antigenic by themselves but can become antigenic if bound to a larger carrier molecule.

34.3 Adaptive Immunity Can Be Earned or Borrowed

- Immunity can be acquired by natural means—actively through infection or passively through receipt of preformed antibodies, as through colostrum (**figure 34.3**).
- Immunity can be acquired by artificial means—actively through immunization or passively through receipt of preformed antibodies, as with antisera.

34.4 Recognition of Foreignness Is Critical for a Strong Defense

- MHC molecules are cell-surface proteins coded by a group of genes termed the major histocompatibility complex. Class I MHC proteins are found on all nucleated cells of mammals. Class II MHC proteins are expressed on macrophages, dendritic cells, and B cells. The human MHC gene products are called the human leukocyte antigens (HLAs) (**figure 34.4**).
- Class I MHC proteins collect foreign peptides processed by the proteasome and present them to cytotoxic T cells (**figure 34.5**).
- Class II MHC proteins collect foreign peptides processed by the phagosome (macrophages and dendritic cells) or endosome (B cells) and present them to T-helper cells.

34.5 T Cells Oversee and Participate in Immune Functions

- T cells are pivotal elements of the immune response. T cells have antigen-specific receptor proteins (**figure 34.6**).
- Antigen-presenting cells—macrophages, dendritic cells, and B cells—take in foreign antigens or pathogens, process them, and present antigenic fragments complexed with MHC molecules to T-helper cells.
- T cells control the development of other cells, including effector B and T cells. T-helper cells ($CD4^+$) regulate cell behavior; cytotoxic T cells ($CD8^+$) also regulate cell behavior, but in addition, they can kill altered host cells directly.
- There are five subsets of T-helper cells—T_H1, T_H2, T_H9, T_H17, and T_H22—that arise from the undifferentiated T_H0. T_H1 cells produce various cytokines and are involved in cellular immunity. T_H2 cells also produce various cytokines but are involved in humoral immunity. T_H9 cells primarily produce IL-9 to inhibit apoptosis. T_H17 cells primarily produce IL-17 and induce inflammation by recruiting neutrophils. T_H22 cells produce IL-22, IL-13, and TNF-alpha to facilitate wound healing (**figure 34.9**).
- Regulatory T (Treg) cells can arise from both $CD4^+$ and $CD8^+$ T cells and can downregulate specific immune reactions, especially those rare reactions attacking self.
- Cytotoxic T lymphocytes recognize target host cells such as virus-infected cells that have foreign antigens and class I MHC molecules on their surface. The CTLs then attack and destroy the target cells using the CD95 pathway, the perforin pathway, or both.

34.6 B Cells Make Antibodies and Do a Whole Lot More

- B cells defend against antigens by differentiating into plasma cells that secrete antibodies into the blood and lymph, providing humoral or antibody-mediated immunity.
- B cells can be stimulated to divide or differentiate to secrete antibody when triggered by the appropriate signals. One type of such a signal is the microbe-associated molecular pattern (MAMP) that binds to B-cell toll-like receptors.
- B cells have receptor immunoglobulins on their plasma membrane surface that are specific for given three-dimensional epitopes. Contact with the epitope is required for the B cell to divide and differentiate into plasma cells and memory cells (**figures 34.10** and **34.11**).

34.7 Antibodies Are Proteins That Bind Specific 3-D Structures

- Antibodies (immunoglobulins) are a group of glycoproteins present in the blood, tissue fluids, and mucous membranes of vertebrates. All immunoglobulins have a basic structure composed of four polypeptide chains (two light and two heavy) connected to each other by disulfide bonds (**figure 34.12**). In humans, five immunoglobulin classes exist: IgG, IgA, IgM, IgD, and IgE (**figures 34.13** and **34.14** and **table 34.2**).
- The primary antibody response in a host occurs following initial exposure to the antigen. This response has lag, log, plateau, and decline phases. Upon secondary antigen challenge, the B cells mount a heightened and accelerated response (**figure 34.15**).

- Antibody diversity results from the rearrangement and splicing of the individual gene segments on the antibody-coding chromosomes, somatic mutations, the generation of different codons during splicing, and the independent assortment of light- and heavy-chain genes (**figures 34.16** and **34.17**).
- Immunologic specificity and memory are partly explained by the clonal selection theory (**figure 34.18**).

34.8 Antibody Binding Dooms the Target

- Various types of antigen-antibody reactions occur in vertebrates and initiate the participation of other body processes that determine the ultimate fate of the antigen.
- The complement system can be activated, leading to cell lysis, phagocytosis, chemotaxis, or stimulation of the inflammatory response.
- Other defensive antigen-antibody interactions include toxin neutralization, viral neutralization, adherence inhibition, opsonization, and immune complex formation (**figure 34.19**).

34.9 Not Responding Is Also Part of Immunity

- Acquired immune tolerance is the ability of a host to react against nonself antigens while tolerating self antigens. It can be induced in several ways.
- Anergy is a state of immune unresponsiveness.

34.10 Sometimes the Immune System Doesn't Work the Way It Should

- When the immune response occurs in an exaggerated form and results in tissue damage to the individual, the term hypersensitivity is applied. There are four types of hypersensitivity reactions, designated as types I through IV (**figures 34.20–34.25**).
- Autoimmune diseases result when self-reactive T and B cells attack the body and cause tissue damage. A variety of factors can influence the development of autoimmune disease (**table 34.4**).
- The immune system can act detrimentally and reject tissue transplants. There are different types of transplants. Xenografts involve transplants of privileged tissue between different species, and allografts are transplants between genetically different individuals of the same species (**figure 34.26**).
- Immunodeficiency diseases are a diverse group of conditions in which an individual's susceptibility to various infections is increased; several severe diseases can arise because of one or more defects in the adaptive or innate immune responses.

Compare, Hypothesize, Invent

1. What properties of proteins make them suitable molecules from which to make antibodies?
2. What other biotechnologies could be invented based upon clonal selection theory (in addition to monoclonal antibody technique)s?
3. Speculate as to how MHC, TCR, and BCR molecules evolved to require accessory proteins or coreceptors for a signal to be sent within the cell?
4. Why do you think two signals are required for B- and T-cell activation but only one signal is required for activation of an APC?
5. Most immunizations require multiple exposures to the vaccine (i.e., boosters). Why is this the case?
6. In an effort to better understandf the mechanisms by which hosts tolerate their normal gut flora, researchers introduced the Gram-negative bacterium *Bacteroides thetaiotaomicron* (a normal inhabitant of the guts of both mice and humans) into gnotobiotic mice. They discovered that the more sIgA the mice produced, the better the microbe was tolerated, as monitored by the level of intestinal inflammation. We usually think of antibody production and inflammation as partners in the fight against infectious agents. Why do you think that in this case, the production of antibody was not coupled with inflammation and, to the contrary, protected the host against inflammation? What does this suggest about the mechanism by which normal flora is "permitted" to make a specific host its home?

   Read the original paper: Peterson, D. A., et al. 2007. IgA response to symbiotic bacteria as a mediator of gut homeostasis. *Cell Host Microbe* 2:328–39.
7. While the distribution of memory T cells is well understood, the distribution of memory B cells after an infection has not been as well studied. To address this, Joo and coworkers used a mouse influenza pneumonia model to track the distribution of IgG and IgA memory B cells. The influenza infection was limited to the lung; no virus was detected outside the lung. During and after infection, memory B cells were widely dispersed to secondary lymphoid tissues as well as into the lung itself. Why do you think memory B cells localize to secondary lymphoid tissues if this virus is specific to lung tissue? What might the implications of this study be for the distribution of memory B cells following vaccination, particularly for a subunit vaccine that does not localize to the normal site of infection?

   Read the original paper: Joo, H. M. 2008. Broad dispersion and lung localization of virus-specific memory B cells induced by influenza pneumonia. *Proc. Natl. Acad. Sci. USA* 105:3485–90.

35

Pathogenicity and Infection

Staphylococcus aureus *is notorious for its ability to acquire virulence factors by horizontal gene transfer. This scanning electron micrograph (SEM) shows a vancomycin-resistant strain of* **S. aureus** *bacteria (20,000x).*

Sneaky Little Buggers

Have you ever wondered why some microorganisms seem to be more infectious than others? Scientists from the Pasteur Institute, the University of Lisbon (Portugal), and Harvard University also think about this. In separate studies, these "microbiology detectives" used bioinformatics, genomics, epidemiology, and evolutionary biology techniques to investigate the question of why specific numbers of microorganisms are needed to initiate disease. One measurement is called the infectious dose 50% (ID_{50}), and it refers to the number of microorganisms needed to infect 50% of the test hosts. The French and Portuguese scientists scoured the literature to find 48 different bacterial pathogens whose ID_{50} they could correlate with motility, growth rate, immune cell interactions, and use of quorum sensing. They determined that bacteria with a higher infectivity (a lower ID_{50}) were less motile, slower to reproduce, and had little interaction with others of their kind. By contrast, the faster, more social, and more rapid reproducers had lower infectivity, requiring a greater ID_{50}. One important interpretation of these data is that distantly related bacteria use the same common mechanisms to cause infectious disease; that is, ID_{50} correlates better with acquisition of virulence factors by horizontal gene transfer (HGT) than with taxonomy and phylogenetics.

The U.S. study evaluated the genetic changes that occur in bacteria during their encounters with human hosts. These researchers used large-scale genomic sequencing of hundreds of *Burkholderia* samples that infected cystic fibrosis patients to identify selective pressures (host immunity and medical treatment) on bacterial chromosomal genes over generations. The scientists compared the *Burkholderia* genes that had mutated multiple times to those that had mutated only once. They found that the selective pressures imposed while in the human host leads to mutation in at least 17 genes including genes encoding antibiotic resistance, adhesion molecules, secretion system proteins, proteins for oxygen sensing and regulation, and, unexpectedly, a gene for modifying lipopolysaccharide (LPS).

Both studies suggest that successful pathogens adapt to selective pressures imposed by the host, mutating or acquiring genes by HGT to overcome survival challenges. Infection of subsequent hosts, as in an epidemic, alters the selective pressures (different hosts with different immune responses, medical therapies, etc.), revealing the important challenges for survival as a pathogen. Together, these studies confirm that bacterial genomes are extremely flexible and resilient, enabling many species to live in and adapt to the harshest of environmental conditions.

Chapter 32 introduces the concept of symbiosis and deals with its subordinate categories, including commensalism and mutualism. In this chapter, the process of parasitism is presented along with one of its possible consequences—pathogenicity. The parasitic way of life is so successful, it has evolved independently in nearly all groups of organisms. Understanding host-parasite relationships requires an interdisciplinary approach, drawing on knowledge of cell biology, microbiology, entomology, immunology, ecology, and zoology. This chapter examines the parasitic way of life in terms of health and disease with an emphasis on viral and bacterial disease mechanisms.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Explain symbiosis and differentiate the true definition of parasitism from several common uses of the word (sections 32.1 and 32.2)
- ✔ Generalize the principles of symbiosis to human-microbe interactions (section 32.2)
- ✔ Identify the major structures and their functions of bacteria, protists, fungi, and viruses, including their replication processes and energy requirements (chapters 3, 5, 6, 7, 10, and 12)

35.1 Pathogenicity Drives Infectious Disease

After reading this section, you should be able to:

- Compare and contrast competition between microbial species with competition between microbial and human cells
- Predict the microbial virulence factors and host cell responses that result in disease
- Relate the infectious disease process to time, identifying events associated with each stage of the process

Microorganisms actively seek host-specific sites that meet their unique growth and replication requirements. These are molecular determinants that optimize microbial survival. Thus, host and tissue specificity offer microorganisms shelter and access to resources. However, relationships between two organisms can be very complex. A larger organism that supports the survival and growth of a smaller organism is called the **host.** Any organism that causes disease is known as a **pathogen** (Greek *patho,* disease, and *gennan,* to produce). Its ability to cause disease is called **pathogenicity.** Even normal microbiota, such as those associated with the gut or skin, can become pathogens. An **opportunistic pathogen** is such an organism; it infects a host away from its typical niche, especially in a host with a weakened immune system (a compromised host).

Infectious disease results from antagonism with microbial agents such as viruses, bacteria, fungi, and protozoa. When a pathogen is growing and multiplying within or on a host, the host is said to have an **infection.** The nature of an infection can vary widely with respect to severity, location, and type of organisms involved. An infection may or may not result in overt disease. An **infectious disease** is any change from a state of health in which part or all of the host body is not capable of carrying on its normal functions due to the presence of a pathogen or its products (e.g., toxins).

The fundamental process of infection is essentially a competition for resources. The host is a source of protection, nutrients, and energy for the pathogen to use. Infectious agents must therefore develop mechanisms to access and exploit their hosts. Furthermore, to continue surviving, pathogens must also devise methods to move on to better environments once the immediate one declines in value. Dissemination to another point in one host or into another host must then occur. The **infectious disease chain** represents these events in the form of an intriguing mystery, where the disease process becomes understood only when all of the links of the chain are known (**figure 35.1**). Here we introduce these links and the concepts that will be discussed more thoroughly later in the chapter.

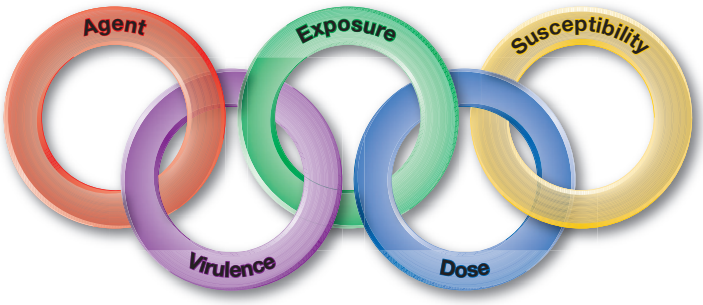


Figure 35.1 The Chain of Infection. The infectious disease process requires that a specific agent of substantial virulence is exposed to a susceptible host in an appropriate dose (number of organisms). All links of the chain are necessary for infectious disease to result. Breaking the chain, by removal of any link, prevents infectious disease.

MICRO INQUIRY *What physical and chemical methods could break the chain of infection?*

Before a microorganism can cause disease in a human, it must contact it. Pathogens come from a source, the location from which the pathogen is immediately transmitted to the host, either directly through the environment or indirectly through an intermediate agent. The source can be either animate (e.g., humans or animals) or inanimate (e.g., water or food). The period of infectivity is the time during which the source—such as a human, or contaminated water—is disseminating the pathogen. If the source of the infection can be eliminated or controlled—by treating the human or disinfecting contaminated water—the infectious disease cycle itself will be interrupted and transmission of the pathogen will be prevented.

A **reservoir** is the natural environmental location in which the pathogen normally resides. It is also the site from which a source acquires the pathogen or where direct infection of the host can occur. Thus a reservoir sometimes functions as a source. Reservoirs also can be animate or inanimate. Examples include birds as reservoir of West Nile virus and contaminated drinking water as the reservoir of *Vibrio cholerae*. The increasing impingement of humans on the environment and increased exposure to antibiotics and mutagens have played significant roles in the substantive change in reservoirs over the last 100 years.

Infectious diseases that can be transmitted from animals to humans are termed **zoonoses** (Greek *zoon,* animal, and *nosos,* disease); thus animals also can serve as reservoirs, as when a rabid dog transmits rabies by biting a human. In addition, being bitten by arthropod **vectors** (organisms that spread disease from one host to another), such as mosquitoes, ticks, fleas, mites, or biting flies, can lead to infection (e.g., West Nile virus, malaria, Lyme disease, Rocky Mountain spotted fever, and plague). These reservoirs are often referred to as vehicles, as they deliver the infectious agent to the host; they are discussed in chapters 38 through 40.

In order for the microorganism to cause disease, it must not just contact the host but be able to survive in it. To survive, the microorganism needs a suitable environment. An overview of the factors leading to infection, from the microorganism's perspective, is presented in **figure 35.2**. We evaluate the transmission of the microorganism from its reservoir to its entry point on the host a little later. But first, we briefly consider the challenges faced when a microorganism initially encounters a human host.

Recall that microorganisms have a range of values—temperature, pH, moisture, oxygen concentration, etc.—in which they can grow and reproduce. Thus, for a pathogen to survive in its human host, the host must provide conditions that fall within those values. When a pathogen is introduced to the human host, it needs to adapt to the realities of its new environment to meet its metabolic and physiological needs. One of those realities is that the microorganism must compete with the cells of its eukaryotic host. The successful pathogen will outcompete host cells and evade host immune defenses through the use of **virulence factors.** We discuss these in the next section, but suffice it to say, virulence factors enable the microbe to counter the challenges of the host environment.

⏮ *Environmental factors affect microbial growth (section 7.4)*

Survival of the microorganism in the host also depends heavily on its abilities to "find shelter." Some microorganisms survive and replicate inside of host cells; in some cases, they reside in the

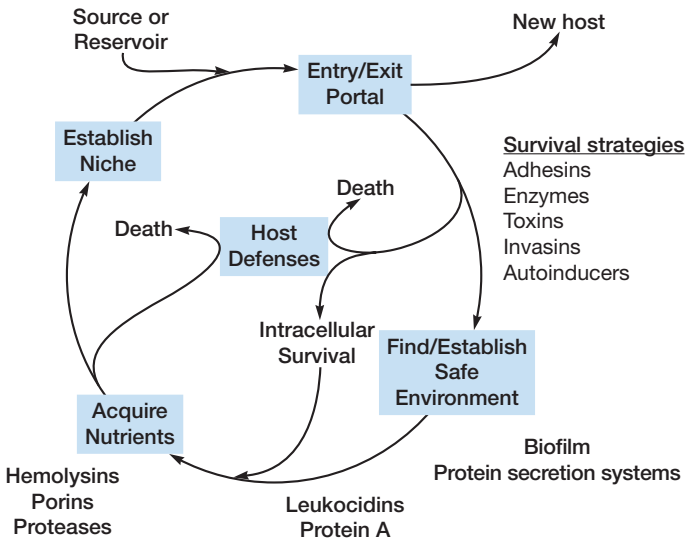

Figure 35.2 Overview of the Infection Process. The infectious disease process is complex and dynamic. To the host, infection is at best an annoyance and at worst lethal, if the microorganism succeeds. To microorganisms, infection is focused on finding a suitable environment, obtaining nutrients, and avoiding host immune responses to establish a niche. Microorganisms use numerous physical and chemical strategies to survive.

very cells that are supposed to destroy them. Other organisms attach to and between host cells, make capsules, burrow under mucus, and secrete exopolysaccharides to form communal shelters within biofilms. Some microorganisms produce enzymes that inactivate innate resistance mechanisms. Still other organisms have evolved specialized protein secretion systems to selectively kill host cells. These physical and chemical characteristics reflect microbial virulence; they facilitate microbial survival.

Some microorganisms are pathogenic due to their rapid replication and explosive departure from host cells. Still others are pathogens because they integrate parts of their genome into the host cell DNA, commandeering that cell in the future. Many microorganisms, particularly bacteria, use a strategy that poisons host cells; they use toxins. A **toxin** (Latin *toxicum,* poison) is a substance that alters the normal metabolism of host cells with deleterious effects on the host. The term toxemia is used when toxins have entered the blood of the host. **Toxigenicity** is the pathogen's ability to produce toxins. **Intoxications** are diseases that result from a specific toxin (e.g., botulinum toxin, tetanus toxin) produced by the pathogen. Intoxication diseases do not require the presence of the actively growing pathogen—just its toxin, as in the case of botulism.

Infectious diseases are typically not detected until distinct physical and/or physiological events alert the host of cellular battle. Infectious diseases often have characteristic signs and symptoms. **Signs** are objective changes in the body, such as a fever or rash, that can be directly observed. **Symptoms** are subjective changes, such as pain and loss of appetite, that are experienced by the patient. The term symptom is often used in a broader scope to include the clinical signs. A **disease syndrome** is a set of signs and symptoms that are characteristic of the disease.

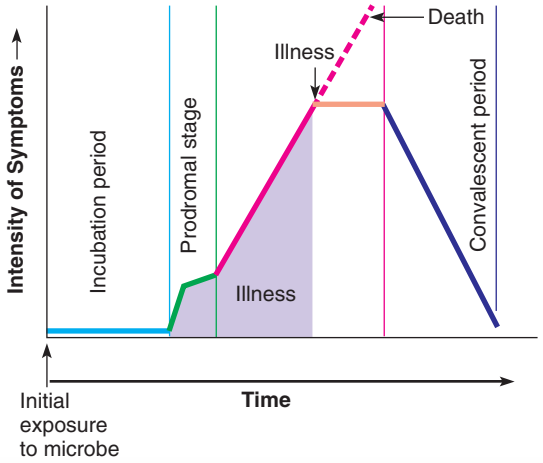

Figure 35.3 The Course of an Infectious Disease. Most infectious diseases occur in four stages. The duration of each stage is a characteristic feature of each disease. The shaded area represents when many diseases are communicable. Should the host be unable to overcome illness, death results.

MICRO INQUIRY *During which stages does the host exhibit signs and symptoms? How does this correlate to when the disease is communicable?*

Clinically, the course of an infectious disease usually has a characteristic pattern and can be divided into several phases (**figure 35.3**). The **incubation period** is the time between pathogen entry and development of signs and symptoms. The pathogen is reproducing but has not reached a sufficient level to cause clinical manifestations. This period's length varies with disease. Next, the **prodromal stage** occurs with an onset of signs and symptoms that are not yet specific enough to make a clear diagnosis. However, the patient often is contagious. This is followed by the **illness period,** when the disease is most severe and displays characteristic signs and symptoms. The host immune response is typically triggered at this stage. Finally, during the period of decline, the signs and symptoms begin to disappear. The recovery stage often is referred to as **convalescence.**

Infectious Dose

The rate at which an infection proceeds (the timing of the incubation period and prodromal stage, for example) and its severity are functions of the initial inoculum of microorganisms and their virulence (in addition to the host's resistance). Some microorganisms are sufficiently adept at entering a host that very few are required to establish an infection. Conversely, other microorganisms are required in high numbers to establish an infection (see the chapter-opening story). The inocula can be measured experimentally to determine the **infectious dose 50** ($\mathbf{ID_{50}}$)—that is, the number of microorganisms required to cause disease in 50% of the inoculated hosts (**figure 35.4**). One example of this is found in the oral transmission of *Salmonella* spp., which are shed in the feces of infected hosts and often contaminate fingers and hands. During food preparation, the bacteria are transferred to foods, where they can then be ingested. The ID_{50} for *Salmonella* spp. ingested in contaminated food is approximately 1×10^5 bacteria. Suffice it to say, the reason for thorough handwashing as a means of maintaining public health is to decrease the number

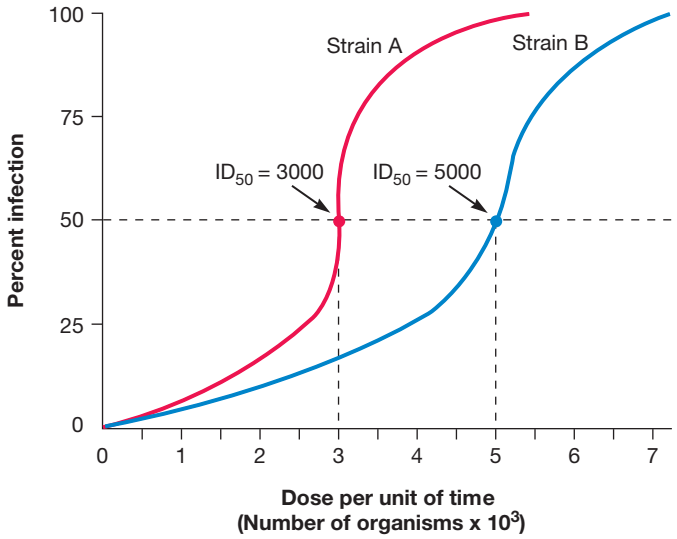

Figure 35.4 Determination of the ID_{50} of a Pathogenic Microorganism. Various doses of a specific pathogen are introduced into experimental host animals. Infections are recorded and a graph constructed. In this example, the graph represents the susceptibility of host animals to two different strains of a pathogen—strain A and strain B. For strain A, the ID_{50} is 3000, and for strain B, it is 5000. Hence strain A is more virulent than strain B.

of pathogens that can be transmitted. For the most part, the lower the infectious dose (the fewer organisms needed for infection), the higher the risk of infection.

Another measure of infectivity, and thus virulence, is the experimental determination of the number of microorganisms required to be lethal to a host species. This is known as the **lethal dose 50** (**LD_{50}**) and refers to the dose or number of pathogens that kills 50% of an experimental group of hosts within a specified period. Highly virulent pathogens kill at a much reduced dose as compared to less virulent organisms.

Host Susceptibility

The final link in the infectious disease cycle is the host (figure 35.1). The susceptibility of the host to a pathogen depends on the pathogenicity of the organism, the innate host resistance factors, and the adaptive immune mechanisms of the host. Host immunity is the subject of chapters 33 and 34 and will not be discussed here. In addition to host defense mechanisms, nutrition, genetic predisposition, cleanliness, and stress also influence host susceptibility to infection.

Extracellular and Intracellular Pathogens

As noted earlier, a successful pathogen must find an appropriate environment in the host. This can be provided outside host cells or inside host cells, depending on the pathogen. Infectious microorganisms are considered **extracellular pathogens** if, during the course of disease, they remain in tissues and fluids but never enter host cells. For instance, some bacteria and fungi can actively grow and multiply in the blood or tissue spaces. *Y. pestis* and *Aspergillus* (the cause of a variety of fungal infections) are good examples of extremely virulent extracellular pathogens. Microbes that grow and multiply within host cells are called **intracellular pathogens;** they can be further subdivided into two groups. **Facultative intracellular pathogens** are those organisms that can reside within the cells of the host or in the environment. A bacterial example is *Brucella abortus,* which is capable of growth and replication within macrophages, neutrophils, and trophoblast cells (cells that surround the developing embryo). A protozoal example is *Histoplasma capsulatum,* which grows within phagocytes. However, facultative intracellular pathogens can also be grown in pure culture without host cell support. In contrast, **obligate intracellular pathogens** are incapable of growth and multiplication outside a host cell. By definition, all viruses are obligate intracellular pathogens in that they require a host cell for replication, often to the detriment of that cell. Some bacteria are also obligate intracellular bacterial pathogens, such as *Chlamydia* spp. and rickettsias (which cause diseases such as Rocky Mountain Spotted Fever and typhus). These microbes cannot be grown in the laboratory outside of their host cells. Malarial parasites are examples of protozoa that require host cells for growth and differentiation.

The survival of an invading microorganism depends on its ability to rapidly adapt to the host. Host cues often activate specific microbial genes whose products equip the microbe with specific survival means, such as exotoxins, specialized attachment proteins, tissue-altering enzymes, and biofilm synthesis. These products and the methods by which they are used in the infection process are collectively referred to as virulence factors. They are discussed next.

Retrieve, Infer, Apply

1. Define infection, infectious disease, pathogenicity, virulence, and opportunistic pathogen.
2. What factors determine the outcome of most host-pathogen relationships?
3. Why would a psychrophile not be a human pathogen?
4. What are some important characteristics of a pathogen?
5. Define source and reservoir. How are they related?
6. How would you determine the ID_{50} of a suspected pathogen?
7. What is an obligate intracellular pathogen? How might it survive?
8. Which phase of an infectious disease usually coincides with spread of the disease? Suppose an individual is contagious in the incubation period or in the early prodromal stage. How would that alter the ease with which the pathogen is spread to new hosts?

35.2 Virulence Defines a Pathogen's Success

After reading this section, you should be able to:

- Identify and describe the features that allow microorganisms to overcome host resistance and immunity
- Discuss strategies microorganisms have evolved to exploit human cells and tissues as resources for their survival
- Compare the molecular mechanisms by which microorganisms adhere to and invade human cells and tissues
- Illustrate the mechanisms by which microbial toxins impact human cells
- Model disease processes and explain virulence

While pathogenicity is a general term that refers to an organism's potential to cause disease, virulence refers more specifically to the magnitude of harm (pathogenicity) caused. Any structural or soluble product that increases pathogenicity is a virulence factor. For bacteria, protozoa, and fungi virulence also is often directly correlated with a pathogen's ability to survive in the external environment. If a pathogen cannot survive well outside its host and does not use a vector, it depends on host survival and will tend to be less virulent (e.g., rhinoviruses that cause the common cold). When a cellular pathogen can survive for long periods outside its host, it can afford to leave the host and simply wait for a new one to come along. This seems to promote increased virulence. Host health is not critical, but extensive multiplication within the host will increase the efficiency of transmission. Good examples are tuberculosis, diphtheria, and measles caused by *Mycobacterium tuberculosis, Corynebacterium diphtheriae,* and measles viruses, respectively. These microbes survive for a relatively long time, from hours to days and weeks, outside human hosts. Many bacterial virulence factors that facilitate survival are encoded in unique sequences of DNA that are readily swapped between bacteria through conjugation, transduction, or transformation (horizontal gene transfer). We now consider the genes and proteins that encode virulence factors. ◀◀ *Horizontal gene transfer (section 16.4)*; *Microbial evolutionary processes (section 19.5)*

Pathogenicity Islands

Large segments (10 to 200 kilobases) of bacterial chromosomal and plasmid DNA have been found to encode virulence factors. These DNA segments are called **pathogenicity islands,** as they appear to have been inserted into the existing DNA. Many bacteria (e.g., *Yersinia* spp., *Pseudomonas aeruginosa, Shigella flexneri, Salmonella* spp., enteropathogenic *Escherichia coli*) carry at least one pathogenicity island. Pathogenicity islands generally increase bacterial virulence and are absent in nonpathogenic members of the same genus or species (**table 35.1**). For example, the *Staphylococcus aureus* pathogenicity island encodes several superantigen genes, including the gene for the toxin that causes toxic shock syndrome. The detection of pathogenicity islands within a microbe's genome is explained in chapter 18. ◀◀ *Comparative genomics (section 18.7)*

Virulence Factors

Virulence factors can be encoded in the microbial chromosome or as extrachromosomal elements. These factors enable the pathogen to establish an infection (adherence and colonization factors), spread to other tissues (invasion factors), and harm the host (e.g., toxins). Virulence factors are upregulated by specific host triggers, enabling the microorganism to better survive its residency in the host. Examples of their association with the infectious disease process are included in figure 35.2, illustrating how they are used by the microorganism. This is discussed next.

Adherence and Colonization Factors

The first step in the infectious disease process is the entrance and attachment of the microorganism to a susceptible host. Entrance may be accomplished through one of the body surfaces, the **portal of entry:** skin, respiratory system, gastrointestinal system, urogenital system, or the conjunctiva of the eye. Some pathogens enter the host by sexual contact, needle sticks, blood transfusions and organ transplants, or insect vectors.

After gaining access to the host, the pathogen must be able to adhere to and colonize host cells or tissues. In this context, colonization means the establishment of a site of microbial replication on or within a host. It does not necessarily result in tissue

Table 35.1 Examples of Pathogenicity Islands and the Products They Encode

Organism	Pathogenicity Island[1]	Gene Product	Function
Escherichia coli	cagPI	Type IV secretion proteins	Cytotoxin
Helicobacter pylori	PAI-III	Type 1 pili Secreted protein	Attachment Hemolysin, cytotoxic necrosing factor, uropathogenic protein
Legionella pneumophila	icm/dot	Type IV secretion proteins	Intracellular survival
Rhodococcus equi	PAI-vap	Secreted proteins	Intracellular survival
Salmonella enterica	SPI-1, SPI-2	Type III secretion proteins	Cytotoxin
Shigella flexneri	SHI-1, SHI-2	Type III secretion proteins	Cytotoxin
Staphylococcus aureus	SaPI	Secreted proteins	Superantigens
Vibrio cholerae	VPI	Secreted protein	Toxin
Yersinia pestis	HPI-1	Siderophore synthesis	Iron uptake and storage

1 PI and PAI are both common abbreviations for pathogenicity island.

invasion or damage. Adherence can be thought of as a two-step process. Step 1 is nonspecific and often reversible. It results from hydrophobic, electrostatic, and vibrational forces that encourage "docking." Step 2 is specific and permanent, as complementary molecules (cognate receptors) fulfill a lock-in-key style bonding. This latter event seems to have co-evolved, permitting pathogen exploitation of the characteristics of host cell surfaces. Thus, pathogens adhere with a high degree of specificity to target tissues. Adherence structures, also known as adhesins, such as pili and fimbriae (**table 35.2**), membrane and capsular materials, and specialized adhesion molecules on the invading cell surface bind to host sites (**figure 35.5**). These microbial products and structural components contribute to infectivity, thus they are one type of virulence factor. Examples of pathogen adherence are discussed in the context of specific diseases (*see chapters 38–40*).

Invasion Factors

Pathogens can be described in terms of their infectivity and invasiveness. **Infectivity** is the ability of the organism to establish a discrete focal point of infection. Attachment to specific cell surface proteins permits microbe-mediated infection but may also induce cell-mediated microbe internalization. Viruses are adept at these methods of infectivity. **Invasiveness** is the ability of the organism to spread to adjacent or other tissues. For some pathogens, a localized infection is sufficient to cause disease. However, many pathogens invade other tissues.

Pathogens can either actively or passively penetrate the host's mucous membranes and epithelium. Active penetration may be accomplished through production of lytic substances that alter the host tissue by (1) attacking the extracellular matrix and basement membranes of integuments and intestinal linings, (2) degrading carbohydrate-protein complexes between cells or

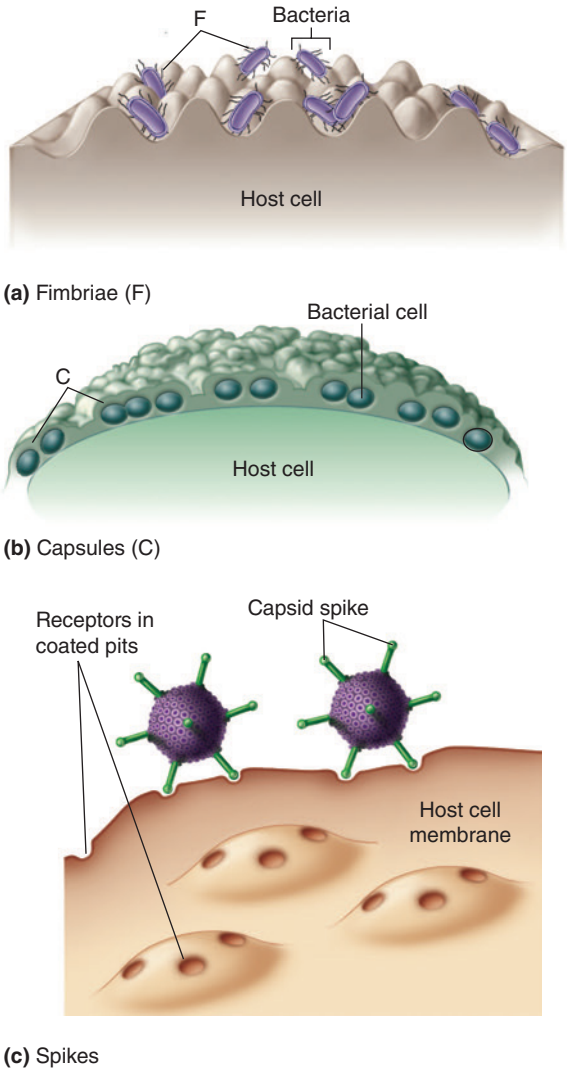

Figure 35.5 Microbial Adherence Mechanisms. (a) Bacterial fimbriae. (b) Bacterial capsules. (c) Viral protein spikes.

Table 35.2 Examples of Microbial Attachment Mechanisms

Microbe	Disease	Adhesion Mechanism	Host Receptor
Neisseria gonorrheae	Gonorrhea	Type IV fimbriae	Mannose on urethral epithelium
Escherichia coli	Diarrhea	Type I fimbriae	Sugar residue on intestinal epithelium
	Hemolytic uremic syndrome	P pili	Sugar residue on kidney cell
	Urinary tract infection	P-pili	Sugar residue on urethral epithelium
Treponema pallidum	Syphilis	Outer membrane protein	Fibronectin on mucosal cell
Mycoplasma pneumoniae	Pneumonia	Membrane protein	Sialic acid on lung cell
Streptococcus pyogenes	Sore throat	Protein F	Protein residue on upper respiratory tract cell
Streptococcus mutans	Dental caries	Sugar residue	Salivary glycoprotein on tooth
Influenza virus	Influenza	Hemagglutinin spike protein	Protein residue on upper respiratory tract cell
HIV-1	AIDS	gp120 protein	CD4 receptor on T cells
Polio virus	Poliomyelitis	Capsid protein VP1	CD 155 protein on intestinal and nerve cells

on the cell surface (the glycocalyx), or (3) disrupting the host cell surface. Passive mechanisms of penetration are not related to the pathogen itself. Examples include (1) small breaks, lesions, or ulcers in a mucous membrane that permit initial entry; (2) wounds, abrasions, or burns on the skin's surface; (3) arthropod vectors that create small wounds while feeding; (4) separation of tight junctions between cells during inflammation, and (5) tissue damage caused by other organisms (e.g., a dog bite).

Once under the mucous membrane, a pathogen may penetrate to deeper tissues and continue disseminating throughout the body of the host. One way the pathogen accomplishes this is by producing specific structures or enzymes that promote spreading (**table 35.3**). These products are also considered virulence factors because they contribute to pathogen success within the host. Bacteria may also enter the small terminal lymphatic capillaries that surround epithelial cells. These capillaries merge into large lymphatic vessels that eventually drain into the circulatory system. Once the circulatory system is reached, the bacteria have access to all organs and systems of the host. The presence of viable bacteria in the bloodstream is called **bacteremia.** The infectious disease process caused by bacterial or fungal toxins in the blood is termed **septicemia** (Greek *septikos,* produced by putrefaction, and *haima,* blood).

Invasiveness varies greatly among pathogens. For example, *Clostridium tetani* (the cause of tetanus) is considered noninvasive because it does not spread from one tissue to another, but its

Table 35.3 Bacterial Virulence Factors Involved in Bacterial Pathogen Invasion and Dissemination

Product	Organism Involved	Mechanism of Action
Coagulase	*Staphylococcus aureus*	Coagulates (clots) the fibrinogen in plasma. The clot protects the pathogen from phagocytosis and isolates it from other host defenses.
Collagenase	*Clostridium* spp.	Breaks down collagen that forms the framework of connective tissues; allows the pathogen to spread
Deoxyribonuclease	Group A streptococci, staphylococci, *Clostridium perfringens*	Lowers viscosity of exudates, giving the pathogen more mobility
Elastase and alkaline protease	*Pseudomonas aeruginosa*	Cleaves laminin associated with basement membranes
Hemolysins	Staphylococci, streptococci, *Escherichia coli, Clostridium perfringens*	Lyse erythrocytes; make iron available for microbial growth
Hyaluronidase	Groups A, B, C, and G streptococci, staphylococci, clostridia	Hydrolyzes hyaluronic acid, a constituent of the extracellular matrix that cements cells together and renders the intercellular spaces amenable to passage by the pathogen
Hydrogen peroxide (H_2O_2) and ammonia (NH_3)	*Mycoplasma* spp., *Ureaplasma* spp.	Are produced as metabolic wastes. These are toxic and damage epithelia in respiratory and urogenital systems.
Immunoglobulin A protease	*Streptococcus pneumoniae*	Cleaves immunoglobulin A into Fab and Fc fragments
Lecithinase or phospholipase	*Clostridium* spp.	Destroys the lecithin (phosphatidylcholine) component of plasma membranes, allowing pathogen to spread
Leukocidins	Staphylococci, pneumococci, and other streptococci	Pore-forming exotoxins that kill leukocytes; cause degranulation of lysosomes within leukocytes, which decreases host resistance
Porins	*Salmonella enterica* serovar Typhimurium	Inhibit leukocyte phagocytosis by activating the adenylate cyclase system
Protein A Protein G	*Staphylococcus aureus* *Streptococcus pyogenes*	Located on cell wall. Immunoglobulin G (IgG) binds to either protein A or protein G by its Fc end, thereby preventing complement from interacting with bound IgG.
Pyrogenic exotoxin B (cysteine protease)	Group A streptococci *(Streptococcus pyogenes)*	Degrades proteins
Streptokinase (fibrinolysin, staphylokinase)	Groups A, C, and G streptococci, staphylococci	A protein that binds to plasminogen and activates the production of plasmin, thus digesting fibrin clots; this allows the pathogen to move from the clotted area

toxin becomes blood-borne, thereby causing disease. *Bacillus anthracis* (the cause of anthrax) and *Yersinia pestis* (the cause of plague) also produce toxins but the bacteria are also highly invasive. Members of the genus *Streptococcus* span the spectrum of virulence factors and invasiveness. *Microsporidia* spp. use a novel polar tubule to bore into host cells (*see figure 26.17*), whereas many other fungi use hydrolytic enzymes to invade cells and tissues. These virulence factors are discussed in more detail in chapters 39 and 40.

Exotoxins

Exotoxins are soluble, heat-labile proteins (inactivated at 60 to 80°C) that usually are released into the surroundings as the bacterial pathogen grows. Often exotoxins travel from the site of infection to other body tissues or target cells, where they exert their effects (**figure 35.6**). Exotoxins are often encoded by genes carried on plasmids or prophages carried by specific bacteria. They are associated with specific diseases and often are named for the disease they produce (e.g., the diphtheria toxin). Some are among the most lethal substances known—toxic in nanogram-per-kilogram of body weight concentrations (e.g., botulinum toxin).

Exotoxins exert their biological activity by specific mechanisms and are grouped by either mechanism of action (e.g., a cytotoxin kills cells) or their protein structure. A common type is the **AB toxin,** which gets its name from the fact that it has two distinct toxin subunits, an "A" (or active) component and a "B (or binding) component." The B portion of the toxin binds to a host cell receptor and is separate from the A portion, which enters the cell and has enzyme activity that causes toxicity (figure 35.6*a*). Thus the B component determines the cell type the toxin will affect, whereas the A component exerts the deleterious effect. AB toxins act on cells by different mechanisms. Many A subunits have ADP ribosylation activity, which catalyzes the transfer of adenosine diphosphate and ribose moieties of host NAD^+ to target host molecules. Another type of exotoxin disrupts membranes. Examples of this type of exotoxin are the channel (pore)-forming toxins (figure 35.6*b*). They destabilize membrane integrity so that the cell lyses and dies. The general properties of several exotoxins are presented in **table 35.4**. As proteins, toxins are easily recognized by the host immune system, which produces antitoxin—antibodies that recognize and bind to their respective toxins—to inactivate and remove them.

Finally, exotoxins called **superantigens** act by stimulating as many as 30% of host T cells to overexpress and release massive amounts of cytokines from other host immune cells in the absence of a specific antigen (**figure 35.7**). The excessive concentration of cytokines causes multiple host organs to fail, giving the pathogen time to disseminate. By triggering this "cytokine storm," superantigens cause life-threatening disease; fever, fluid loss, and low blood pressure result in shock and death. The mechanism by which superantigens provoke the T-cell release of cytokines is discussed in chapter 34. Examples of each specific toxin type are discussed as part of the disease process in

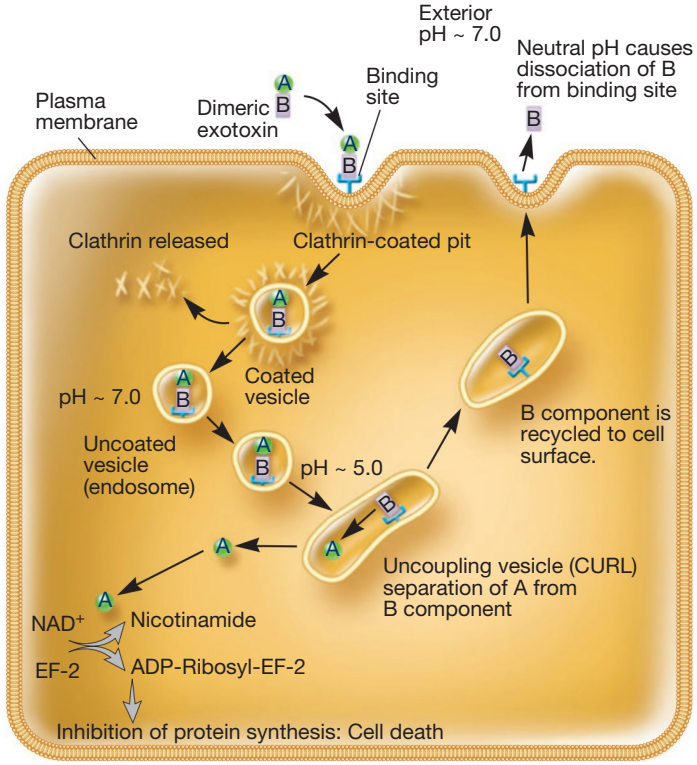

Figure 35.6 Two Examples of Exotoxin Mechanisms. (a) This AB toxin binds to the cell receptor within clathrin-coated pits by the B subunit. The intact toxin is endocytosed, and the pH change within the endosome causes the subunits to separate. An endosome in which this separation occurs is sometimes called a compartment of uncoupling of receptor and ligand (CURL). The B subunit is then recycled. The active toxin (A) subunit exerts its effect on its target, in this case the elongation factor-2 (EF-2) of protein synthesis, by enzymatically attaching an ADP-ribose to EF-2. The altered EF-2 is inhibited from assisting in protein synthesis, leading to cell death. (b) This channel-forming (pore-forming) toxin inserts itself into the host cell membrane, forming a channel (or pore). Multiple membrane pores results in an osmolarity shift, as water enters the cell and cytoplasmic contents move out. The resulting effect of this toxin is cell lysis.

Table 35.4 Exotoxins Produced by Human Bacterial Pathogens

Toxin	Organism	Gene Location	Toxin Type	Mechanism of Action
Edema factor (EF) Lethal factor (LF) Protective antigen (PA)	*Bacillus anthracis*	Plasmid	Tripartite AB	EF causes edema. LF is a cytotoxin. PA is a B component.
Pertussis toxin	*Bordetella pertussis*	Chromosome	AB	↓ATP, ↑ cAMP alters cell function, leading to death.
Botulinum toxin	*Clostridium botulinum*	Prophage	AB	Blocks neurotransmitter release, leading to paralysis
CPE enterotoxin	*Clostridium perfringens*	Chromosome	Cytotoxin	Hemolysis
Tetanospasmin	*Clostridium tetani*	Plasmid	AB	Blocks neurotransmitter, leading to spastic paralysis
Diphtheria toxin	*Corynebacterium diphtheriae*	Phage	AB	Alters translation, leading to protein synthesis inhibition
Enterotoxin Shiga-like toxin	*Escherichia coli* *E. coli* O157:H7	Plasmid Phage gene integrated into chromosome	AB AB	↑cAMP, leading to water secretion from cell Inhibits protein synthesis leading to death
Cytolysin	*Salmonella* spp.	Chromosome	Cytotoxin	↑cAMP, leading to water secretion from cell
Shiga toxin	*Shigella dysenteriae*	Chromosome	AB	Inhibits protein synthesis, leading to death
Exfolative toxin Toxic shock syndrome toxin-1 Panton-Valentine leukocidin	*Staphylococcus aureus*	Chromosome Chromosome Phage	Protease Superantigen Cytotoxin	Skin peeling Cytokine-induced shock Necrotizing pneumonia
Streptolysin O Erythrogenic toxin	*Streptococcus pyogenes*	Chromosome Phage	Cytolysin Superantigen	Hemolysis Cytokine-induced shock
Cholera toxin	*Vibrio cholerae*	Phage	AB	↑cAMP, leading to water secretion from cell

chapters 38 through 40. ⏮ *Cytokines are chemical messages between cells (section 33.3); Superantigens (section 34.5)*

Endotoxins

The lipopolysaccharide (LPS) in the outer membrane of Gram-negative bacteria is toxic to humans. Thus LPS is called an **endotoxin** because it is bound to the bacterium and is released when the microorganism lyses, although some may also be released during cell division. The toxic component of LPS is the lipid portion, called lipid A (*see figure 3.25*). **Lipid A** is not a single macromolecular structure; rather, it is a complex array of lipid residues. Lipid A is heat stable and toxic in nanogram amounts but only weakly immunogenic. ⏮ *Typical Gram-negative cell walls include additional layers besides peptidoglycan (section 3.4)*

Unlike the structural and functional diversity of exotoxins, the lipid A of various Gram-negative bacteria produces similar systemic effects regardless of the microbe from which it is derived. These include fever (i.e., endotoxin is pyrogenic), shock, blood coagulation, weakness, diarrhea, inflammation, intestinal hemorrhage, and fibrinolysis (enzymatic breakdown of fibrin, the major protein component of blood clots) (**figure 35.8**).

The main biological effect of lipid A is an indirect one, mediated by host molecules and systems, rather than by lipid A itself. For example, endotoxins initially activate a protein called the Hageman factor (blood clotting factor XII), which in turn results in unregulated blood clotting within capillaries (disseminated intravascular coagulation) and multiorgan failure (figure 35.8). Endotoxins also indirectly induce a fever in the host by causing macrophages to release endogenous pyrogens that reset the hypothalamic thermostat. One important endogenous pyrogen is the cytokine interleukin-1 (IL-1). Other cytokines released by macrophages, such as the tumor necrosis factor, also produce fever. The net effect is often called **septic shock** and can also be

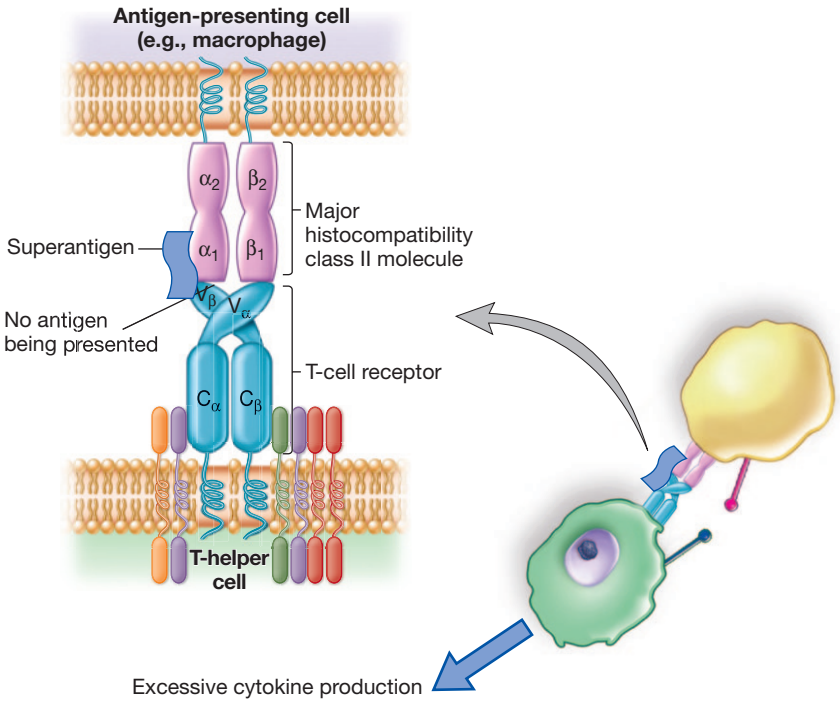

Figure 35.7 Superantigen. Nonspecific activation of T cells by a superantigen, in the absence of antigen, stimulates massive amounts of cytokines that overwhelm the host and result in shock and death.

induced by certain pathogenic fungi and Gram-positive bacteria. All drugs, especially those given intravenously or intramuscularly, must be free of endotoxin for this reason. ◀◀ *Cytokines are chemical messages between cells (section 33.3)*

Mycotoxins

Mycotoxins are toxins produced by fungi. For example, *Aspergillus flavus* and *A. parasiticus* produce aflatoxins, and *Stachybotrys* spp. produce satratoxins. These fungi commonly contaminate food crops and water-damaged buildings, respectively. An estimated 4.5 billion people in developing countries may be exposed chronically to aflatoxins through their diet. Exposure to aflatoxins is known to cause both chronic and acute liver disease and liver cancer. Aflatoxins are extremely carcinogenic, mutagenic, and immunosuppressive. Approximately 18 different types of aflatoxins exist. Aflatoxins are classified in two broad groups according to their chemical structure (*see figure 41.6*). *Stachybotrys trichothecene* mycotoxins are potent inhibitors of DNA, RNA, and protein synthesis. They induce inflammation, disrupt surfactant phospholipids in the lungs, and may lead to pathological changes in tissues.

The fungus *Claviceps purpurea* also produces toxic substances. The products are generically referred to as ergots, reflecting the name of the tuberlike structure of the fungi (*see figure 26.12*). The ergot is a fungal resting stage and is composed of a compact mass of hyphae. The ergots from various *Claviceps* spp. produce alkaloids that have varying physiological effects on humans. One such alkaloid is lysergic acid, the psychotropic hallucinogen LSD.

Biofilm Development

Most bacteria live within stable, sessile communities surrounded by a hydrated polymeric matrix of their own production. These biofilm bacteria are protected from nutrient deprivation, predators, environmental shifts, antimicrobial agents, and host immune cells. In contrast to free-swimming (planktonic) bacteria of the same species, biofilm bacteria are phenotypically different, expressing genes that favor survival when attached and in poor nutrient conditions. However, the role of the biofilm is much more complex, especially for biofilms that cause chronic infections in humans. Using high throughput sequencing, fluorescent in situ hybridization, and global gene analysis, studies have revealed that some pathogenic bacteria within biofilms exchange plasmids, nutrients, and quorum-sensing molecules so as to behave differently than planktonic forms. The differences are striking in that biofilm bacteria coordinate gene expression to upregulate mechanisms that make the biofilm community less sensitive to antibiotics and more resistant to host defense mechanisms. For example, studies on *P. aeruginosa* biofilms reveal that shared communication signals activate global response regulators, which increase the activity of multidrug efflux pumps, increase starvation or stress responses, stimulate exopolysaccharide secretion, increase resistance to host cell attack, suppress host cell killing mechanisms, and change rapidly growing, antibiotic-sensitive cells into slower-growing, antibiotic-resistant persister cells. ◀◀ *Microbial growth in natural environments (section 7.5)*

Importantly, one remarkable activity of biofilms formed by pathogenic *P. aeruginosa* is the ability to suppress host immune responses (**figure 35.9**). This is evident in studies evaluating *P. aeruginosa* mixed with antibiotics, antibodies, and the phagocytic white blood cells macrophages and neutrophils. Antibiotics, antibodies, and the phagocytes readily attack and kill planktonic *P. aeruginosa* using hydrolytic enzymes (lysozyme, lactoferrin, etc.) and free radicals of oxygen and nitrogen. However, antibiotics, antibodies, and phagocytes are ineffective at killing *P. aeruginosa* in biofilms. *P. aeruginosa* in biofilms appears to prevent penetration of antibiotics and antibodies, and to cause phagocytes to downregulate killing mechanisms. In addition, host hydrolytic enzymes are decreased, while enzymes that create super- and nitric oxides are inhibited. In essence, the *P. aeruginosa* biofilms "frustrate" phagocytes by reducing the magnitude of some antibacterial responses and preventing others altogether.

Resisting Host Defenses

Most microorganisms do not cause disease, in part because they are eliminated by the host's normal microbiota or its immune system before infection begins. However, pathogens have evolved

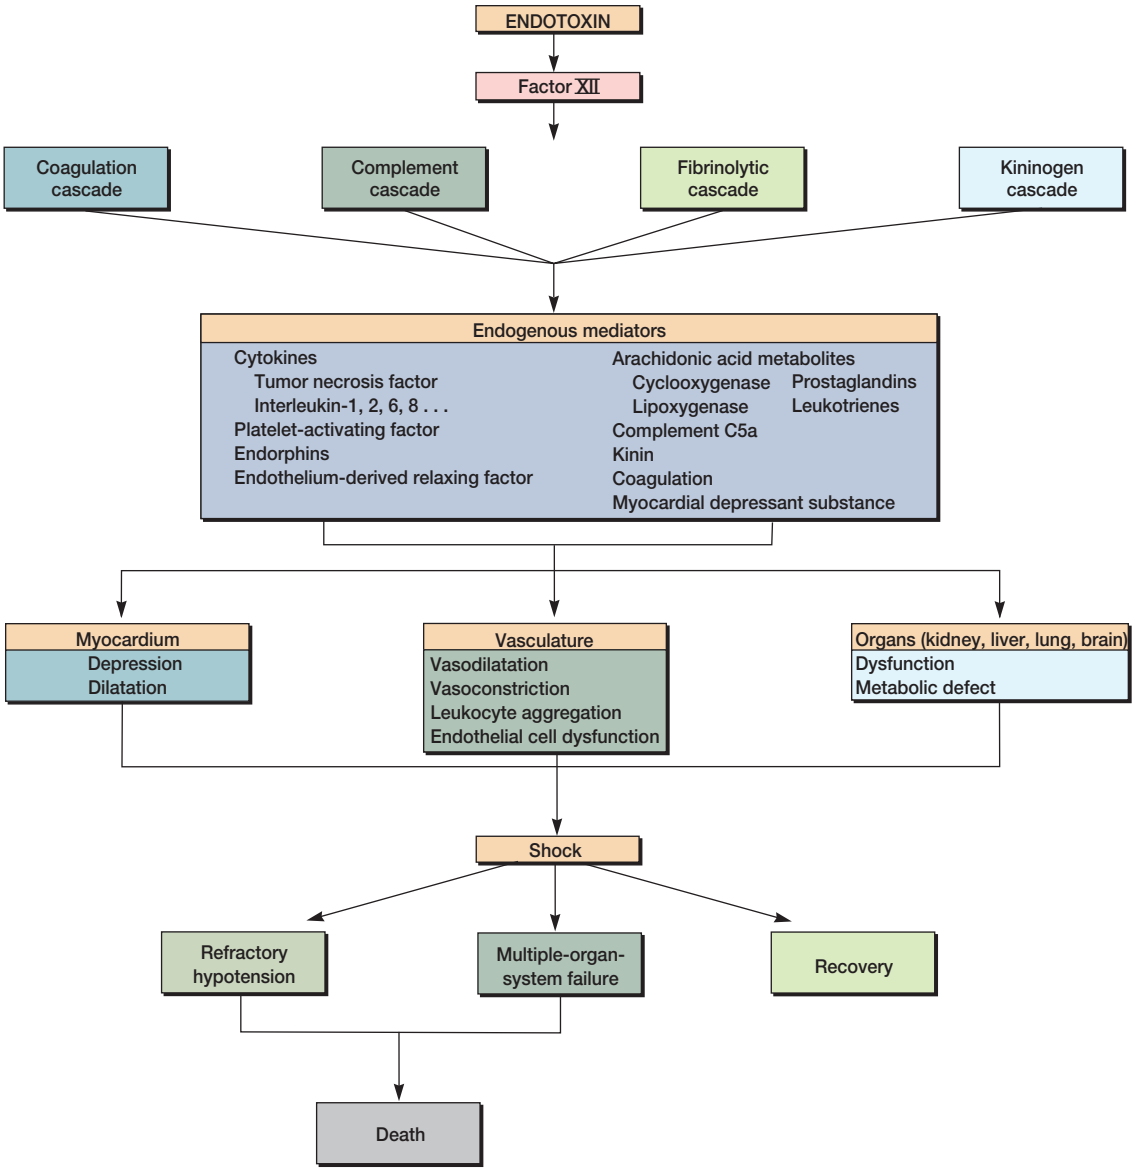

Figure 35.8 The Septic Shock Cascade. Gram-negative bacterial endotoxin triggers biochemical events that lead to such serious complications as shock, acute respiratory distress syndrome, and disseminated intravascular coagulation.

many mechanisms to evade host defenses. As we just discussed, biofilms are one example of how many microorganisms resist host defenses. Although host innate defense mechanisms come into play upon initial host exposure, specific immune responses normally become paramount in preventing further proliferation of infectious agents. Thus successful pathogens have evolved mechanisms that enable them to elude both the initial host responses as well as those governed by the adaptive immune system.

Some viruses, most notably the human immunodeficiency virus (HIV), infect cells of the immune system and diminish their function. HIV as well as measles virus and cytomegalovirus cause fusion of host cells. This allows these viruses to spread from an infected cell to an uninfected cell with minimal exposure to host defenses. Some bacteria such as *Streptococcus pneumoniae, Neisseria meningitidis,* and *Haemophilus influenzae* can produce a slippery mucoid capsule that prevents the host immune cells from effectively capturing the bacterium. Other bacteria evade phagocytosis by producing specialized surface proteins such as the M protein on *S. pyogenes* (*see figure 39.5*).

Many pathogens have devised methods to prevent detection by host antimicrobial proteins (e.g., defensins) that either directly or indirectly cause membrane (envelope) lysis. Hepatitis B virus–infected cells produce large amounts of proteins not associated with the complete virus particle. These proteins serve as decoys, binding the available antimicrobial proteins so that the virus goes unnoticed. Some Gram-negative bacteria can lengthen the O side chains in their lipopolysaccharide to prevent host detection. Others such as *Neisseria gonorrhoeae* have modified the

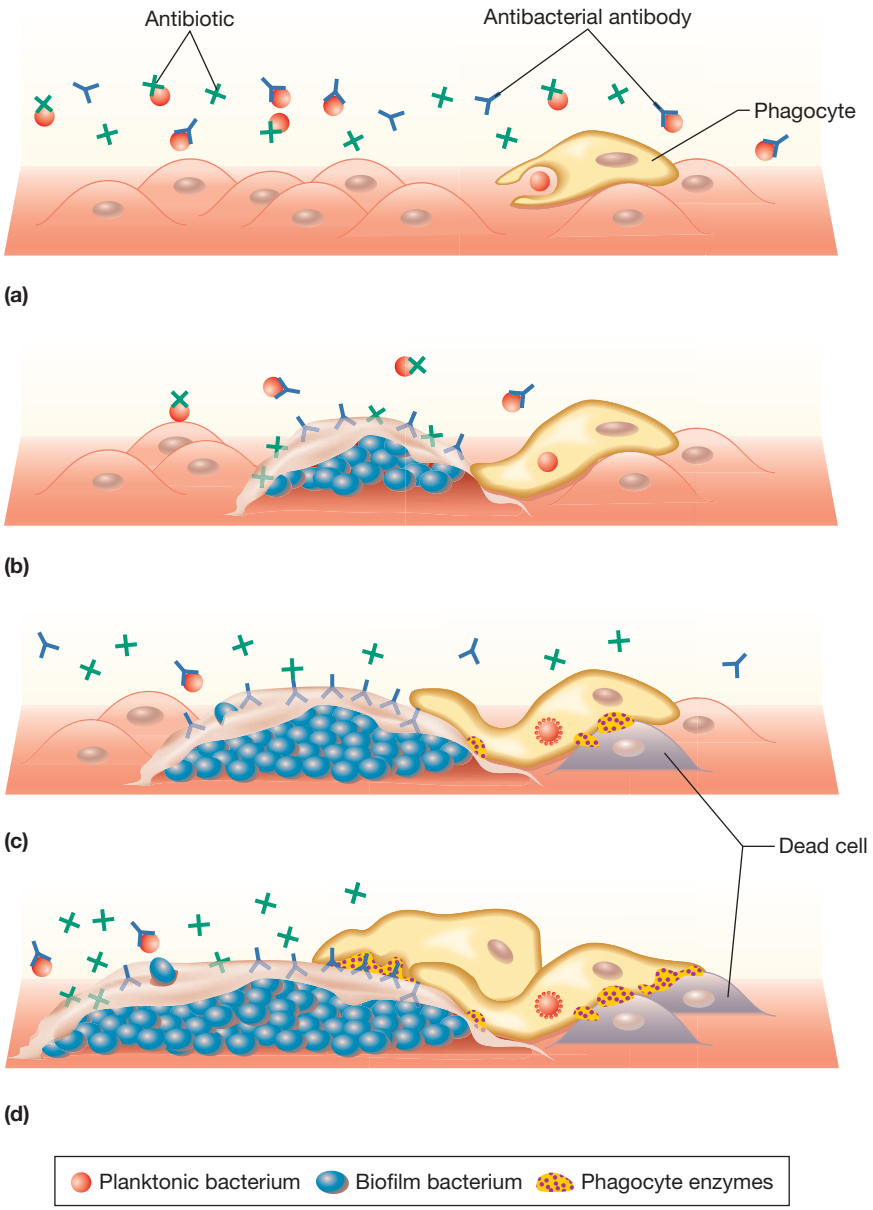

Figure 35.9 Frustrated Phagocytosis. (a) Planktonic cells are sensitive to antibiotics and are detected by host phagocytes and antibodies. (b) Planktonic cells settle to form a biofilm and become biofilm cells. (c) Biofilm cells resist antibiotics and antibody detection. Host phagocytes detect and attempt to destroy biofilm cells. (d) Unable to capture biofilm cells, phagocytes release antimicrobial products that kill host cells but not biofilm cells.

lipooligosaccharides on their surface that interfere with host mechanisms that normally lyse *N. gonorrhoeae.* ⏮ *Antimicrobial peptides and proteins (section 33.3)*

Some bacteria have evolved the ability to survive inside the host cells that otherwise would destroy bacteria. These microorganisms are very pathogenic because they are impervious to an important innate resistance mechanism of the host (p. 780). One method of evasion is to escape by ejecting themselves from the host cell, as seen with *Listeria monocytogenes, Shigella* spp., and *Rickettsia* spp. These bacteria use actin-based motility to move within mammalian host cells and spread between them. They activate the assembly of an actin tail using host cell actin and other cytoskeletal proteins (**figure 35.10**). The actin tails propel the bacteria through the cytoplasm of the infected cell to its

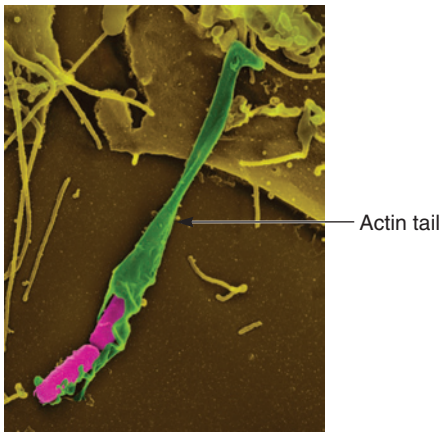

Figure 35.10 Formation of Actin Tails by Intracellular Bacterial Pathogens. Scanning electron micrograph of *Listeria monocytogenes* in a host macrophage. The bacterium has polymerized host actin into a long tail at only one pole that it uses for intracellular propulsion and to move from one host cell to another.

surface, where they push out against the plasma membrane and form protrusions. The protrusions are engulfed by adjacent cells, and the bacteria enter the unsuspecting neighboring host cell. In this way, the infection spreads to adjacent cells.

Pathogens have evolved a variety of ways to suppress or evade the host's immune response. For instance, some change their surface proteins by mutation or recombination (e.g., the influenza virus), or downregulate the level of expression of cell surface proteins. To further evade the specific immune response, some bacteria (e.g., *S. pyogenes*) produce capsules that resemble host tissue components and thus remain covert. *N. gonorrhoeae* can evade the specific immune response by two mechanisms: (1) It makes changes in the gene encoding the pili protein through a process called phase variation, resulting in altered pilin protein sequence and expression. This renders specific host responses useless against the new pili, so that adherence to host tissue is not obstructed. (2) It produces proteases that degrade host proteins that bind the bacteria. This allows adherence. Finally, some bacteria produce special proteins (such as staphylococcal protein A and protein G of *S. pyogenes*) that interfere with the host's ability to detect and remove them (*see figure 23.11b*).

Retrieve, Infer, Apply

1. Describe several specific adhesins by which bacterial pathogens attach to host cells.
2. What are virulence factors?
3. What are pathogenicity islands and why are they important?
4. Describe some general characteristics of exotoxins.
5. What is a biofilm? How is it a virulence factor?

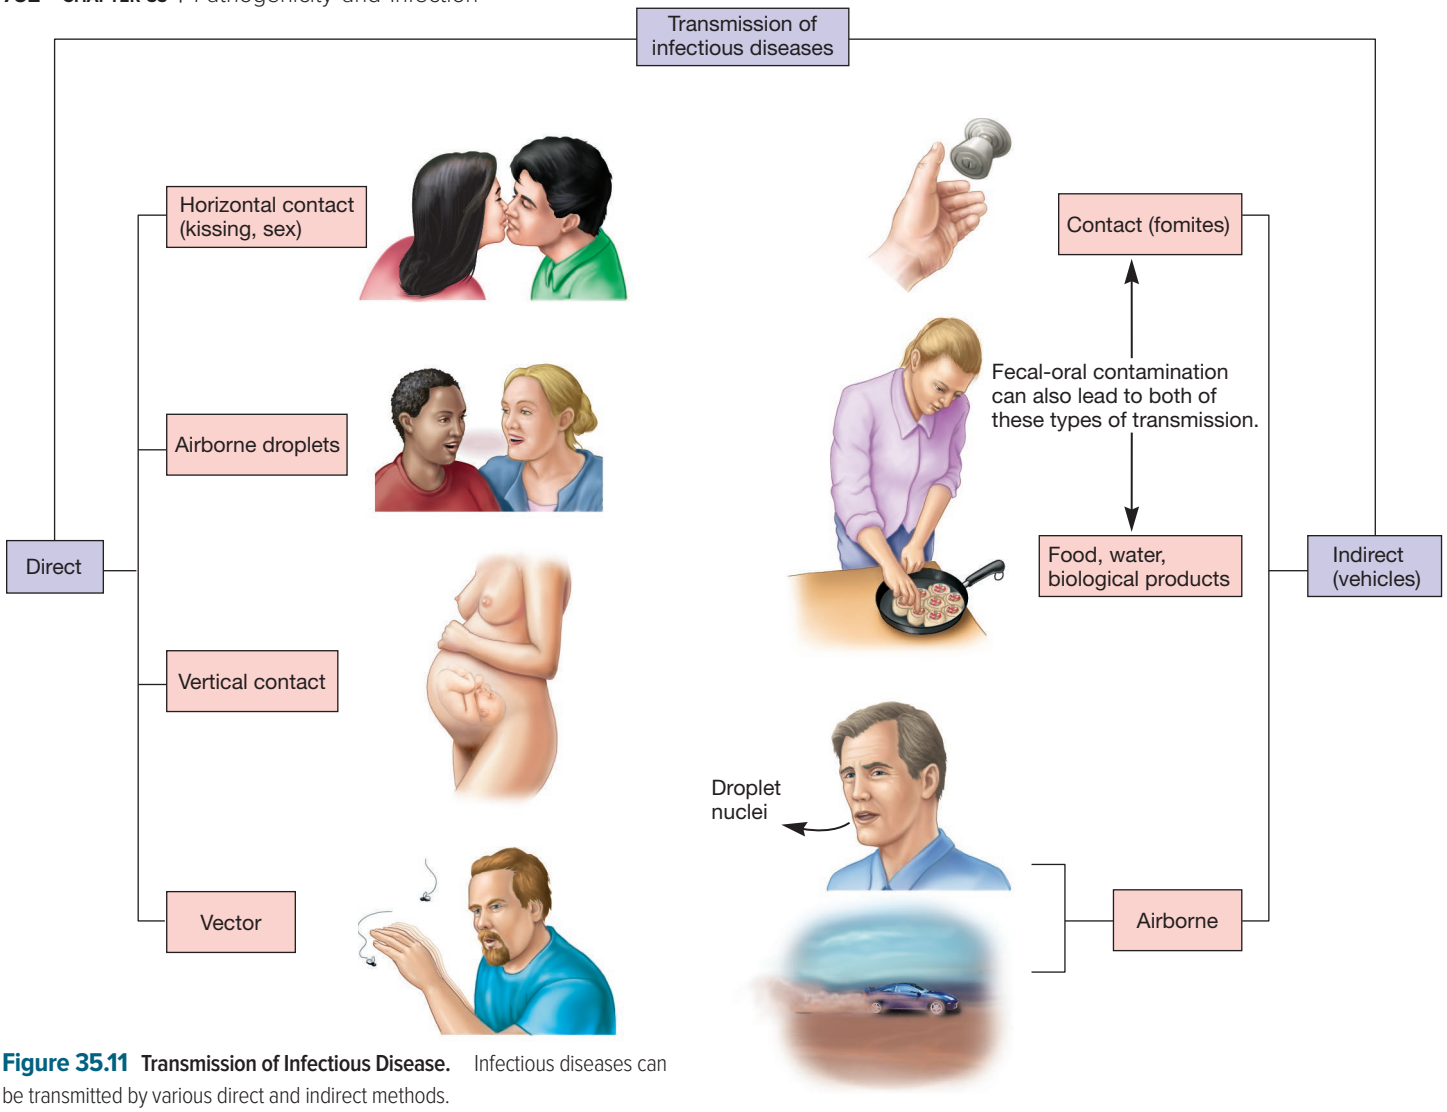

Figure 35.11 Transmission of Infectious Disease. Infectious diseases can be transmitted by various direct and indirect methods.

35.3 Exposure and Transmission Can Lead to Infectious Disease

After reading this section, you should be able to:

- List and describe the means by which microorganisms access humans to cause disease
- Correlate initial microbial numbers and replication rates to infection and lethality
- Synthesize a concept map of the infectious process

An essential feature in the development of an infectious disease is the initial exposure of the host to the pathogen; the pathogen must be transmitted from one host or source to another (figure 35.2). Thus, transmission is a critical component of the infection process and is the next link in the infectious disease chain, occurring directly or indirectly by four main routes: airborne, contact, vehicle, and vector-borne (**figure 35.11**).

As mentioned, a pathogen's virulence may be strongly influenced by its mode of transmission and ability to live outside its host (**Historical Highlights 35.1**). When the pathogen uses a mode of transmission such as direct contact, it cannot afford to make the host so ill that it will not be transmitted effectively. This is the case with the common cold, which is caused by rhinoviruses and several other respiratory viruses. Cold sufferers must be able to move about and directly contact others. Thus virulence is low and people are not incapacitated by the common cold. If the virus replicates too rapidly and damages its host extensively, the person would be bedridden and not contact others. The efficiency of transmission would drop further because the rhinoviruses would be inactivated by lack of exposure.

On the other hand, if a pathogen uses a mode of transmission not dependent on host health and mobility, then the person's health will not be a critical matter. The pathogen might be quite successful; that is, it may be transmitted to many new hosts even though it kills its host relatively quickly. Host death means the end of any resident pathogens, but the species as a whole can spread and flourish as long as the increased transmission rate outbalances the loss due to host death. This situation may arise in several ways. In general, such pathogens are highly contagious.

Exposure alone is not sufficient for infection to occur. Rather, the pathogen must also make contact with the appropriate

HISTORICAL HIGHLIGHTS

35.1 The First Indications of Person-to-Person Spread of an Infectious Disease

In 1773 Charles White, an English surgeon and obstetrician, published his "Treatise on the Management of Pregnant and Lying-in Women." In it, he appealed for surgical cleanliness to combat childbed or puerperal fever, an acute febrile condition that can follow childbirth and is caused by streptococcal infection of the uterus or adjacent regions. In 1795 Alexander Gordon, a Scottish obstetrician, published his "Treatise on the Epidemic Puerperal Fever of Aberdeen," which demonstrated for the first time the contagiousness of the disease. In 1843 Oliver Wendell Holmes, a noted physician and anatomist in the United States, published a paper entitled "On the Contagiousness of Puerperal Fever" and also appealed for surgical cleanliness to combat this disease.

However, the first person to realize that a pathogen could be transmitted from one person to another was the Hungarian physician Ignaz Phillip Semmelweis. Between 1847 and 1849, Semmelweis observed that women who had their babies at the hospital with the help of medical students and physicians were four times as likely to contract puerperal fever as those who gave birth with the help of midwives. He concluded that the physicians and students were infecting women with material remaining on their hands after autopsies and other activities (amazingly, these individuals did not wash their hands after such procedures!). Semmelweis thus began washing his hands with a calcium chloride solution before examining patients or delivering babies. This simple procedure led to a dramatic decrease in the number of cases of puerperal fever and saved the lives of many women. As a result, Semmelweis is credited with being the pioneer of antisepsis in obstetrics. Unfortunately, in his own time, most of the medical establishment refused to acknowledge his contribution and adopt his procedures. After years of rejection, Semmelweis had a nervous breakdown in 1865. He died a short time later of a wound infection. It is very probable that it was a streptococcal infection, arising from the same pathogen he had struggled against his whole professional life.

host tissue. For instance, rhinoviruses are spread by airborne transmission from one host to another. Once the virus makes contact with the upper respiratory tract epithelia, the virus invades to cause disease only in the upper respiratory tract; rhinoviruses do not usually infect anywhere else in the host. This specificity is called a **tropism** (Greek *trope,* turning). Many pathogens exhibit cell, tissue, and organ specificities. A tropism by a specific microbe usually reflects the presence of specific cell surface receptors for that microbe on the host cell.

Airborne Transmission

Because air is not a suitable medium for the growth of pathogens, any pathogen that is airborne must have originated from a source such as humans, other animals, plants, soil, food, or water. In **airborne transmission,** the pathogen is suspended in the air in droplets, droplet nuclei, or dust, which travel over a meter or more from the source to the host. Typically, this results from host-to-host interaction (coughing, sneezing).

Droplets form from saliva and mucus. They are 5 μm or more in diameter and form when liquids are placed under force. The route of transmission to humans is through the air for a very short distance, so droplet transmission of a pathogen depends on the proximity of the source and the host. Chickenpox and measles are examples of droplet-spread diseases. **Droplet nuclei** are smaller particles, 1 to 4 μm in diameter, that result from the evaporation of the larger droplets. In contrast to droplets, the much smaller droplet nuclei can remain airborne for hours or days and travel long distances. Contact with oral secretions may result when droplet nuclei contaminate body surfaces that touch mucous membranes (e.g., respiratory secretions on hands that contact eyes).

Dust also is an important route of airborne transmission. Adhering to dust particles, microorganisms contribute to the number of airborne pathogens when the dust is resuspended by some disturbance. A pathogen that can survive for relatively long periods in or on dust creates an epidemiological problem, particularly in hospitals, where dust can be the source of hospital-acquired (nosocomial) infections. Many systemic mycoses (fungal infections) are examples of transmission in dust.

Contact Transmission

Contact transmission implies the coming together or touching of the source or reservoir of the pathogen and the host. Contact can be direct or indirect. Direct contact implies an actual physical interaction with the infectious source (figure 35.11). This route is frequently called person-to-person contact. Person-to-person transmission occurs primarily by touching, kissing, or sexual contact; by contact with oral secretions or body lesions (e.g., herpes and boils); by nursing mothers (e.g., AIDS, staphylococcal infections); and through the placenta (e.g., syphilis). Some pathogens also can be transmitted by direct contact with animals or animal products (e.g., members of the genera *Salmonella* and *Campylobacter*). Indirect contact transmission occurs when something "transfers" the infectious agent between hosts.

Vehicle Transmission

Inanimate materials that indirectly transmit pathogens are called **vehicles** (**figure 35.12**). In vehicle transmission, a single inanimate vehicle or source serves to spread the pathogen to multiple hosts. Examples include surgical instruments, drinking vessels,

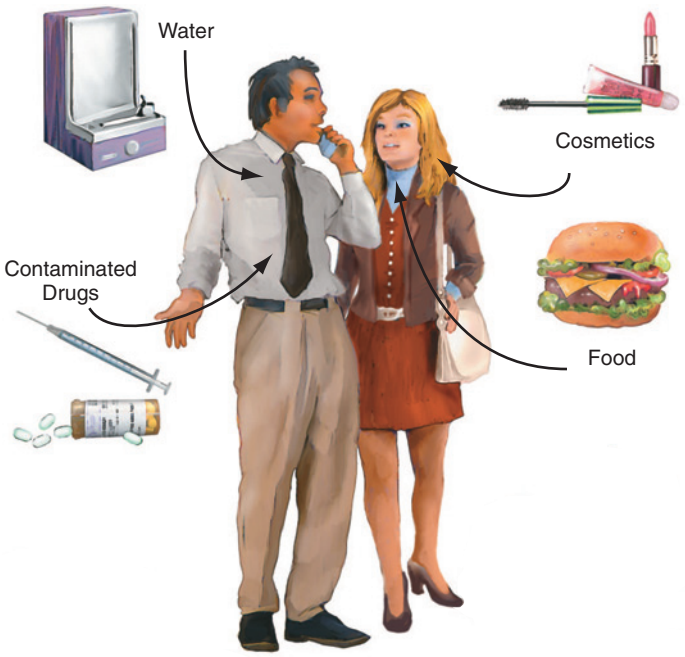

Figure 35.12 Common Vehicles of Microbial Contamination. Any inanimate object that transmits infectious agents to humans is referred to as a vehicle.

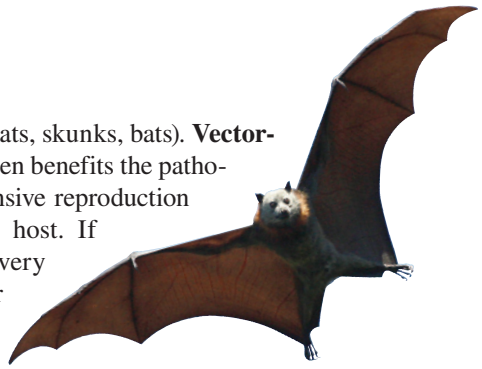
stethoscopes, bedding, eating utensils, and neckties. These common vehicles are called **fomites** (s., fomes or fomite). A single source containing pathogens (e.g., blood, drugs, intravenous fluids) can contaminate a common vehicle that causes multiple infections. Food, water, and biological materials (fluids and tissues) are important common vehicles for many human diseases. They often support pathogen reproduction.

Vector-Borne Transmission

Direct living transmitters of a pathogen are called vectors. Most vectors are arthropods (e.g., insects, ticks, mites, fleas) or vertebrates (e.g., dogs, cats, skunks, bats). **Vector-borne transmission** often benefits the pathogen by permitting extensive reproduction and spread within the host. If pathogen levels are very high in the host, a vector such as a biting insect has a better chance of picking up the pathogen and transferring it to a new host. Indeed, pathogens transmitted by biting arthropods often are very virulent (e.g., malaria, typhus, sleeping sickness). It is important that such pathogens do not harm their vectors and the vector generally remains healthy, at least long enough for pathogen transmission.



Vertical Transmission

Direct transmission of pathogens is not only mediated by horizontal, person-to-person passage but by vertical passage as well. **Vertical transmission** of pathogens occurs when the unborn child acquires a pathogen from an infected mother. While vertical transmission does not occur as frequently as horizontal transmission, a number of microorganisms exploit this route, extending their host range. Babies born with an infectious disease are said to have a congenital (*Latin*: with birth) infection. Examples of congenital infections include gonorrhea, syphilis, herpes, German measles, and toxoplasmosis. These diseases are discussed in chapters 38–40.

Retrieve, Infer, Apply

1. Describe the four main types of infectious disease transmission methods and give examples of each.
2. Define droplet nuclei, vehicle, fomite, and vector.
3. Why are pathogens that are transmitted person-to-person often less virulent than those transmitted by arthropod vectors?

Key Concepts

35.1 Pathogenicity Drives Infectious Disease

- Infections occur when microorganisms enter a larger organism, the host, and compete for resources.
- The infectious disease process is represented by a chain to demonstrate how each link is required for it to occur (**figure 35.1**).
- Signs of an infectious disease are objective changes in the body. Symptoms are subjective.
- Microorganisms require a suitable environment to survive. They use a number of survival strategies inside the host. These are collectively known as virulence factors (**figure 35.2**).
- The course of an infection follows a characteristic pattern: the incubation period, the prodromal stage, the illness period, and convalescence (**figure 35.3**).
- Pathogens reside in various environments, termed reservoirs. They infect the host from the reservoir and can return to it.
- Infectious diseases passed from animals to humans are called zoonoses.

35.2 Virulence Defines a Pathogen's Success

- Virulence refers to the magnitude of harm that a pathogen can exert on its host.
- Specific gene sequences called pathogenicity islands encode virulence factors (**table 35.1**).
- Pathogens require virulence factors to assist them in accessing a host. These include the ability to adhere to host cells, chemicals that permit cell and tissue degradation, and processes and mediators that overcome host defenses (**tables 35.2** and **35.3**).

- Exotoxins are secreted proteins that have biological activity. Endotoxins are the lipid A components of the lipopolysaccharide found in most Gram-negative bacterial envelopes (**figure 35.6** and **table 35.4**).
- Mycotoxins are metabolites of fungi. Their effects include hallucinations, cancer, and immunosuppression.
- Biofilms provide a unique environment for bacteria to exchange genetic information and collectively resist antimicrobial agents and host defense mechanisms (**figure 35.9**).
- Microorganisms have evolved many strategies for avoiding host defenses.

35.3 Exposure and Transmission Can Lead to Infectious Disease

- Pathogens are transmitted to and between hosts by several common routes, including air, direct contact, arthropod vectors, and vehicles (**figures 35.11** and **35.12**).
- Microorganism growth can be rapid or slow and may occur as extracellular or intracellular.
- Host susceptibility is an additional factor in determining infectious disease.

Compare, Hypothesize, Invent

1. Why does a parasitic organism not have to be a parasite?
2. In general, infectious diseases that are commonly fatal are newly evolved relationships between the parasitic organism and the host. Why is this so?
3. Explain the observation that different pathogens infect different parts of the host.
4. Intracellular bacterial infections present a particular difficulty for the host. Why is it harder to defend against these infections than against viral infections and extracellular bacterial infections?
5. Among the many diseases caused by *Staphylococcus aureus,* necrotizing pneumonia is particularly aggressive, causing lung inflammation, tissue death (necrosis), and hemorrhage. Only *S. aureus* strains that produce the toxin Panton-Valentine leukocidin (PVL) cause necrotizing pneumonia. PVL is a leukocidin because it forms pores in membranes of white blood cells (leukocytes) that would otherwise engulf and phagocytose the pathogen. When *S. aureus* infects the respiratory tract, it relies on adhesins to mediate attachment to airway cells. One of the most important adhesins is called staphylococcal protein A (Spa). Spa also blocks the engulfment activity of host phagocytes. *S. aureus* strains that produce PVL also produce high levels of Spa.

   How could you assess the contributions of each protein independently to pathogenesis and their combined effect (note that a mouse model system has been developed for this disease)? Your answer should state your hypotheses (predictions) about each protein tested alone and together, followed by the approach you would take to test each hypothesis.

   Read the original paper: Labandeira-Rey, M., et al., 2007. *Staphylococcus aureus* Panton-Valentine leukocidin causes necrotizing pneumonia. *Science* 315:1130.
6. The Ebola virus outbreak of 2013 was unprecedented in its geographic distribution and number of infections. Yet the incubation period, duration of illness, disease symptomology (i.e., clinical course of infection), and virus transmissibility were similar to those in earlier Ebola outbreaks stemming back to the 1970s. Direct contact with viable virus has been understood to be the route of transmission, especially when contact is made with sick or dead relatives. All individuals who contracted Ebola had direct contact with highly infectious body fluids from other ebola patients. However, speculation regarding the airborne transmission of Ebola virus has been voiced. Experimentally, Ebola virus particles can be aerosolized. Importantly, family members residing in the same apartment as the Dallas index case did not acquire the disease.

   Given that the genomes of several strains of Ebola virus have been sequenced, what experiments could you do to test whether airborne Ebola virus is infectious?

Clinical Microbiology and Immunology

Vibrio cholerae *would be easily detected in contaminated water, appearing as "holographic commas," using a new microscope developed at UCLA.*

Seeing the Next Frontier

The headline could have read "*Star Trek* device now real" when scientists at the University of California–Los Angeles announced their creation of a portable, inexpensive, holographic microscope. The "microscope" does not use glass lenses to focus light the way a traditional microscope does. Rather, it uses a laser and electronic components to "view" specimens. The device is about the size of a small cell phone. It uses inexpensive photosensors to digitally capture specimens and advanced electronics to process the data into high-resolution images. Similar to an electron microscope, it is able to scan solid specimens to provide a three-dimensional hologram of the superstructures, as well as penetrate thin specimens to create a holographic image of intracellular components.

In the "reflection" mode, the laser is divided into two beams using a mirror such that one of the beams illuminates the specimen and is then recombined with the other. Software integrates the information from the two light beams to create a three-dimensional hologram of the specimen. In the "transmission" mode, the laser light penetrates through thin structures to be detected on the other side. Denser structures slow the laser penetration by fractions of nanoseconds compared to the light penetrating less dense areas. The result is also a hologram, but this one is a three-dimensional representation of cellular ultrastructure. To keep the price below $100, there is no display device on the microscope; rather, the data is sent for viewing to a computer, which has more processing power. This technological breakthrough now allows field investigators to rapidly detect bacteria or protozoa in water and blood specimens, identify insect vectors, and even monitor disease states in plants and animals. Microbiologists are now hearing the mandate, "To boldly go...."

Microorganisms are everywhere. Because pathogens, particularly bacteria and yeasts, coexist with harmless microorganisms on or in the host, their rapid detection and identification are essential to prevent or treat disease. The challenge for the fields of clinical microbiology and clinical immunology is to integrate reliable technology and evidence-based practices to achieve these goals. A variety of approaches may be used to detect and identify microorganisms based on morphological, biochemical, immunologic, and molecular procedures. In the absence of a culture, DNA-based and immunologic tests can be used to detect pathogens in specimens such as blood and sputum. Importantly, laboratory safety should always be the highest priority. In the final analysis, the patient's well-being and health can benefit significantly from information provided by the clinical laboratory—the subject of this chapter.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Describe the infectious disease process (chapter 35)
- ✔ Discuss the uses of tools and techniques used to culture and characterize microorganisms (chapters 2, 7, 17, 18, and 29)
- ✔ Outline important aspects of microbial structure, function, survival requirements, and replication strategies (chapters 3, 4, 5, 6, 7, 13, and 15)
- ✔ List products of immune cells and their functions (sections 34.2, 34.4, 34.7, and 34.8)
- ✔ Describe the mechanisms by which microorganisms can be controlled (chapters 8 and 9)

36.1 The Clinical Microbiology Laboratory Is the Front Line for Infectious Disease Detection

After reading this section, you should be able to:

- Explain the workflow approach to identifying microorganisms in the clinical lab
- Practice biosafety, especially with clinical specimens
- Describe the various scientific disciplines involved in clinical microbiology
- Report the two general methods used to identify pathogens in clinical specimens

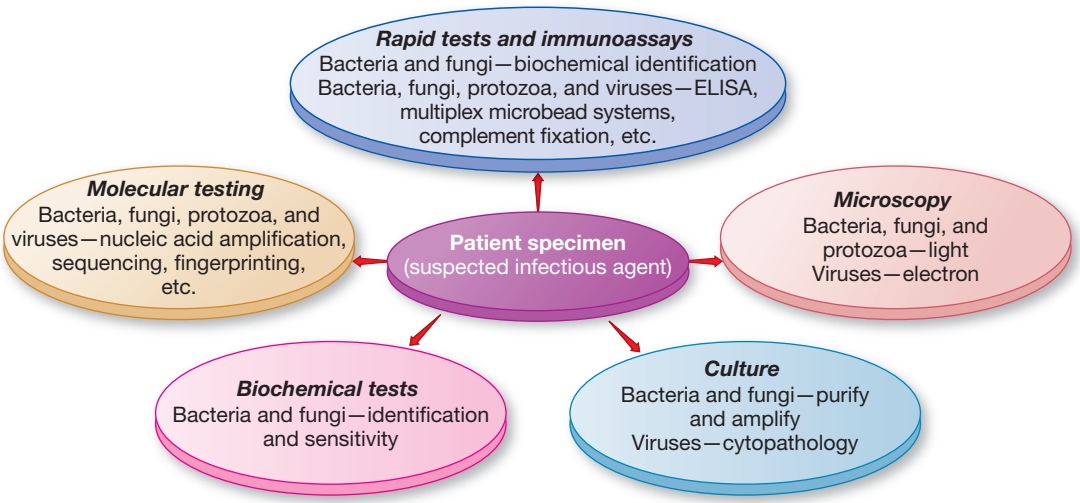

Figure 36.1 The Patient Specimen Is Evaluated by Various Techniques. The specimen source and patient history guide the decision for use of tests and techniques. Not all tests are performed on all specimens, but all laboratories need to be able to perform these tests or refer the specimen to other laboratories.

The clinical microbiology laboratory is the primary site for the diagnosis of human infectious disease; it is often found in a hospital, although it may also be a stand-alone facility. The clinical microbiology lab also supports public health infrastructure, acting as a sentinel in the rapid detection of naturally occurring outbreaks of infection and bioterrorism. The major goals of the **clinical microbiologist** are (1) rapid and accurate identification of disease-causing microorganisms from clinical specimens, and (2) accurate antimicrobial susceptibility testing of those isolated organisms. Clinical microbiology is interdisciplinary, and the clinical microbiologist must have a working knowledge of microbial morphology, metabolism, growth, reproduction, biochemistry, and physiology. Additionally, the clinical microbiologist needs to understand the principles of immunology, molecular biology, genomics, aseptic technique, sterilization, disinfection, and the dynamics of host-parasite relationships. Importantly, tests developed to exploit (1) the antigen-antibody binding capabilities (the focus of clinical immunology) and (2) nucleic acid sequencing and amplification techniques (genomics) can often detect microorganisms in specimens by identifying microbial antigens and genes or gene products, respectively (**figure 36.1**).

The clinical microbiology laboratory provides both preliminary and definitive identification of microorganisms using various tests and procedures that have the highest probability of rapid identification based on (1) direct recovery of the infectious agent from the clinical specimen or (2) indirect evidence that a specific pathogen was the likely source of the infection. Testing a clinical sample must follow a prescribed process to avoid contamination and waste. Thus, a workflow paradigm is often established in the laboratory to rapidly move the specimen through the testing processes while maintaining its integrity. In hospital laboratories, inpatient specimens arrive barcoded to link them to respective patients and to track their progress. Outpatient samples may be received with barcodes or with paperwork that must be entered into the laboratory information system (LIS). The LIS prints barcodes to be affixed to the outpatient specimens. A barcode reader attached to the LIS interfaces automated testing machines to request tests. The LIS tracks the testing process and manages the test results. The LIS data are accessible directly to the other hospital departments, reducing the time in which results are delivered to the clinical staff attending the patient.

36.2 Biosafety Practices Protect Lab Workers

After reading this section, you should be able to:

- Describe the risk assessment process leading to a safe laboratory
- Paraphrase the "standard microbiological practices" that guide lab safety
- Differentiate between biosafety levels and provide examples of microorganisms assigned to each level
- Integrate safety practices into laboratory workflow

As a potentially infectious material, the patient specimen is itself a possible hazard to the laboratory professional. Safety for the patient, the hospital or other clinical site, and laboratory staff is of utmost importance. Thus we discuss biosafety and safe working practices before we begin our discussion of clinical microbiology processes.

The Need for Safety Guidance

Although appalling today, not so long ago a visitor could see mouth pipetting, smoking, and eating in the microbiology laboratory. Over the years, several key events have slowly but quite significantly changed laboratory culture to promote safety. Pioneering biosafety techniques developed by Arnold G. Wedum, M.D., Ph.D., at the Army Biological Research Laboratory, Fort Detrick, Maryland, during the 1950s and 1960s set a standard for physical containment strategies and best practices to keep microbiologists from acquiring

laboratory infections. Later, the ground-breaking methods for manipulating DNA by Paul Berg in the 1970s sparked an international discussion about the possible hazards of recombinant DNA technology and drove the requirement for the systematic evaluation of safe practices in the laboratory. Subsequently concern over standards needed to safely study cancer-causing viruses prompted the National Institutes of Health to establish criteria for ascending levels of physical containment and specific procedures to prevent human contamination. Together, these best methods and work practices were assembled into the *Biosafety in Microbiological and Biomedical Laboratories,* or BMBL. The fifth and current edition of the BMBL was published in 2007 and updated in 2009. Importantly, the editors insightfully prefaced the fifth edition with the caveat that "the intent was and is to establish a voluntary code of practice, one that all members of a laboratory community will together embrace to safeguard themselves and their colleagues, and to protect the public health and environment."

To help prevent laboratory-acquired infections (LAIs), microbiologists today follow strict procedures, often called standard microbiological practices, based on the thoughtful work by Wedum, Berg, and countless others, and codified in the BMBL (**table 36.1**). In addition, some events have led to the formation of laws affecting how microbiologists think about and practice laboratory safety and security. For example (1) the recognition that the human immunodeficiency virus (HIV) and other viruses are transmitted by blood led to the 1991 Bloodborne Pathogens Act, (2) the use of anthrax as a bioterrorism agent led to the Public Health Security and Bioterrorism Preparedness and Response Act of 2002, and (3) the response to emerging viruses with high infectivity or high lethality (such as SARS and avian influenza) resulted in the 2005 Pandemic and All-Hazards Preparedness Act. Additionally, the accidental *Salmonella* infections from 2010 through 2014 in U.S. teaching labs, along with the 2014 and 2015 events revealing unsecured U.S. laboratory samples of plague and tularemia bacteria, smallpox and H5N1 flu viruses, as well as ricin and botulinum toxins, have reignited efforts to integrate safety into all aspects of microbiology practice. Regardless of the reason, the message is clear: safety in the microbiology lab must be a high priority.

Practicing Biosafety

Safety planning for the microbiology laboratory focuses on assessing the likelihood of an LAI in light of the potential consequences of infection. Inherent in this assessment is not just the potential to cause disease in the user but also the potential for contamination beyond the laboratory. Typically, the laboratory design (e.g., airflow, sink access, decontamination processes) and access to biosafety cabinets are surveyed to minimize the hazard (*see figure 8.6*). Following this initial survey, potential risks associated with manipulation of microorganisms are considered, including: (1) procedure(s) used with each agent, (2) experience of those using the laboratory, and (3) infectious agent risk group. There are four risk groups (RGs) into which pathogens are assigned. These RGs reflect increasing danger to humans (**table 36.2**) and are determined based on a number of criteria, including pathogenicity, virulence factors, mode of transmission, availability of protective vaccines and chemotherapeutic agents, and DNA content beyond wild type, among others.

The rest of the risk assessment determines the biosafety level (BSL). The BSL designation indicates that a particular risk is acknowledged and that a specific set of work practices, safety equipment, and facility engineering controls will be used in an assigned laboratory space to keep risk low. The four biosafety levels reflect an appropriate containment level used to prevent LAI and environmental contamination (**table 36.3**). Each subsequent level builds on the previous. The common component to all

Table 36.1 Standard Microbiological Practices

1.	Persons must wash their hands after working with potentially hazardous materials and before leaving the laboratory.
2.	Eating, drinking, smoking, handling contact lenses, applying cosmetics, and storing food for human consumption must not be permitted in laboratory.
3.	Mouth pipetting is prohibited; mechanical pipetting devices must be used.
4.	Policies for the safe handling of sharps (such as needles, scalpels, pipettes, and broken glassware) must be developed and implemented.
5.	Procedures must be developed and implemented to minimize the creation of splashes and/or aerosols.
6.	Work surfaces must be decontaminated with an appropriate disinfectant after completion of work and after any spill or splash of potentially infectious material.
7.	All cultures, stocks, and other potentially infectious materials must be decontaminated using an effective method before disposal.
8.	A sign incorporating the universal biohazard symbol must be posted at the entrance to the laboratory when infectious agents are present. The sign may include the biosafety level, name of the agent(s) in use, and the name and phone number of the laboratory supervisor or other responsible personnel. Information should be posted according to institutional policy.
9.	Persons must report all injuries incurred in the laboratory to the laboratory supervisor as soon as possible.

Biosafety guidelines for handling microorganisms in the teaching laboratory: Development and rationale.* J. Microbiol. & Biol. Educ. *14(1). doi:10.1128/jmbe.v14i1.531.*

Table 36.2 Microbiology Risk Group (RG) Characterization with Example Organisms

1.	Not known to consistently cause disease in healthy adults (e.g., *Lactobacillus casei, Vibrio fischeri*)
2.	Associated with human disease; potential hazard if percutaneous injury, ingestion, or mucous membrane exposure occurs (e.g., *Salmonella typhi, Escherichia coli* O157:H7, *Staphylococcus aureus*)
3.	Indigenous or exotic agents with potential for aerosol transmission; disease may have serious or lethal consequences (e.g., *Coxiella burnetti, Yersinia pestis,* herpesviruses)
4.	Dangerous/exotic agents that pose high risk of life-threatening disease, aerosol-transmitted lab infections; or related agents with unknown risk of transmission (e.g., variola major [smallpox virus], Ebola virus, hemorrhagic fever viruses)

Adapted from: Chosewood, L. C., and Wilson, D. E., 2009. Biosafety in Microbiological and Biomedical Laboratories, *5th ed. Washington, D.C.: U.S. Department of Health and Human Services, CDC, National Institutes of Health.*

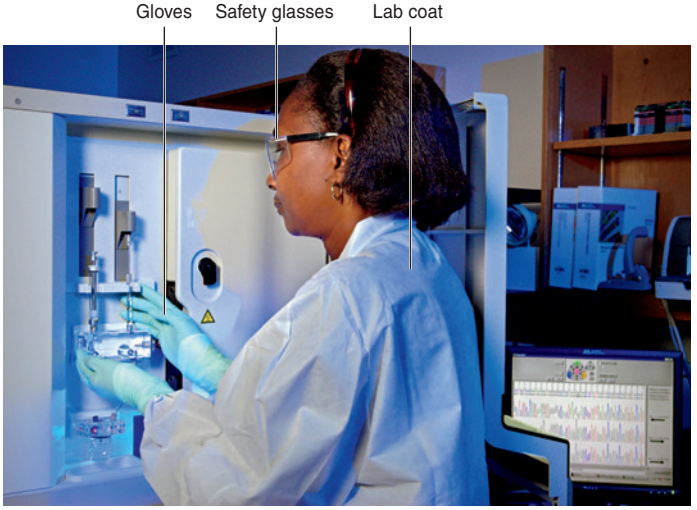

Figure 36.2 Personal Protective Equipment. This person is wearing a lab coat, safety glasses, and gloves to prevent contamination of the laboratory and herself from infectious agents.

levels is the foundational standard microbiology practices, encompassing the behaviors directly under the user's control. These represent minimum guidelines for laboratory safety.

In addition to accepted laboratory behaviors, specific pieces of safety equipment are often recommended for each BSL. Personal protective equipment (PPE) includes (1) protective coverings (coats, gowns, or uniforms), (2) protective eyewear, and (3) gloves. PPE should prevent transmission of infectious agents by blocking their access to entry portals (**figure 36.2**). Additional PPE (e.g., face shield, respiratory protection) may be necessary as determined by the risk assessment.

Table 36.3 Biosafety Recommendations for BSL 1-4 Microbiology Laboratories

Biosafety Level	Work Practices	Safety Equipment	Facilities
1.	Standard microbiology practices	No barriers required. Personal protective equipment (PPE): laboratory coats and gloves; eye, face protection, as needed	Laboratory bench and sink required
2.	BSL-1 practice plus: Limited lab access Biohazard warning signs "Sharps" precautions Biosafety manual defining any needed waste decontamination or medical surveillance policies	Biosafety cabinets (BSCs) or other physical containment devices used for all manipulations of agents that cause splashes or aerosols of infectious materials PPE: Laboratory coats, gloves, face and eye protection, as needed	BSL-1 facilities plus autoclave available
3.	BSL-2 practice plus: Controlled lab access All waste decontaminated Lab clothing decontaminated before laundering Baseline serum testing	BSCs or other physical containment devices used for all open manipulations of agents PPE: Protective lab clothing, gloves, respiratory protection as needed	BSL-2 facilities plus self-closing double door, negative air pressure, room exhaust not recirculated, away from access corridors
4.	BSL-3 practice plus: Different clothing to enter Shower to exit Decontaminate all material on exit	Class III (glove box) cabinet-based work or Class II (laminar flow) BSC with full-body, positive pressure suit	BSL-3 facilities plus separate building or zone, dedicated heat, ventilation, and air conditioning system, vacuum, and decontamination systems

36.3 Identification of Microorganisms from Specimens

After reading this section, you should be able to:

- Construct a work plan for the identification of a specific microorganism from a clinical specimen
- Define and provide examples of appropriately collected specimens
- Describe the use of microscopy to identify microorganisms in patient specimens
- Explain common methods for culturing common bacteria, fungi, and viruses from patient specimens
- Interpret the microscopy, culture, biochemical, and molecular assays used to identify microorganisms from patient specimens

The clinical specimen is an unknown, and microbiology laboratory scientists are the detectives who can identify the microorganism(s) in the specimen. In doing so, they determine the cause of a patient's infection. There are two types of clinical specimens: those from normally sterile body sites, such as cerebrospinal fluid or bone, and those from nonsterile sites, such as skin, mucous membranes, or feces. An important consideration for the clinical microbiologist is to remember that any microorganism found in a sterile-site specimen is a potential problem for the patient and thus should be rapidly identified. Analogously, assessment of nonsterile-site specimens requires a working knowledge of the normal microbiota associated with that site *(see table 32.2)*. The challenge for the microbiologist is to identify the source of the infection amid the background "noise" of the normal microbiota.

The Clinical Specimen

A clinical specimen represents a portion or quantity of human material that is tested, examined, or studied to determine the presence or absence of particular microorganisms (**figure 36.3**). In general, the clinical specimen should:

1. Adequately represent the diseased area and may include additional sites (e.g., urine and blood specimens) to isolate and identify potential agents of the particular disease process.
2. Be of sufficient quality and quantity to allow a variety of diagnostic should they be necessary.
3. Avoid contamination from the normal microbiota of the skin, mucous membranes, and environment.
4. Be collected in appropriate containers, kept at an appropriate temperature, and forwarded promptly to the clinical laboratory.
5. Be obtained before antimicrobial agents have been administered to the patient, if possible.
6. Be accompanied by a putative diagnosis permitting laboratory personnel to contact the physician suggesting tests necessary to "rule out" other pathogens.

A number of techniques are used in the modern clinical microbiology laboratory. Choosing the appropriate test or procedure is determined by the specimen and what is generically expected to be in the specimen based on a patient's signs and symptoms. Most laboratories have prescribed algorithms that dictate how each specimen is processed when it enters the laboratory. In general, the specimen is evaluated for microorganisms by direct techniques, including methods that first require replication or growth of the microbe prior to testing. Indirect techniques are used to identify circumstantial evidence of infection. These are often used when direct techniques do not reveal a pathogen. We highlight a number of these, acknowledging that many of the classical microbiological methods previously performed by the medical laboratory technologist at the bench have been integrated into automated mechanical systems.

Direct Identification of Infectious Agents

The direct recovery and identification of a pathogen is the best evidence documenting the source of an infectious disease. To accomplish this task, the clinical laboratory scientist (CLS) can employ several tests to determine the presence of a pathogen in a specimen. First, however, the CLS must ensure the integrity of the specimen; having more than one species of organism in a specimen collected from a normally sterile site could bias test results. Furthermore, adequate numbers of organisms are required for each laboratory test. Thus to rule out contamination, isolate pure cultures, and amplify organisms for testing, the specimen is often cultured.

(a) (b) (c)

Figure 36.3 Collection of Patient Specimen for Microorganism Testing. (a) The identification of the microorganism begins with proper instruction for specimen collection. (b) The specimen is protected by transport media and transported in a biohazard containment bag to prevent contamination and spillage. (c) The specimen is processed in a biosafety cabinet. In this case, the specimen is cultured to identify the infectious agent and determine the agent's sensitivity to antimicrobial drugs.

Table 36.4 Media Used for Isolation of Pure Bacterial Cultures from Specimens

Selective Media
A selective medium is prepared by the addition of specific substances to a culture medium that will permit growth of one group of bacteria while inhibiting growth of some other groups. These are examples:
Salmonella-Shigella agar (SS) is used to isolate *Salmonella* and *Shigella* species. Its bile salt mixture inhibits many groups of coliforms. Both *Salmonella* and *Shigella* species produce colorless colonies because they are unable to ferment lactose. Lactose-fermenting bacteria produce pink colonies.
Mannitol salt agar (MS) is used for the isolation of staphylococci. The selectivity is obtained by the high (7.5%) salt concentration that inhibits growth of many groups of bacteria. The mannitol helps differentiate pathogenic from nonpathogenic staphylococci, as the former ferment mannitol to form acid, whereas the latter do not. Thus this medium is also differential.
Bismuth sulfite agar (BS) is used for the isolation of *Salmonella enterica* serovar Typhi, especially from stool and food specimens. *S. enterica* serovar Typhi reduces the sulfite to sulfide, resulting in black colonies with a metallic sheen.
Hektoen enteric agar is used to increase the yield of *Salmonella* and *Shigella* species relative to other microbiota. The high bile salt concentration inhibits the growth of Gram-positive bacteria and retards the growth of many coliform strains.
Differential Media
The incorporation of certain chemicals into a medium may result in diagnostically useful growth or visible change in the medium after incubation. These are examples:
Eosin methylene blue agar (EMB) differentiates between lactose fermenters and nonlactose fermenters. EMB contains lactose, salts, and two dyes—eosin and methylene blue. *E. coli,* which is a lactose fermenter, produces a dark colony or one that has a metallic sheen. *S. enterica* serovar Typhi, a nonlactose fermenter, appears colorless.
MacConkey agar is used for the selection and recovery of members of *Enterobacteriaceae* and related Gram-negative rods. The bile salts and crystal violet in this medium inhibit the growth of Gram-positive bacteria and some fastidious Gram-negative bacteria. Because lactose is the sole carbohydrate, lactose-fermenting bacteria produce colonies that are various shades of red, whereas nonlactose fermenters produce colorless colonies.
Blood agar: addition of citrated blood to tryptic soy agar makes possible variable hemolysis, which permits differentiation of some species of bacteria. Three hemolytic patterns can be observed on blood agar. 1. α-hemolysis—greenish to brownish halo around the colony (e.g., *Streptococcus gordonii* and *S. pneumoniae*) 2. β-hemolysis—complete lysis of blood cells resulting in clearing around the colony (e.g., *Staphylococcus aureus* and *Streptococcus pyogenes*) 3. Nonhemolytic—no change in medium (e.g., *Staphylococcus epidermidis* and *S. saprophyticus*)

Culture-Based Methods

For those bacteria and fungi that can be grown in culture, the identification process begins by isolating them in pure culture. This is often done on certain types of selective or differential media that provide the first clues to the identity of the microbe. The choice of media used depends in part on the source of the specimen and knowledge of likely causes of the infection. Some examples of media used are described in **table 36.4** (*also see table 22.7*). Once isolated in pure culture, growth characteristics of the bacterium are examined and specific biochemical tests are performed. Some of the most common biochemical tests used to identify bacterial isolates are listed in **table 36.5**. Classic dichotomous keys are coupled with the biochemical tests for the identification of bacteria from specimens. Generally, fewer than 20 tests are required to identify clinical bacterial isolates to the species level (**figure 36.4**).

Miniaturization into kits and robotic automation of biochemical tests have accelerated significantly the time for identification of pathogens in specimens. Some smaller laboratories use a "kit approach" biochemical system, such as the API 20E, for the identification of members of the family *Enterobacteriaceae* and other Gram-negative bacteria. The API 20E consists of a plastic strip with 20 microtubes containing dehydrated biochemical substrates that can detect certain biochemical characteristics (**figure 36.5**). The biochemical substrates are inoculated with a pure culture of bacteria evenly suspended in sterile saline. After 5 to 12 hours of incubation, the 20 test results are converted to a seven- or nine-digit profile. This profile number can be used with a computer or a book called the *API Profile Index* to identify the bacterium.

In addition to traditional techniques and kits, larger laboratories also use semiautomated robotic systems to detect microorganisms. Some of these are culture-independent systems, reporting infectious agents by directly identifying microbial DNA within the patient specimen, with or without PCR amplification. Several of these technologies couple pure culture isolates with electrospray ionization-mass spectroscopy, peptide nucleic acid fluorescence *in situ* hybridization (PNA-FISH), or matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF)-mass spectrometry to provide high-throughput, high-reliability identification capabilities. ⏮ *Polymerase chain reaction amplifies targeted DNA (section 17.2); Genomic libraries (section 17.5); Molecular characteristics (section 19.3); Molecular techniques (section 29.2)*

One example of an independent identification system is the automated blood culture system. It measures CO_2 concentration

Table 36.5 Some Common Biochemical Tests Used in the Identification and Differentiation of Bacteria

Biochemical Test	Description	Laboratory Application
Carbohydrate fermentation	Acid and/or gas are produced during fermentative growth with sugars or sugar alcohols.	Fermentation of specific sugars used to differentiate enteric bacteria as well as other genera or species
Casein hydrolysis	Detects the presence of caseinase, an enzyme that hydrolyzes the milk protein casein. Bacteria that use casein appear as colonies surrounded by a clear zone.	Used to cultivate and differentiate aerobic actinomycetes based on casein utilization. For example, *Streptomyces* uses casein and *Nocardia* does not.
Catalase	Detects the presence of catalase, which converts hydrogen peroxide to water and O_2	Used to differentiate *Streptococcus* (−) from *Staphylococcus* (+) and *Bacillus* (+) from *Clostridium* (−)
Citrate utilization	When citrate is used as the sole carbon source, this results in alkalinization of the medium.	Used in the identification of enteric bacteria. *Klebsiella* (+), *Enterobacter* (+), *Salmonella* (often +); *Escherichia* (−), *Edwardsiella* (−)
Coagulase	Detects the presence of coagulase. Coagulase causes plasma to clot.	This is an important test to differentiate *Staphylococcus aureus* (+) from *S. epidermidis* (−).
Decarboxylases (arginine, lysine, ornithine)	The decarboxylation of amino acids releases CO_2 and amine.	Used in the identification of enteric bacteria
Esculin hydrolysis	Tests for the cleavage of a glycoside	Used in the differentiation of *Staphylococcus aureus, Streptococcus mitis,* and others (−) from *S. bovis, S. mutans,* and enterococci (+)
β-galactosidase (ONPG) test	Demonstrates the presence of an enzyme that cleaves lactose to glucose and galactose	Used to separate enterics (*Citrobacter* +, *Salmonella* −) and to identify pseudomonads
Gelatin liquefaction	Detects whether or not a bacterium can produce proteases that hydrolyze gelatin and liquefy solid gelatin medium	Used in the identification of *Clostridium, Serratia, Pseudomonas,* and *Flavobacterium*
Hydrogen sulfide (H_2S)	Detects the formation of hydrogen sulfide from the amino acid cysteine due to cysteine desulfurase	Important in the identification of *Edwardsiella, Proteus,* and *Salmonella*
IMViC (indole; methyl red; Voges-Proskauer; citrate)	The indole test detects the production of indole from the amino acid tryptophan. Methyl red is a pH indicator to determine whether the bacterium carries out mixed acid fermentation. Voges-Proskauer (VP) detects the production of acetoin. The citrate test determines whether or not the bacterium can use sodium citrate as a sole source of carbon.	Used to separate *Escherichia* (MR+, VP−, indole+) from *Enterobacter* (MR−, VP+, indole−) and *Klebsiella pneumoniae* (MR−, VP+, indole−); also used to characterize members of the genus *Bacillus*
Lipid hydrolysis	Detects the presence of lipase, which breaks down lipids into simple fatty acids and glycerol	Used in the separation of clostridia
Nitrate reduction	Detects whether a bacterium can use nitrate as an electron acceptor	Used in the identification of enteric bacteria, which are usually +
Oxidase	Detects the presence of cytochrome *c* oxidase which is able to reduce O_2 and artificial electron acceptors	Important in distinguishing *Neisseria* and *Moraxella* spp. (+) from *Acinetobacter* (−) and enterics (all −) from pseudomonads (+)
Phenylalanine deaminase	Deamination of phenylalanine produces phenylpyruvic acid, which can be detected colorimetrically.	Used in the characterization of the genera *Proteus* and *Providencia*
Starch hydrolysis	Detects the presence of the enzyme amylase, which hydrolyzes starch	Used to identify typical starch hydrolyzers such as *Bacillus* spp.
SIM (sulfide, indole, motility medium	Detects sulfides, indole (a metabolic product of tryptophan utilization), and motility	Used to differentiate enteric organisms colorimetrically
TSI (triple sugar iron) medium	Detects metabolism of glucose, lactose or sucrose, and sulfides from ammonium sulfate or sodium thiosulfate	Used to identify of enteric organisms colorimetrically
Urease	Detects the enzyme that splits urea to NH_3 and CO_2	Used to distinguish *Proteus, Providencia rettgeri,* and *Klebsiella pneumoniae* (+) from *Salmonella, Shigella* and *Escherichia* (−)

Continued

and gas pressure changes due to glucose utilization as a presumptive indicator of microorganism growth and metabolism. This has reduced the time to detect blood-borne infections to less than 24 hours. Other automated systems not only detect and identify microorganisms (**figure 36.6**), they also determine their antibiotic susceptibility. Bacterial and fungal antimicrobial susceptibility is determined by evaluating organism growth when exposed to various antimicrobial agents and reported by similar means. The "gold standard" for antimicrobial susceptibility testing is still the agar dilution method. However, the most common practice is an automated microbroth dilution susceptibility test, although the manual Etest and Kirby-Bauer tests are still used in many laboratories (*see figures 9.2–9.4*). Together, the organism's identity and its sensitivity to a panel of antibiotics (a profile called its antibiogram) are determined, often within hours.

Cultures remain the standard for the recovery of fungi from patient specimens; however, the time needed to culture fungi varies anywhere from a few days to several weeks, depending on the organism. Cultures of fungi are evaluated for rate and appearance of growth on at least one selective and one nonselective agar medium, with careful examination of colonial morphology, color, and dimorphism. Typically, the isolation of fungi is accomplished by concurrent culture of the specimen on media that is respectively supplemented and unsupplemented with antibiotics and cycloheximide. Antibiotics inhibit bacteria that may be in the specimen, and cycloheximide inhibits saprophytic (living on decaying matter) molds. However, a number of media formulations are routinely used to culture specific fungi (**table 36.6**). Physicians who suspect pathogenic fungal infections will also order serological tests for antibodies to specific fungal pathogens. Culture of viruses and protozoa from clinical specimens is not routine. Their detection and identification is by microscopy, molecular techniques, or both.

Microscopy

Sometimes the specimen or the cultured microorganisms can be visualized by microscopy to aid in the identification process. Wet-mount, heat-fixed, or chemically fixed specimens can be examined

with an ordinary bright-field microscope. Examination can be enhanced with either phase-contrast or dark-field microscopy, found in some laboratories. The latter is the procedure of choice for the detection of spirochetes in skin lesions associated with early syphilis or Lyme disease. Many stains can be used to examine specimens for specific microorganisms. Two of the more widely used bacterial stains are the Gram stain and the fluorescence stain (*see figure 2.19*). Because these stains are based on the chemical composition of cell walls, they are not useful in identifying specific bacteria. However, preliminary reports often indicate the Gram-morphology, such as "Gram-positive cocci in pairs and chains." Depending on the patient symptoms, such information may be helpful in ensuring appropriate antibiotic therapy. Note in figure 36.4 that the Gram reaction and shape of a bacterium are critical pieces of information

Table 36.6 Examples of Media Used to Isolate Fungi

Culture Medium	Target Fungi
Antibiotic agar	Fungi in polymicrobial specimens
Caffeine agar	*Aspergillus, Rhizopus,* and others
Chlamydospore agar	Dimorphic fungi
Cornmeal agar	Most fungi, including pathogens
Malt agar	Ascomycetes
Malt extract agar	Basidiomycetes
Potato dextrose-yeast extract agar	Mushrooms
Sabouraud dextrose agar (SAB)	Most fungi
SAB + chloramphenicol + cyclohexamide	Dimorphic fungi and dermatophytes

Figure 36.7 Direct and Indirect Immunofluorescence. (a) In the direct fluorescent antibody (DFA) technique, the specimen containing the antigen is fixed to a slide. Fluorescently labeled antibodies that recognize the antigen are then added, and the specimen is examined with a fluorescence microscope for fluorescence. (b) The indirect fluorescent antibody technique (IFA) detects an antibody (Ab) that recognizes a known antigen affixed to a slide. The antigen-antibody complex is located with a fluorescently labeled second or secondary Ab that recognizes other antibodies. (c) A photomicrograph of cells infected with cytomegalovirus (green fluorescence) and adenovirus (yellow fluorescence) using an indirect immunofluorescent staining procedure.

MICRO INQUIRY *Which type of immunofluorescence would most likely be used to test a clinical sample for the presence of an intracellular pathogen such as hepatitis C virus?*

used to decide which biochemical tests are appropriate to perform.

Definitive identification of most fungi is based on the morphology of reproductive structures (spores). Identification and characterization of ova, trophozoites, and cysts in the specimen result in the definitive diagnosis of protozoa infection. These are typically accomplished by direct microscopic evaluation of the clinical specimen. Typical histological staining of blood is routinely used in the identification of blood parasites. Concentrated wet mounts of stool or urine specimens can be examined microscopically for the presence of eggs, cysts, larvae, or vegetative cells of protozoa and helminths.

The fluorescence microscope can be used to visualize microorganisms after staining with fluorochromes such as acridine orange, which stains nucleic acids. Viruses are too small to visualize with the light microscope, but they can be diagnosed using fluorescence microscopy. ⏮ *Antibodies are proteins that bind to specific 3-D molecules (section 34.7)*

With the use of sensitive techniques such as fluorescence microscopy, it is possible to perform antibody-based microbial identifications with improved accuracy, speed, and fewer organisms. The sensitivity and specificity of the antigen-antibody reaction have led to their exploitation for various microbial detection and identification techniques. Since antibodies are the focus of immunology, we discuss them in more detail in section 36.4. In general, though, two main kinds of fluorescent antibody techniques are used for microscopy: direct and indirect. **Direct immunofluorescence** involves fixing the specimen containing the antigen of interest onto a slide (**figure 36.7*a***). Fluorochrome-labeled antibodies are then added to the slide and incubated. The slide is washed to remove any unbound antibody and examined with the fluorescence microscope (*see figures 2.12 and 2.13*) for fluorescence. The pattern of fluorescence reveals the antigen's location. Direct immunofluorescence is used to identify antigens such as those found on

the surface of group A streptococci and to diagnose enteropathogenic *Escherichia coli, Neisseria meningitidis, Salmonella* spp., *Shigella sonnei, Listeria monocytogenes, Mycobacterium tuberculosis,* and *M. avium,* and *Haemophilus influenzae* type b.

Fungi and protozoa can also be identified using fluorescence microscopy. Calcofluor white is typically used to stain fungi from cultures because it binds to the chitan in their cell walls. Fungi in specimens often are diagnosed by direct microscopic examination of specimens using fluorescence. Identification of hyphae in clinical specimens is a presumptive positive result for fungal infection.

Molecular Methods

Probably the most accurate and sensitive methods for the identification of microorganisms are those that report their presence through the analysis of proteins and nucleic acids. Examples include comparison of proteins; physical, kinetic, and regulatory properties of microbial enzymes; nucleic acid–base composition; nucleic acid hybridization; and nucleic acid sequencing (*see figures 17.7 and 18.2–18.3*). Other molecular methods being widely used are nucleic acid probes, real-time PCR amplification of DNA, and DNA fingerprinting. Details of tests that use microbial DNA, RNA, or protein are presented in chapters 17–19. ◀◀ *Microbial taxonomy and phylogeny are largely based on molecular characterization (section 19.3)*

Nucleic acid–based diagnostic methods for the detection and identification of microorganisms have become routine in clinical microbiology laboratories. For example, DNA hybridization technology can identify a microorganism by probing its genetic composition. This type of technology is more sensitive than conventional microbiological techniques, gives results in 2 hours or less, and requires the presence of fewer microorganisms. DNA probe sensitivity can be increased by over 1 million times if the target DNA is first amplified using PCR. PCR can also be monitored in "real time" to detect microbial DNA amplification after each replicative cycle, identifying the microorganisms after only 25 to 30 amplification cycles (**figure 36.8**; also *see figure 17.8*). The most sensitive methods for demonstrating chlamydiae in clinical specimens involves nucleic acid sequencing and PCR-based methods. ◀◀ *Polymerase chain reaction amplifies targeted DNA (section 17.2)* *DNA Hybridization*

The nucleotide sequence of small subunit ribosomal RNA (rRNA) can be used to identify bacterial genera (*see figure 19.3*). Usually the rRNA gene or gene fragment is amplified by PCR. After nucleotide sequencing, the sequence is compared with those in international databases. This method of bacterial identification, called **ribotyping,** is based on the high level of 16S rRNA conservation among bacteria. As discussed in chapter 19, multiple "housekeeping" genes, instead of 16S rRNA genes, may be sequenced and analyzed in a technique called **multilocus sequence typing** (**MLST**) (*see p. 472*).

Genomic fingerprinting is also used in identifying pathogens. This does not involve nucleotide sequencing; rather, it compares the similarity of specific DNA fragments generated by restriction endonuclease digestion (*see figure 19.4*). Plasmids can also be used in DNA fingerprinting. **Plasmid fingerprinting** can identify microbial isolates of the same or similar strains because related strains often contain the same plasmids. In contrast, microbial isolates that are phenotypically distinct have different plasmid fingerprints. Plasmid fingerprinting of many *E. coli, Salmonella, Campylobacter,* and *Pseudomonas* strains and species has demonstrated that this method often is more accurate than phenotyping methods such as biotyping, antibiotic-resistance patterns, phage typing, and serotyping. Just as in genomic fingerprinting, isolated plasmid DNA is cut with specific restriction endonucleases (*see table 17.2*). The DNA fragments are then separated by gel electrophoresis to yield a pattern of fragments, which appear as bands in the gel. The molecular weight of each plasmid species can then be determined and patterns of restriction fragments compared. ◀◀ *Gel electrophoresis (section 17.1)*

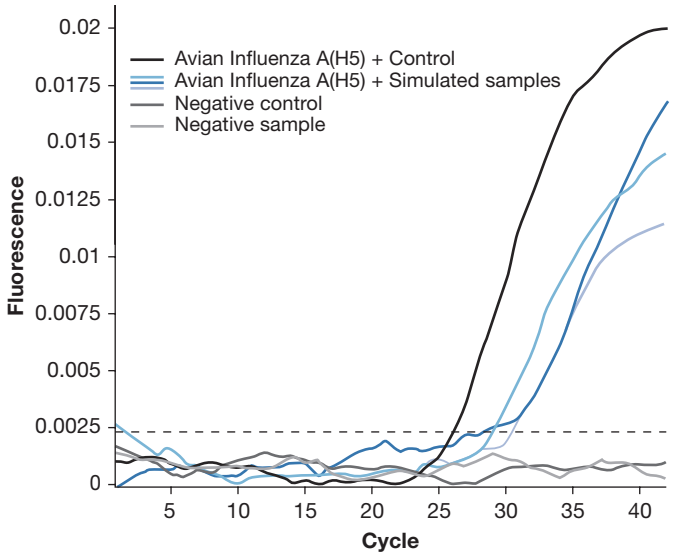

Figure 36.8 PCR Kit Results. Real-time detection of avian influenza is possible using a PCR kit. Note that sufficient DNA amplification occurs after 25 to 30 cycles.

Indirect Identification of Infectious Agents

When an infectious agent cannot be identified by direct methods, methods that indirectly implicate a specific microorganism are used. Indirect evidence does not reveal a live or replicating microbe; it can, however, suggest the cause of infectious disease, especially when no other evidence can refute it. Several techniques are used in the clinical laboratory for this purpose. They include **serology,** the testing and use of serum for antibody evidence of an infection, and molecular biology methods that find evidence of microbial DNA, RNA, and proteins. We discuss serological techniques in detail as a method of clinical immunology.

Briefly, the presence of antimicrobial antibodies in a patient's serum (the liquid portion of blood devoid of clotting factors) is indirect evidence of an infection. In fact, identification of antibody classes (i.e., IgM or IgG) can also reveal when (relatively speaking)

a specific infection occurred. Similarly, antibodies can be used to create tests that detect and identify microbial antigens in clinical specimens. The concept is like that described above for antibody-directed fluorescence microscopy. Modern antibody derivatives, known as monoclonal antibodies, have increased identification sensitivity by several orders of magnitude. ◀◀ *Techniques and Applications 34.1*

Indirect immunofluorescence (figure 36.7*b*) is used to detect the presence of antibodies in serum following an individual's exposure to microorganisms. In this technique, a known antigen (e.g., a virus) is fixed onto a slide. The patient serum suspected of containing (antiviral) antibodies is then added, and if the specific antibody is present, it reacts with antigen to form a complex. When a second, fluorescein-labeled antibody (not from the patient's serum) is added, it reacts with the fixed antibody. After incubation and washing, the slide is examined with the fluorescence microscope. The occurrence of fluorescence shows that antibody specific to the (viral) antigen is present in the serum and that its presence is reported by the fluorescence of the secondary antibody that has attached to the serum antibody (figure 36.7*c*). A common application of indirect immunofluorescence is the identification of *Treponema pallidum* antibodies in the diagnosis of syphilis.

Because serology is so commonly used, numerous microbial detection kits are available to indirectly screen clinical specimens for the presence of specific microorganism antibodies (**table 36.7**). Monoclonal antibodies in these kits have been produced against a wide variety of bacterial, viral, fungal, and protozoal antigens. Coupling sensitive visualization technologies such as fluorescence or scanning tunneling microscopy to mAb detection systems makes it possible to perform microbial identifications with improved accuracy, speed, and fewer organisms.

Table 36.7 Some Common Rapid Immunologic Test Kits for the Detection of Bacteria and Viruses in Clinical Specimens

BioKit HSV-2 (American Screening Corporation, Shreveport, LA) Detects anti-HSV-2 antibody (IgG) in blood or serum.
Directigen (Becton, Dickinson, and Company, Franklin Lakes, NJ) The Directigen Meningitis Combo Test kit is used to detect *S. pneumoniae*, *H. influenzae* type b, *N. meningitidis* groups A, B, C, Y, and W135, Group B Streptococcus, and *E. coli* K1. The Directigen Flu Test kit is used for the direct detection of types A and B influenza.
GonoGen II Test Kit (Becton, Dickinson, and Company, Franklin Lakes, NJ) This test uses monoclonal antibody in a colorimetric assay for the confirmatory testing of *Neisseria gonorrhea* from cultures.
OraQuick detects HIV antibodies in saliva in 10 minutes.
QuickView InLine Strep A Test (Quidel Corporation, San Diego, CA) The test detects group A streptococcal antigen directly from patient throat swab specimens.
Staphaurex (Remel, Thermo Scientific, Lenexa, KS) Staphaurex screens and confirms *Staphylococcus aureus* in 30 seconds.

Retrieve, Infer, Apply

1. Name two specimens for which microscopy would be used in the initial diagnosis of an infectious disease.
2. Describe in general how biochemical tests are used in the API 20E system to identify bacteria.
3. What are the advantages of using monoclonal antibody (mAb) immunofluorescence in the identification of viruses?
4. How can a clinical microbiologist determine the initial identity of a bacterium?
5. Describe a dichotomous key that could be used to identify a bacterium.
6. How can nucleic acid–based detection methods be used by the clinical microbiologist?
7. How can a suspect bacterium be fingerprinted?

36.4 Immune Responses Can Be Measured or Exploited to Detect Infections

After reading this section, you should be able to:

- Diagram the methods by which antibodies are used to identify microorganisms
- Interpret immunologic data used to identify microorganisms from patient specimens
- Design an antibody-based test for the identification of a specific microorganism from a patient specimen

It may not be possible to culture certain microorganisms from clinical specimens because the methodology remains undeveloped (e.g., *Treponema pallidum;* hepatitis A, B, and C viruses; and Epstein-Barr virus), the microbe is unsafe (e.g., rickettsias and HIV), or it is impractical for all but a few microbiology laboratories (e.g., mycobacteria, strict anaerobes, *Borrelia* spp.). Cultures also may be "negative" because of prior antimicrobial therapy. Under these circumstances, detection of antibodies or antigens can be quite valuable.

Immunologic systems for the detection and identification of pathogens from clinical specimens are easy to use, give relatively rapid reaction end points, and are sensitive and specific with a low percentage of false positives and negatives. Some of the more popular immunologic rapid test kits for viruses and bacteria are presented in table 36.7.

Dramatic advances in clinical immunology have given rise to a marked increase in the number, sensitivity, and specificity of serological tests. This reflects a better understanding of (1) immune cell surface antigens (CD antigens; *see table 34.1*), (2) lymphocyte biology, (3) the production of monoclonal antibodies, and (4) the development of sensitive antibody-binding reporter systems. For a number of reasons, the utility of these tests depends on proper test selection and timing of specimen collection. For instance, each individual's immunologic response to a microorganism is quite variable, making the interpretation of immunologic tests potentially difficult. For example, a single, elevated IgG titer does not distinguish between active and past infections. Rather, an elevated IgM titer typically indicates an active infection, especially when subsidence of symptoms

correlates with a four-fold (or greater) decrease in antibody titer. Furthermore, a lack of a measurable antibody titer may reflect an organism's lack of immunogenicity or insufficient time for an antibody response to develop following the onset of the infectious disease. Some patients are also immunosuppressed due to other disease processes or treatment procedures (e.g., cancer and AIDS patients) and therefore do not respond. In this section, some of the more common antibody-based techniques employed in the diagnosis of microbial and immunological diseases are discussed. ⏮ *Immunoglobulin (antibody) structure (section 34.7)*

Serotyping

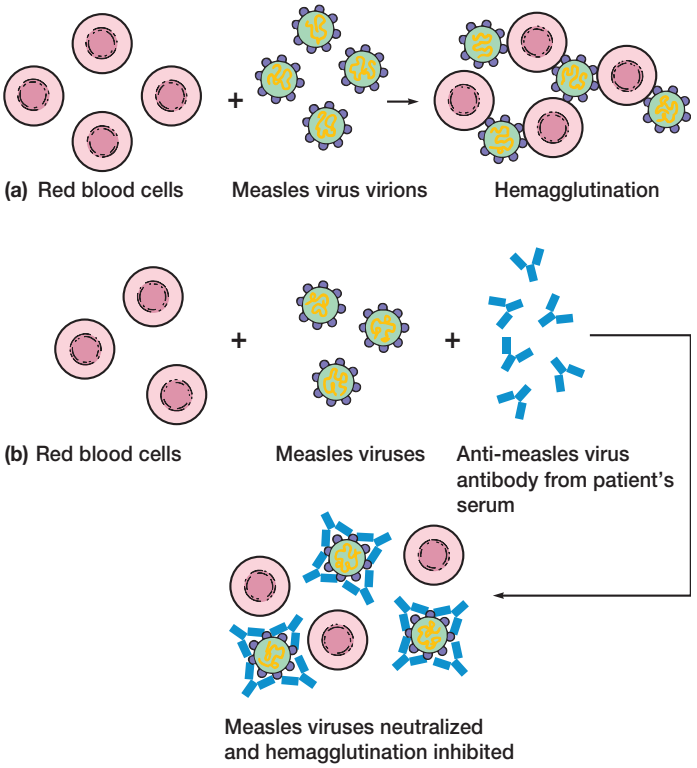
Serum contains many different components, especially the immunoglobulins (antibodies). **Serotyping** refers to the use of serum or purified antibodies to specifically detect and identify other molecules. Serotyping can be used to identify specific white blood cells or the proteins on cell surfaces. Serotyping can also be used to differentiate strains (serovars or serotypes) of microorganisms that differ in the antigenic composition of a structure or product. Therefore, it is sometimes possible to identify a pathogen serologically by testing for cell antigens. For example, there are 90 different strains of *Streptococcus pneumoniae,* each unique in the nature of its capsular material.

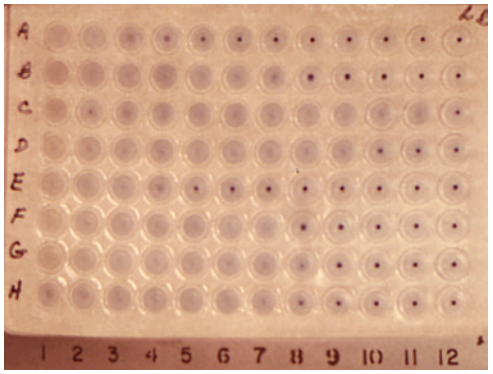
Agglutination

An **agglutination reaction** occurs when an immune complex is formed by cross-linking cells or particles with specific antibodies (*see figure 34.19*). Agglutination reactions usually form visible aggregates or clumps, called **agglutinates,** that can be seen with the unaided eye. Direct agglutination reactions are very useful in the diagnosis of certain diseases. For example, the Rapid Plasma Reagin test is used to screen for syphilis. Antigenic cardiolipin released from spirochete-damaged host cells stimulates the production of reagin antibodies. These antibodies, collected from syphilis-suspect patients, will agglutinate syphilis bacteria in vitro, yielding a positive test. ⏮ *Immune complex formation (section 34.8)*

Techniques have also been developed that employ microscopic synthetic latex spheres coated with antigens. These coated microspheres bind antibodies in a patient's serum specimen to identify viral disease rapidly when cultures are not feasible (e.g., HIV). Latex agglutination tests are also used to detect antibodies that develop during certain mycotic (fungal), helminthic (worm), and bacterial infections, as well as in drug testing. Microspheres can also be coated with monoclonal antibodies to capture antigens from patient specimens. Multiplex microbead test systems are increasingly used in larger laboratories where high throughput is needed to balance the workload.

Hemagglutination usually results from antibodies cross-linking red blood cells through attachment to surface antigens and is routinely used in blood typing. In addition, some viruses can accomplish **viral hemagglutination.** For example, if a person has a certain viral disease, such as measles, antibodies will be present in the serum to react with the measles virus particles and neutralize them. Normally hemagglutination occurs when measles virus particles and red blood cells are mixed. However, when a person's serum is mixed first with virions, followed by the addition of red blood cells, the lack of hemagglutination indicates that serum antibodies have neutralized the measles viruses. This is considered a positive test result for the presence of virus-specific antibodies (**figure 36.9**).





(c)

Figure 36.9 Viral Hemagglutination. (a) The virions of certain viruses can bind to red blood cells, causing hemagglutination. (b) If patient serum containing specific antibodies to the virus is mixed with the red blood cells, the antibodies will neutralize the virus and inhibit hemagglutination (a positive test). (c) Reovirus hemagglutination test results.

MICRO INQUIRY *Which wells show hemagglutination as characterized by cellular clumping?*

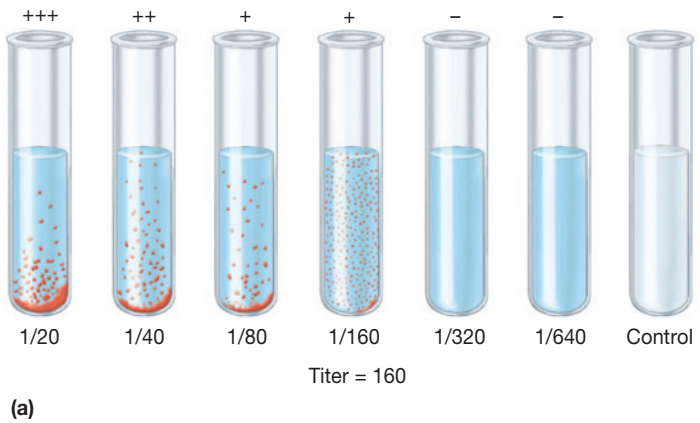


Figure 36.10 Agglutination Tests. (a) Tube agglutination test for determining antibody titer. The titer in this example is 160 because there is no agglutination in the next tube in the dilution series (1/320). The blue in the dilution tubes indicates the presence of the patient's serum. (b) A microtiter plate illustrating hemagglutination. The antibody is placed in the wells (rows 1–10). Positive controls (row 11) and negative controls (row 12) are included. Red blood cells are added to each well. If sufficient antibody is present to agglutinate the cells, they sink as a mat to the bottom of the well. If insufficient antibody is present, they form a pellet at the bottom.

MICRO INQUIRY *What is the titer for the antibody tested in row E?*

Agglutination tests are also used to measure antibody titer. In tube or well agglutination tests, a specific amount of antigen is added to a series of tubes or shallow wells in a microtiter plate (**figure 36.10**). Serial dilutions of serum (1/20, 1/40, 1/80, 1/160, etc.) containing the antibody are then added to each tube or well. The greatest dilution of serum showing an agglutination reaction is determined, and the reciprocal of this dilution is the serum antibody titer.

Complement Fixation

When complement binds to an antigen-antibody complex, it becomes "fixed" and "used up." Complement fixation tests are very sensitive and can be used to detect extremely small amounts of an antibody directed against a suspect microorganism in an individual's serum. A known antigen is mixed with test serum lacking complement (**figure 36.11*a***). When immune complexes have had time to form, complement is added (figure 36.11*b*) to the mixture. If immune complexes are present, they fix and consume complement. Afterward, sensitized indicator cells, usually sheep red blood cells previously coated with complement-fixing antibodies, are added to the mixture. If specific antibodies are present in the test serum and complement is consumed by the immune complexes, insufficient amounts of complement will be available to lyse the indicator cells. On the other hand, in the absence of antibodies, complement remains and lyses the indicator cells (figure 36.11*c*). Thus the absence of lysis shows that specific antibodies are present in the test serum. Complement fixation was once used in the diagnosis of syphilis (the Wassermann test) and is still used as a rapid, inexpensive screening method in the diagnosis of certain viral, fungal, rickettsial, chlamydial, and protozoan diseases. *Complement Fixation Test*

Enzyme-Linked Immunosorbent Assay

The ***e*nzyme-*l*inked *i*mmuno*s*orbent *a*ssay** (**ELISA**) has become one of the most widely used serological tests for antibody or antigen detection. The science behind the technique is similar to that described on page 795 for fluorescence microscopy and involves the linking of various "reporting" enzymes to either antigens or antibodies. Two methods are used: the indirect immunosorbent assay and the direct (also called the double antibody sandwich assay).

The indirect immunosorbent assay detects antibodies, rather than antigens. In this assay, antigen in appropriate buffer is incubated in the wells of a microtiter plate (**figure 36.12*a***) and is adsorbed onto the walls of the wells. Free antigen is washed away. Test serum is added, and if specific antibody is present, it binds to the antigen. Unbound antibody is washed away. Alternatively, the test sample can be incubated with a suspension of latex beads that have the desired antigen attached to their surface. After allowing time for antibody-antigen complex formation, the beads are trapped on a filter and unbound antibody is washed away. An anti-antibody that has been covalently coupled to an enzyme, such as horseradish peroxidase, is added next. The antibody-enzyme complex (the

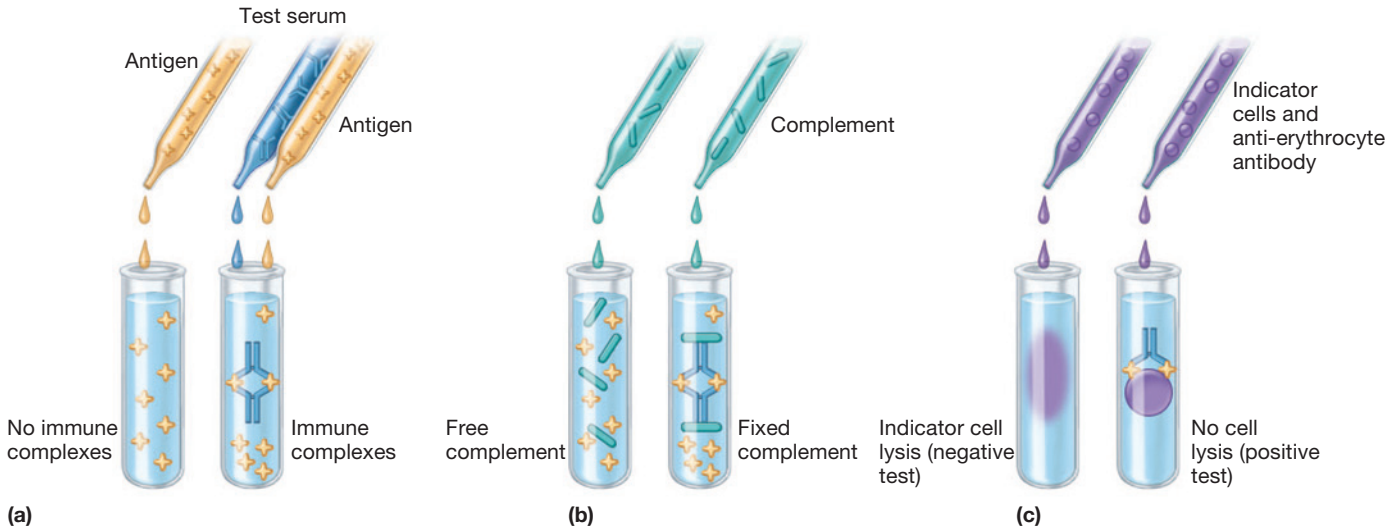

Figure 36.11 Complement Fixation. (a) Test serum is added to one test tube. A fixed amount of antigen is then added to both tubes. If antibody is present in the test serum, immune complexes form. (b) When complement is added, if complexes are present, they fix complement and consume it. (c) Indicator cells and a small amount of anti-erythrocyte antibody are added to the two tubes. If there is complement present, the indicator cells will lyse (a negative test): if the complement has been consumed by the immune complex, no lysis will occur (a positive test).

conjugate) binds to the test antibody, and after unbound conjugate is washed away, the attached indicator antibody is visualized by the addition of a **chromogen.** A chromogen is a colorless substrate acted on by the enzyme portion of the indicator antibody to produce a colored product. The indirect immunosorbent assay currently is used to test for antibodies to HIV and rubella virus (German measles), and to detect certain drugs in serum. For example, antigen-coated nitrocellulose membranes are used in the OraQuick HIV-1 test to detect HIV serum antibodies in about 10 minutes.

The direct ELISA (also known as the double antibody sandwich, or capture, assay) is used for the detection of antigens (figure 36.12*c*). In this assay, specific antibody is placed in wells of a microtiter plate (or it may be attached to a membrane). The antibody is absorbed onto the walls, coating the plate. A test antigen (in serum, urine, etc.) is then added to each well. If the antigen reacts with the antibody, the antigen is retained when the well is washed to remove unbound antigen. A commercially prepared antibody-enzyme conjugate specific for the antigen is then added to each well. The final complex formed is an outer antibody-enzyme, middle antigen, and inner antibody; that is, it is a layered (Ab-Ag-Ab) sandwich. A substrate that the enzyme will convert to a colored product is then added, and any resulting product is quantitatively measured by optical density scanning of the plate. If the antigen has reacted with the absorbed antibodies in the first step, the ELISA test is positive (i.e., it is colored). If the antigen is not recognized by the absorbed antibody, the ELISA test is negative because the unattached antigen has been washed away and no antibody-enzyme is bound (it is colorless). This assay is currently used for the diagnosis of *Helicobacter pylori* infections, brucellosis, salmonellosis, and cholera. Many other antigens also can be detected by the sandwich method. For example, some ELISA kits on the market test for food allergens. *ELISA: Enzyme-Linked Immunosorbent Assay*

Immunoblotting (Western Blotting)

Another immunologic technique used in the clinical microbiology laboratory is immunoblotting, also known as Western blotting. **Immunoblotting** involves polyacrylamide gel electrophoresis of a protein specimen followed by transfer of the separated proteins to sheets of nitrocellulose or polyvinyl difluoride. Protein bands are then visualized by treating the nitrocellulose sheets with solutions of enzyme-tagged antibodies. This procedure demonstrates the presence of common and specific proteins among different strains of microorganisms. Immunoblotting also can be used to show strain-specific immune responses to microorganisms, to serve as an important diagnostic indicator of a recent infection with a particular strain of microorganism, and to allow for prognostic implications with severe infectious diseases (**figure 36.13**). ◀◀ *Gel electrophoresis (section 17.1)*

Immunoprecipitation

The **immunoprecipitation** technique detects soluble antigens that react with antibodies called **precipitins.** The precipitin reaction occurs when bivalent or multivalent antibodies and antigens are mixed in the proper proportions. The antibodies link the antigen to form a large antibody-antigen network or lattice that settles out of solution when it becomes sufficiently large (**figure 36.14*a***). Immunoprecipitation reactions occur only at the equivalence zone when there is an optimal ratio of antigen to antibody so that an insoluble lattice forms. If the precipitin reaction takes place in a test tube (figure 36.14*b*), a precipitation ring forms in the area in which the optimal ratio or equivalence zone develops. ◀◀ *Immune complex formation (section 34.8)*

MICRO INQUIRY *Why do you think an indirect ELISA is used to test for HIV?*

Immunodiffusion

Immunodiffusion refers to a precipitation reaction that occurs between an antibody and antigen in an agar gel medium. Two techniques are routinely used: single radial immunodiffusion and double diffusion in agar.

The **single *r*adial *i*mmuno*d*iffusion (RID) assay** or Mancini technique quantitates antigens. Antibody is added to agar, then the mixture is poured onto slides and allowed to set. Wells are cut in the agar and known amounts of standard antigen added. The unknown test antigen is added to a separate well. The slide is incubated for 24 hours or until equilibrium has been reached,

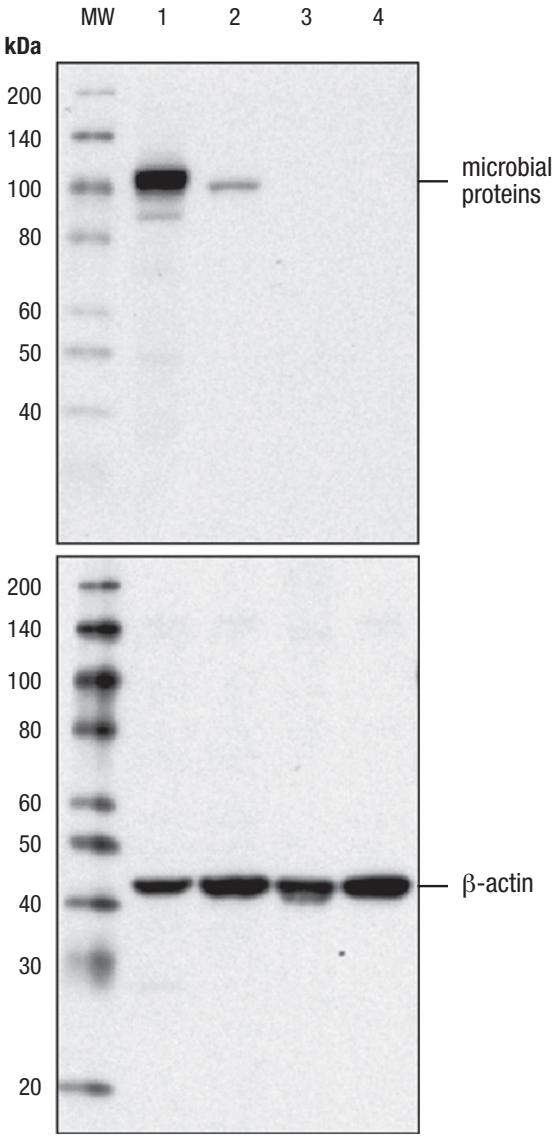

Figure 36.13 The Western Blot. Microbial proteins are separated by gel electrophoresis. For example, lane 1 might have HIV proteins; lane 2, treponemal proteins; lane 3, gonococcal proteins; and lane 4, chlamydial proteins. The proteins in the gel are then blotted onto nitrocellulose filter strips. The nitrocellulose strips are incubated with patient serum samples to permit serum antibody to bind to the proteins. The strips are developed by probing for antibody using radioactive or colorimetric methods. Molecular weight (MW) standards are included to determine antigen mass. To ensure that equal amounts of protein are applied to the gel, a protein control is used (i.e., β-actin in the lower blot).

MICRO INQUIRY *To what microorganism(s) do you think the patient who donated the serum for the above Western blot has been exposed?*

during which time the antigen diffuses out of the wells to form insoluble complexes with antibodies. The size of the resulting precipitation ring surrounding various dilutions of antigen is proportional to the amount of antigen in the well (the wider the ring, the greater the antigen concentration). This is because antigen concentration drops as it diffuses farther out into the agar. The antigen forms a precipitin ring in the agar when its level has decreased sufficiently to reach equivalence and combine with the antibody to produce a large, insoluble network. This method is commonly used to quantitate serum immunoglobulins, complement proteins, and other substances.

The **double diffusion agar assay** (**Öuchterlony technique**) is based on the principle that diffusion of both antibody and antigen (hence double diffusion) through agar can form stable and easily observable immune complexes. Test solutions of antigen and antibody are added to the separate wells punched in agar. The solutions diffuse outward, and when antigen and the appropriate antibody meet, they combine and precipitate at the equivalence zone, producing an indicator line (or lines) (**figure 36.15**). The visible line of precipitation permits a comparison of antigens for identity (same antigenic determinants), partial identity, or nonidentity against a given selected antibody.

Immunoelectrophoresis

Some antigen mixtures are too complex to be resolved by simple diffusion and precipitation. Greater resolution is obtained by the technique of **immunoelectrophoresis** in which antigens are first separated based on their electrical charge, then visualized by the

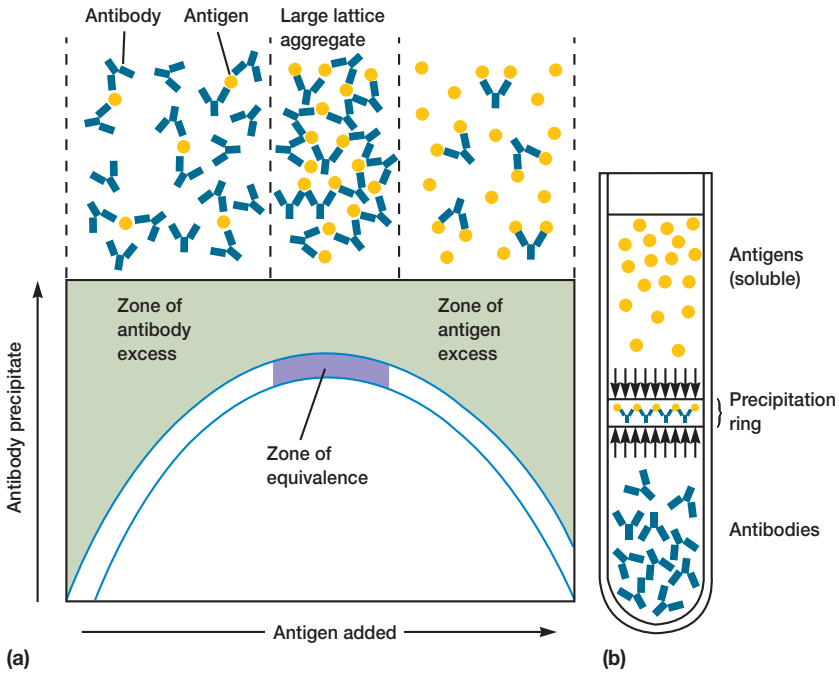

Figure 36.14 Immunoprecipitation. (a) Graph showing that a precipitation curve is based on the ratio of antigen to antibody. The zone of equivalence represents the optimal ratio for precipitation. (b) A precipitation ring test. Antibodies and antigens diffuse toward each other in a test tube. A precipitation ring is formed at the zone of equivalence.

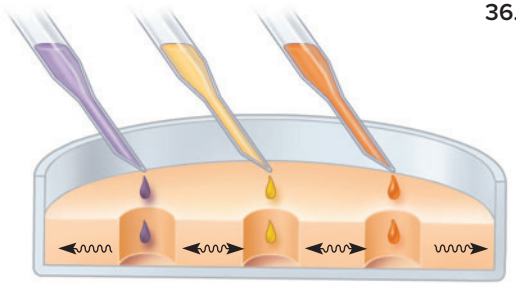
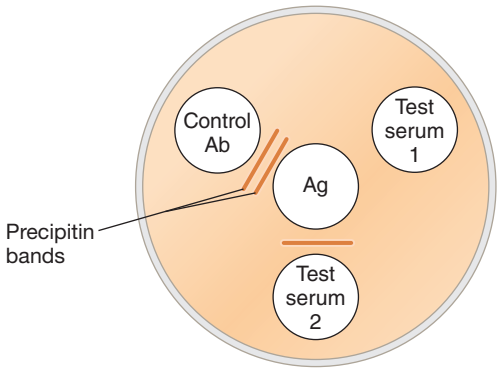
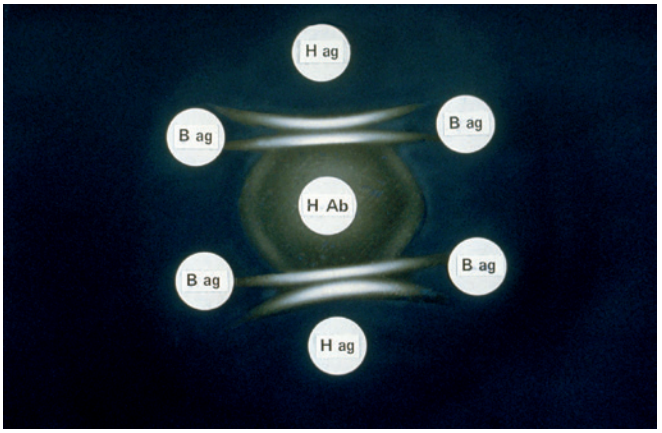


Side view

(a) In one method of setting up a double-diffusion test, wells are punctured in soft agar, and antibodies and antigens are added in a pattern. As the contents of the wells diffuse toward each other, a number of reactions can result, depending on whether antibodies meet and precipitate antigens.



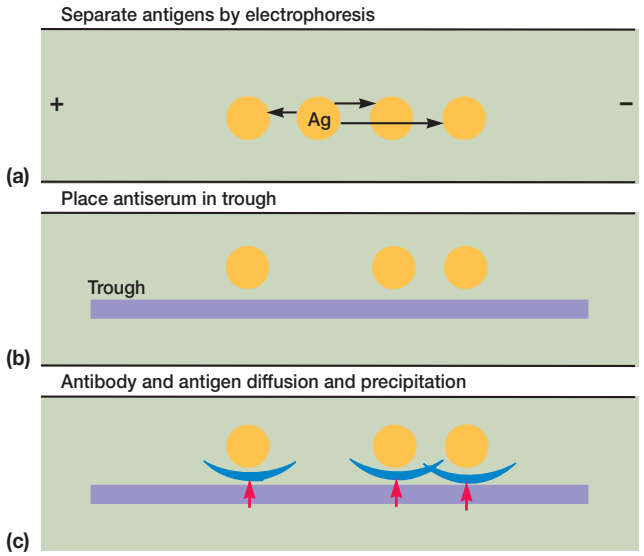
(b) Example of test pattern and results. Antigen (Ag) is placed in the center well and antibody (Ab) samples are placed in outer wells. The control contains known Abs to the test Ag. Note bands that form where Ab and Ag meet. The other wells (1, 2) contain unknown test sera. One is positive and the other is negative. Double bands indicate more than one antigen and antibody that can react.



(c) Actual test results for detecting infection with the fungal pathogen *Histoplasma* sp.

Figure 36.15 Immunodiffusion. Double diffusion agar assay showing characteristics of identity (test serum 2) and a reaction of nonidentity (test serum 1).

precipitation reaction. In this procedure, antigens are separated by electrophoresis in an agar gel. Positively charged proteins move to the negative electrode, and negatively charged proteins move to the positive electrode (**figure 36.16*a***). A trough is then cut next to the wells (figure 36.16*b*) and filled with antibody. When the plate is incubated, the antibodies and antigens diffuse and form



(d)

Figure 36.16 Classical Immunoelectrophoresis. (a) Antigens are separated in an agar gel by an electrical charge. (b) Antibody (antiserum) is then placed in a trough cut parallel to the direction of the antigen migration. (c) The antigens and antibodies diffuse through the agar and form precipitin arcs. (d) After staining, better visualization is possible.

precipitation bands or arcs (figure 36.16*c*) that can be better visualized by staining (figure 36.16*d*). This assay is used to separate the major blood proteins in serum for certain diagnostic tests. ⏮ *Gel electrophoresis (section 17.1)*

Flow Cytometry

Flow cytometry allows detection of specific lymphocyte subsets ($CD4^+$ T-cells, for example, in HIV-infected blood) in an easy, reliable, fast way. In flow cytometry, cells are identified on the basis of their unique cytometric parameters or by means of fluorochromes that can be used either independently or bound to specific antibodies. The flow cytometer forces a suspension of cells through a laser beam and measures the light they scatter or the florescence the cells emit as they pass through the beam (*see figure 29.4*). For example, cells can be tagged with a fluorescent antibody directed against a specific surface antigen. As the stream of cells flows past the laser beam, each fluorescent cell can be detected, counted, and even separated from the other cells in the suspension. The cytometer also can measure a cell's shape, size, and content of DNA and RNA. This technique has enabled the development of quantitative methods to assess antimicrobial susceptibility and drug cytotoxicity in a rapid, accurate, and highly reproducible way.

Radioimmunoassay

The ***radio**immuno**assay*** (**RIA**) technique has become an extremely important tool in biomedical research and clinical practice (e.g., in cardiology, blood banking, diagnosis of allergies, and endocrinology). Indeed, Rosalyn Yalow (1921–2011) won the 1977 Nobel Prize in Physiology or Medicine for its development. RIA uses a purified antigen that is radioisotope-labeled. It competes for antibody with unlabeled standard antigen or test antigen in experimental samples. The radioactivity associated with the antibody is then detected by means of radioisotope analyzers and autoradiography (photographic emulsions that show areas of radioactivity). If there is a lot of antigen in an experimental sample, it will compete with the radioisotope-labeled antigen for antigen-binding sites on the antibody, and little radioactivity will be bound. A large amount of bound radioactivity indicates that little antigen is present in the experimental sample.

Retrieve, Infer, Apply

1. What is serology? Why is serology commonly used to detect syphilis?
2. Why does hemagglutination occur and how can it be used in the clinical laboratory?
3. What does a negative complement fixation test show? A positive test?
4. What are the two types of ELISA methods and how do they work? What is a chromogen?
5. Specifically, when do immunoprecipitation reactions occur?
6. Name two types of immunodiffusion tests and describe how they operate.
7. Describe the immunoelectrophoresis technique.
8. Explain how flow cytometry is both qualitative and quantitative (i.e., how it can determine both the identity and the number of a specific cell type).
9. Describe the RIA technique. How can fungi and protozoa be detected in a clinical specimen? Rickettsias? Chlamydiae? Mycoplasmas?

Key Concepts

36.1 The Clinical Microbiology Laboratory Is the Front Line for Infectious Disease Detection

- The major foci of the clinical microbiologist are the rapid and accurate identification of disease-causing microorganisms from clinical specimens and the accurate antimicrobial susceptibility testing of isolated organisms.
- A variety of laboratory tests and techniques are used (**figure 36.1**). Most of the traditional bench tests have been miniaturized or automated. Some have been abandoned, replaced by faster and more sensitive tests.
- Because each laboratory reflects the clinical environment in which it is housed, some laboratories are relatively small and may only perform a few common or rapid tests. Laboratories associated with large hospitals or public health departments typically analyze a wider diversity of specimens.

36.2 Biosafety Practices Protect Lab Workers

- Over 50 years of pioneering work led to protocols and equipment to protect laboratory workers.
- To prevent laboratory-associated infections, scientists follow standard microbiology practices and wear personal protective equipment (**figure 36.2**).

36.3 Identification of Microorganisms from Specimens

- Detection of disease-causing organisms begins with the collection of patient specimens. The correct selection of body fluid or tissue, and subsequent collection, transport, and preanalytical processing of the specimen, are paramount for identifying infecting agents.
- The clinical microbiology laboratory can provide preliminary or definitive identification of microorganisms from sterile site and nonsterile site specimens. A thorough knowledge of the normal human microbiota is necessary to identify pathogens from host organisms (**tables 36.1** and **36.2; figure 36.3**).
- The type of suspected microorganisms dictates which tests are performed. Bacteria and fungi are often grown in culture to purify and amplify the pathogen for identification. Viruses and protozoa are typically identified by immunologic or molecular tests.
- Identification of pathogens is accomplished by (1) direct recovery and (2) indirect or circumstantial evidence of a pathogen. Direct recovery of infectious agents is by culture and biochemical analysis, as well as molecular techniques. The culturing of many types of bacteria and fungi (filamentous and yeast forms) is routine; however, a few require special consideration.
- Identification of bacteria, fungi, and protozoa often can be made by concentrating and staining the organisms. Gram stain for bacteria, Calcofluor for fungi, and Geimsa for protozoa permit detection using the light microscope.
- The initial identity of a bacterial organism may be suggested by (1) the source of the culture specimen; (2) its microscopic appearance; (3) its pattern of growth on selective, differential, enrichment, or characteristic media; and (4) its hemolytic, metabolic, and fermentative properties. A simple dichotomous key is used to facilitate the identification (**figure 36.4**).
- Immunofluorescence is a process in which fluorochromes are irradiated with ultraviolet, violet, or blue light to make them fluoresce. These dyes can be coupled to an antibody. There are two main kinds of fluorescent antibody assays: direct and indirect (**figure 36.7**).
- Various molecular methods are mostly used to identify microorganisms directly from specimens. Complementary methods like real-time PCR, nucleic acid fingerprinting, PNA-FISH, and MALDI-TOF are used on culture isolates to speed identification.

36.4 Immune Responses Can Be Measured or Exploited to Detect Infections

- Serotyping refers to serological procedures used to differentiate strains (serovars or serotypes) of microorganisms that have differences in the antigenic composition of a structure or product.
- In vitro agglutination reactions usually form aggregates or clumps (agglutinates) visible with the naked eye. Tests have been developed, such as the Rapid Plasma Reagin test, latex microsphere agglutination reaction, hemagglutination, and viral hemagglutination, to detect antigen as well as to determine antibody titer (**figures 36.9** and **36.10**).
- The complement fixation test can be used to detect a specific antibody for a suspect microorganism in an individual's serum (**figure 36.11**).
- The enzyme-linked immunosorbent assay (ELISA) involves linking various enzymes to either antigens or antibodies. Two basic methods are involved: the double antibody sandwich method and the indirect immunosorbent assay (**figure 36.12**). The first method detects antigens and the latter, antibodies.
- Immunoblotting involves polyacrylamide gel electrophoresis of a protein specimen followed by transfer of the separated proteins to nitrocellulose sheets and identification of specific bands by labeled antibodies (**figure 36.13**).
- Immunoprecipitation reactions occur only when there is an optimal ratio of antigen and antibody to produce a lattice at the zone of equivalence, which is evidenced by a visible precipitate (**figure 36.14**).
- Immunodiffusion refers to a precipitation reaction that occurs between antibody and antigen in an agar gel medium. Two techniques are routinely used: single radial diffusion and double diffusion in agar (**figure 36.15**).
- In immunoelectrophoresis, antigens are separated based on their electrical charge, then visualized by precipitation and staining (**figure 36.16**).
- Flow cytometry and fluorescence allow detection of specific cell types, such as $CD4^+$ T-cells in an HIV-infected patient, based on their cytometric parameters or by means of certain dyes called fluorochromes.

Compare, Hypothesize, Invent

1. As more ways of identifying the characteristics of microorganisms emerge, the number of distinguishable microbial strains also seems to increase. Why do you think this is the case?
2. Why are miniaturized identification systems used in clinical microbiology? Describe one such system and its advantage over classic dichotomous keys.
3. ELISA tests usually use a primary and secondary antibody. Why? What are the necessary controls one would need to perform to ensure that the antibody specificities are valid (i.e., no false-positive or false-negative reactions)?
4. *Legionella pneumophila* is a bacterium that is often found in water systems (e.g., shower heads, air-cooling towers). The dispersal of these bacteria can lead to the development of Legionnaires' disease, a particularly virulent pneumonia in the elderly and immunocompromised. Water systems are routinely monitored for *L. pneumophila* contamination using GVPC medium, which contains glycine and the antibiotics vancomycin, polymyxin B, and cyclohexamide. However, this method is known to underestimate the number of *L. pneumophila* cells in the environment. Flow cytometry (FC) is one approach to count cells.

   How would you go about determining if FC is a good way to monitor *L. pneumophila* in the environment? Specifically, how would you collect your samples and compare your results to those obtained by the currently accepted approach (i.e., plating on GVPC medium)? What controls would you need to perform? Based on this information, how do you think the results from FC would compare to those of GVPC cultures obtained from the same samples?

   Read the original paper: Allegra, S. 2008. Use of flow cytometry to monitor *Legionella* viability. *Appl. Environ. Microbiol.* 74:7813.
5. Rotaviruses are double-stranded RNA viruses that cause severe diarrhea in children, resulting in over 600,000 deaths annually, most in developing countries. There are seven serotypes of rotaviruses (A through G; A is the most common). Ideally the diagnosis of rotavirus infection includes the serotype. A PCR-ELISA approach may be the most efficient way to accomplish this. PCR-ELISA uses a 96-well microtiter plate format, thereby maximizing efficiency. PCR products are labeled, usually with a chemical known as digoxigenin, during amplification. A special oligonucleotide called a "capture probe" complementary to the PCR product is then added. The capture probe immobilizes the PCR product to the well and ELISA using antibody against digoxigenin is performed.

   Why do you think it is important to report the serotype of a rotavirus infection? How does PCR-ELISA differ from PCR? How does it differ from a regular ELISA? Why do you think PCR-ELISA might be better than the currently used typing PCR protocol? (Hint: Think about how PCR-ELISA could detect more than one PCR product.)

   Read the original paper: Santos, N., et al. 2008. Development of a microtiter plate hybridization-based PCR-enzyme-linked immunosorbent assay for identification of clinically relevant human group A rotavirus G and P genotypes. *J. Clin. Microbiol.* 46:462.

37

Epidemiology and Public Health Microbiology

One of the most effective methods for preventing infectious disease transmission is still plain old soap and water.

Practice What You Preach

The years 2011 and 2014 marked a practical opportunity for instructors of microbiology laboratories to practice what we preach. Using DNA fingerprinting techniques, investigators from the Centers for Disease Control and Prevention (CDC) tracked two multistate outbreaks of *Salmonella* infection in a total of 150 people. The two groups were approximately 70% female, 30% male, with a median age of 21.5 years. The original illnesses were identified in employees of clinical microbiology laboratories and students in microbiology teaching laboratories who reported working with *Salmonella* bacteria. The outbreak strain associated with several of the ill persons was indistinguishable from a commercially available strain of *Salmonella enterica* serovar Typhimurium found in several clinical and teaching laboratories associated with ill employees and students. Sadly, several children known to reside in households of persons who work or study in a microbiology laboratory using this "lab strain" became seriously ill. Thus we teachers of microbiology were schooled in infectious disease tracking, case definitions, incidence reporting, laboratory testing, disease control, and disease prevention. Certainly, in addition to all the other lessons learned from this outbreak, proper hand washing upon leaving the laboratory should be a best practice that is never overlooked (ever).

In this chapter, we describe the practical goal of epidemiology: to establish effective disease recognition, control, prevention, and eradication measures for a given population. Because emerging and reemerging diseases and pathogens, health-care–acquired (nosocomial) infections, and bioterrorism are major concerns for public health, these topics are also covered here.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Identify specific chemotherapeutic treatments to control infection (chapter 9)
- ✔ Describe innate human host resistance mechanisms (chapter 33)
- ✔ Discuss the human adaptive immune response to pathogens (chapter 34)
- ✔ Explain pathogenicity and the infectious disease process (chapter 35)
- ✔ Summarize the methods by which infectious disease is detected in humans (chapter 36)

37.1 Epidemiology Is an Evidence-Based Science

After reading this section, you should be able to:

- Define the agencies that are responsible for disease prevention and control
- Define the basic vocabulary and processes used in the science of epidemiology

By definition, **epidemiology** (Greek *epi,* upon; *demos,* people or population; and *logy,* study) is the science that evaluates the occurrence, determinants, distribution, and control of health and disease in a defined human population (**figure 37.1**). An individual who practices epidemiology is an **epidemiologist.** Epidemiologists are, in effect, disease detectives. Their major concerns are the discovery of the factors essential to disease occurrence and the development of methods for disease prevention. In the United States, the **Centers for Disease Control and Prevention,** headquartered in Atlanta, Georgia, serves as the national agency for developing and carrying out disease prevention and control, environmental health, and health promotion and education activities (**Historical Highlights 37.1**). Its worldwide counterpart is the **World Health Organization** (WHO), located in Geneva, Switzerland.

The science of epidemiology originated and evolved in response to great epidemic diseases such as cholera, typhoid fever, smallpox, influenza, and yellow fever (**Historical Highlights 37.2**). More recent epidemics of Ebola, HIV/AIDS, cryptosporidiosis, enteropathogenic *Escherichia coli*, SARS, salmonellosis, and novel influenza strains have underscored the importance of epidemiology in preventing global catastrophes caused by infectious diseases

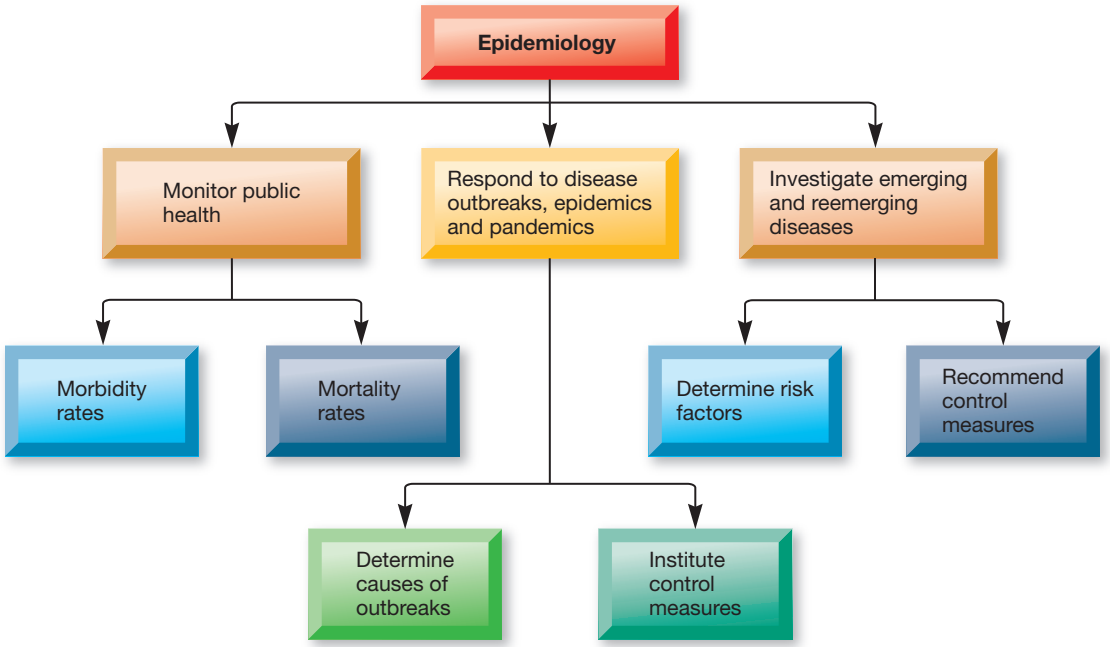


Figure 37.1 Epidemiology. Epidemiology is a multifaceted science that investigates diseases to discover their origin, evaluates diseases to assess their risk, and controls diseases to prevent future outbreaks.

HISTORICAL HIGHLIGHTS

37.1 The Birth of Public Health in the United States

The U.S. Public Health Service was born in 1798 out of the need to keep sailors from becoming sick while at sea. As defenders of the new republic, sailors, or seamen as they were called, could not find adequate health care at port cities of the day. Public hospitals were few in number and often did not have the resources to care for the large numbers of sick seamen that could arrive. As the seamen came from all over the country, their health care was determined to be a national responsibility. Thus the Marine Hospital Act was approved in 1798 and established a network of federal hospitals, called the Marine Hospital Service (MHS). The oversight responsibility was assigned to the Revenue Marine Division of the Treasury Department. The act permitted the taxation (20 cents per month) of the seamen, creating the first medical insurance program in the United States.

In 1878 the MHS was reorganized by congressional action from individually operated hospitals into a centrally controlled, national agency headquartered in Washington, D.C. The new federal agency became a separate bureau of the Treasury Department overseen by a central administrator, the "Supervising Surgeon," who was appointed by the Secretary of the Treasury. The administrative title of Supervising Surgeon was changed to Supervising Surgeon General in 1875. In 1902 the MHS became the Public Health and Marine Hospital Services, and the administrator's title was changed to Surgeon General. A national "hygienic" laboratory was established in 1887 and was located on Staten Island, New York. The Pure Food and Drugs Act was established in 1906. In 1912 the Public Health and Marine Hospital Services was renamed the Public Health Service and authorized to investigate communicable disease.

In 1930 the Hygienic Lab moved to Washington to become the National Institute of Health, but it was not until 1939 that all health, education, and welfare agencies and services created by Congress were combined, under the Federal Security Agency. The Public Health Service opened the Communicable Disease Center in Atlanta, Georgia, in 1946. In 1953 the Federal Security Agency became the Department of Health, Education, and Welfare, and in 1970 the Communicable Disease Center became the Center for Disease Control. Ten years later, the Department of Health, Education, and Welfare became the Department of Health and Human Services, and the Center for Disease Control was renamed the Centers for Disease Control. It was renamed again in 1992 to become the Centers for Disease Control and Prevention (although it is still abbreviated as the CDC).

HISTORICAL HIGHLIGHTS

37.2 John Snow, the First Epidemiologist

Much of what we know today about the epidemiology of cholera is based on the classic studies conducted between 1849 and 1854 by the British physician John Snow. During this period, a series of cholera outbreaks occurred in London, England, and Snow set out to find the source of the disease. Some years earlier when he was still a medical apprentice, Snow was sent to help during a cholera outbreak among coal miners. His observations convinced him that the disease was usually spread by unwashed hands and shared food, not by "bad" air or casual direct contact.

Thus when the outbreak of 1849 occurred, Snow believed that cholera was spread in the same way as among the coal miners. He suspected that water, and not unwashed hands and shared food, was the source of the cholera infection. Snow examined official death records and discovered that most of the victims in the Broad Street area lived close to the Broad Street water pump or were in the habit of drinking from it. He concluded that cholera was spread by drinking water from the Broad Street pump, which was contaminated with raw sewage containing the disease agent. When the pump was disabled by removing its handle, the number of cholera cases dropped dramatically.

In 1854 another cholera outbreak struck London. Part of the city's water supply came from two different suppliers: the Southwark and Vauxhall Company and the Lambeth Company. Snow interviewed cholera patients and found that most of them purchased their drinking water from the Southwark and Vauxhall Company. He also discovered that this company obtained its water from the Thames River below locations at which Londoners discharged their sewage. In contrast, the Lambeth Company took its water from the Thames before the river reached the city. The death rate from cholera was over eight-fold lower in households supplied with Lambeth Company water. Water contaminated by sewage was transmitting the disease. Snow deduced that the cause of the disease must be able to multiply in water. Thus he nearly recognized that cholera was caused by a microorganism, though Robert Koch did not discover the causative bacterium (*Vibrio cholerae*) until 1883.

To commemorate these achievements, the John Snow Pub now stands at the site of the old Broad Street pump. Those who complete the Epidemiologic Intelligence Program at the Centers for Disease Control and Prevention receive an emblem bearing a replica of a barrel of Watney's Ale, the brew dispensed at the John Snow Pub.

(**Historical Highlights 37.3**). Today epidemiology's scope encompasses all public health issues: infectious diseases, genetic abnormalities, metabolic dysfunction, malnutrition, neoplasms, psychiatric disorders, obesity, and aging. This chapter discusses only infectious disease epidemiology.

Epidemiology studies the factors determining and influencing the frequency and distribution of health-related events. When a disease occurs occasionally and at irregular intervals in a human population, it is a sporadic disease (e.g., bacterial meningitis). When it maintains a steady, low-level frequency at a moderately regular interval, it is an **endemic** (Greek *endemos,* dwelling in the same people) **disease** (e.g., the common cold). Hyperendemic diseases gradually increase in frequency beyond the endemic level but not to the epidemic level (e.g., the common cold during winter months). **Incidence** reflects the number of new cases of a disease in a population at risk during a specified time period. An **outbreak** is the sudden, unexpected occurrence of a disease, usually in a limited segment of a population (e.g., the 2014 measles outbreak that occurred at Disneyland California). The **attack rate** is the proportional number of cases that develop in a population that was exposed to an infectious agent. An **epidemic** (Greek *epidemios,* upon the people), on the other hand, is an outbreak affecting many people at once (i.e., there is a sudden increase in the occurrence of a disease above the expected level). Influenza is an example of a disease that may occur suddenly and unexpectedly in a family and often achieves epidemic status in a community. The influenza virus resides in a **reservoir host** (usually birds or pigs) until it is transmitted to a human host. The first case in an epidemic is called the **index case.** Finally, a **pandemic** (Greek *pan,* all) is an increase in disease occurrence within a large population over at least two countries around the world. Usually pandemic diseases spread among continents. The global H1N1 influenza outbreaks of 1918 and 2009 are good examples.

37.2 Epidemiology Is Rooted in Well-Tested Methods

After reading this section, you should be able to:

- Evaluate the effectiveness of public health surveillance methods
- Deduce the impact of public health methods on the quality of U.S. life over the last 100 years
- Describe the use of geographical information systems to track diseases remotely
- Use standardized surveillance data to measure infectious disease frequency
- Calculate rates of incidence, prevalence, morbidity, and mortality

HISTORICAL HIGHLIGHTS

37.3 A Modern Epidemic Exposed

Guinea, Sierra Leone, and Liberia intersect in the southern Forest Region, at Gueckedou Province. It was somewhere near the village of Meliandou (Gueckedou) in December 2013 that a two-year-old boy unknowingly became infected with one of the deadliest viruses known. Within a week he began to feel ill. His three-year-old sister, their mother, and their grandmother nursed him until he died. As was the tradition at West African funerals, mourners washed, embraced, and caressed the boy's body prior to burial. It wasn't long after the funeral, though, that they fell sick. The village midwife and a health-care worker from a nearby town provided the family with traditional medicines and care. But these did not help. Soon the midwife, health-care worker, and two mourners from the boy's funeral were ill. The symptoms were all the same: sudden fever, muscle pain, fatigue, reddened eyes, headache, and sore throat. These were followed by diarrhea, vomiting, a rash, and bleeding around the gums, nose, eyes, and rectum. The local doctors treated the sick for malaria, with no relief. Treatment did not stop the next wave of death, and four more died. Soon even the doctors succumbed to the disease; three died in the early days of the disease. As the numbers of dead escalated, government officials diagnosed the cause as Ebola virus disease. At the time of this writing the 2014 epidemic was still ongoing—although declining in its toll on life. As of August 18, 2015, there were 28,018 cases and 11,301 dead.

Thought to be sequestered in an undescribed species of fruit bat, Ebola virus is well known in Africa. The virus first erupted in 1976, in Yambuku, Zaire (now the Democratic of the Congo), but it was named for the Ebola River to protect from stigma the local village where many had died. Its gruesome hemorrhages instilled much fear. There were 33 more outbreaks of Ebola virus disease recorded over the next three decades, although curiously no cases were reported between 1979 and 1994. Usually fewer than 500 cases were reported with each outbreak.

The 2013 outbreak differed in both geographical distribution and incidence, spreading to at least ten countries (Guinea, Liberia, Sierra Leone, Nigeria, Senegal, Mali, Spain, Scotland, England, and the United States, Clearly, modern roadways and international travel facilitated the migration of the virus, as the infected went about their business until their symptoms stopped them. This was the story of Thomas Eric Duncan, who contracted the virus in Liberia before traveling to the United States. Mr. Duncan was diagnosed with Ebola virus disease in a Dallas, Texas, hospital on September 30, 2014. Although he did not display symptoms of the disease until several days after his arrival in Texas, by the fifth day he was febrile, hemorrhagic, and barely conscious. He died on October 8, 2014. His hospital room, an active BSL-4 environment, was filled with drums of contaminated medical waste. Somehow while caring for Mr. Duncan, two nurses were exposed and ultimately tested positive for Ebola virus.

This modern epidemic of Ebola virus disease is schooling the best of the public health theorists and practitioners. Unknown still is the exact reservoir and source of the virus. (The sale and consumption of bats and other "bushmeat," delicacies in southern Africa, are now banned by the health ministries, in hopes of preventing additional exposures.) Much of the natural history of Ebola virus disease has been revealed during this epidemic. Infection typically occurs through direct contact with blood, vomit, feces, urine, or other bodily fluids of a symptomatic Ebola patient. The virus gains entry to its new host through the broken skin, mouth, nose, or genitalia of the uninfected. This includes direct contact with virus-contaminated bedding, clothing, or environmental surfaces. Exposed but asymptomatic individuals are not infectious to others. An incubation period of 2 to 21 days, but more typically 8 to 10 days, is needed to generate a viral load that causes symptoms. The Ebola virus of 2015 is from the same lineage as the 1976 virus, but it has mutated and evolved to be less lethal. Today it kills about 40% of its victims as compared to 88% in 1976. Passive immunotherapy is effective in controlling infection as long as it is initiated right after symptoms appear. Thus, sera from Ebola survivors cure the newly infected.

Other important lessons have been learned:

- Most people and countries rally in support of disaster—but nongovernmental organizations, like Doctors without Borders, are able to respond more quickly and with less red tape, often supporting with substantial financial and human resources.
- Some people will always be driven by fear of infectious disease (one of the exposed, asymptomatic nurses traveled, with CDC permission, to Akron Ohio, where her parents were later feared and ridiculed).
- Local public health agencies must have policies and procedures to practice emergency response and quarantine for high-consequence diseases (new CDC guidance has been issued to facilitate protecting cities and states).
- U.S. hospitals must now be prepared for BSL-4, worst-case infections (not for "if" they happen, but for "when" they happen).
- Given the right motivation, new vaccines and drugs can be pushed through otherwise choking red tape.
- Ebola virus is quite sensitive to bleach and chlorine-based disinfectants.

Public health is the science of protecting populations and improving the health of human communities through education, promotion of healthy lifestyles, and prevention of disease and injury. Public health practitioners use a methodical approach to identify population health issues to prevent or correct negative outcomes. The methodical approach mirrors the scientific method in that it identifies a population health problem, determines the cause, proposes preventative or corrective action, implements that action, and assesses the outcomes of implementing the action.

Public Health Surveillance

The identification of a population health issue is rooted in public health surveillance. Public health surveillance is the proactive evaluation of genetic background, environmental conditions, human behaviors and lifestyle choices, emerging infectious agents, and microbial responses to chemotherapeutic agents, for example, to monitor the health of a population. In other words, public health practitioners look for cause-and-effect relationships to determine risk. The impact of public health surveillance is obvious when one considers the change in the leading causes of death in the United States from 1900 to 2013 (**table 37.1**). The public health landscape of 1900 was a valley of death due to infectious disease. Surveillance identified infectious disease problems and their associated risks. These were remedied by water treatment, strict sanitation guidelines, and later by the use of antimicrobial agents and vaccines. The result changed the death-by-infection landscape of the early twentieth century to one of very few deaths due to infectious disease by the 1960s. Ironically, the modernization that helped prevent the leading causes of mortality in the 1900s also led to a longer life expectancy and a more sedentary lifestyle in the 2000s. This changed the landscape of 2013 to one of a mountain of metabolic disease.

Public health surveillance really began in the fourteenth century as a means to control bubonic plague. However, it was not until after the germ theory of disease was widely accepted (late 1800s) that a scientifically based monitoring process was used as a means to track communicable disease. This was not the confidential monitoring that we expect today. The first disease tracking practices were intrusive, as people were inspected for signs of clinical disease; those found to be infected were quarantined. The change from inspecting people to monitoring disease occurred around 1940. The emphasis on watching disease progress in a population and disseminating information in advance of the disease radically improved the impact on public health by changing the role of public health practitioners from disease informants to health-care allies (**figure 37.2**). Importantly, disease data come from a number of sources, including mandated clinical reports, laboratory specimens, records and databases, sentinel surveillance, disease registries, and field surveys. These data are used

Table 37.1 Percentage of Total U.S. Citizen Deaths for the 10 Leading Causes of Death in 1900[1] and 2013[2]

Cause	Percentage	
	1900	2013*
Heart diseases	8.0	23.5

most often for the generation of reports informing public health officials of (1) population morbidity and mortality, (2) disease effect on school attendance, (3) impact of epidemics on employee absenteeism, and (4) animal and vector control policies.

In 1878 Congress authorized the U.S. Marine Hospital Service (the forerunner of the Public Health Service; Historical Highlights 37.1) to collect illness data associated with cholera, smallpox, plague, and yellow fever. These data were used to quarantine the sick and prevent the spread of these diseases into the United States. The following year, a congressional appropriation directed the collection and publication of these "notifiable diseases." Congress subsequently directed the Surgeon General to compile and publish the data. The CDC assumed this responsibility in 1961. As of 2014, there are 64 infectious diseases on the list of notifiable diseases; it is updated periodically to reflect emerging infectious diseases (e.g., measles, SARS-CoV, H5N1 influenza A, etc.). Importantly, effective reporting of notifiable (and other) diseases is contingent on reliable surveillance data collection systems.

Effective use of public health surveillance data stems from high-integrity data collection (i.e., documented first-hand information of the data origin and the methods used to collect them). Surveillance of health issues is typically accomplished by two methods: population surveys and case reporting. Population surveys tend to be more of a sentinel surveillance method in that they look for trends and outliers within a given population (e.g., immunization records revealing infection control success). Case reports tend to be retrospective comparisons of specific conditions that assign people to risk groups (e.g., influenza test results to rule out SARS).

Remote Sensing and Geographic Information Systems: Charting Infectious Disease Data

Remote sensing and geographic information systems are map-based tools that can be used to study the distribution, dynamics, and environmental correlates of microbial diseases. **Remote sensing** (**RS**) gathers digital images of Earth's surface from satellites and output from biological sensors, for example, and transforms the data into maps. A **geographic information system** (**GIS**) is a data management system that organizes and displays digital map data from RS and facilitates the analysis of relationships between mapped features. Statistical relationships often exist between mapped features and diseases in natural host or human populations. Examples include the location of the habitats of the malaria parasite and mosquito vectors in Mexico and Asia, tick that transmit Lyme disease in the United States, and African trypanosome in both humans and livestock in the southeastern United States. RS and GIS may also permit the assessment of human risk from pathogens such as Sin Nombre virus (the virus that causes hantavirus pulmonary syndrome in North America). RS and GIS are most useful if disease dynamics and distributions are clearly related to mapped environmental variables. For example, if a microbial disease is associated with certain vegetation types or physical characteristics (e.g., elevation, precipitation), RS and GIS can identify regions in which risk is relatively high.

Measuring Infectious Disease Frequency

To determine if an outbreak, epidemic, or pandemic is occurring, epidemiologists measure disease frequency at single time points and over time. They then use statistics to analyze the data and determine risk factors and other factors associated with disease.

To determine the frequency or rate of an event, an accurate count of the total population, the population exposed, and the number of affected people needs to be made. Disease surveillance practices enable the tracking of infections. Many infectious diseases (e.g., food- and waterborne diseases) must, by law, be reported within a specific time frame. This permits public health agencies to act swiftly to contain the outbreak and mobilize control measures. Timely notification of "reportable" diseases to public health agencies has stemmed numerous epidemics such as cholera and typhoid.

Measures of frequency usually are expressed as fractions. The numerator is the number of individuals experiencing the event—infection—and the denominator is the number of individuals in whom the event could have occurred, that is, the population at risk. The fraction is a proportion or ratio but is commonly called a rate because a time period is specified. (A rate also can be expressed as a percentage.) In population statistics, rates usually are stated per 1,000 individuals, although other powers of 10 may be used for particular diseases (e.g., per 100 for very common diseases and per 10,000 or 100,000 for uncommon diseases). For example, disease incidence is a measure of the number of diseased people during a defined time period, as compared to the total (healthy) population. The incidence of a disease reports not only the rate of occurrence but the relative risk as well. Since disease reflects a change in health status over time, a **morbidity rate** is used. The rate is commonly determined when the number of new cases of illness in the general population is known from clinical reports. It is calculated as follows:

$$\text{Morbidity rate} = \frac{\text{Number of new cases of a disease during a specified period}}{\text{Number of individuals in the population}}$$

For example, if in 1 month, 700 new cases of influenza per 100,000 individuals occur, the morbidity rate would be expressed as 700 per 100,000, or 0.7%.

The **prevalence rate** refers to the total number of individuals infected in a population at any one time, no matter when the disease began. The prevalence rate depends on both the incidence rate and the duration of the illness. Prevalence is calculated as follows:

$$\text{Prevalence} = \frac{\text{Total number of cases in population}}{\text{Total population}} \times 100$$

The **mortality rate** is the relationship between the number of deaths from a given disease and the total number of cases of the disease. The mortality rate is a simple statement of the proportion of all deaths that are assigned to a single cause. It is calculated as follows:

$$\text{Mortality rate} = \frac{\text{Number of deaths due to a given disease}}{\text{Size of the total population with the same disease}}$$

For example, if 15,000 deaths occurred due to AIDS in a year and the total number of people infected was 30,000, the mortality rate would be 15,000 per 30,000, or 1 per 2, or 50%.

The determination of morbidity, prevalence, and mortality rates helps public health personnel direct health-care efforts to control the spread of infectious diseases. For example, a sudden increase in the morbidity rate of a particular disease may indicate a need for implementation of preventive measures designed to reduce the disease.

37.3 Infectious Disease Is Revealed Through Patterns Within a Population

After reading this section, you should be able to:

- Discriminate between a communicable and noncommunicable disease
- Interpret population infection data to define epidemic and pandemic events
- Apply the concept of herd immunity to public health in your community
- Predict potential infectious disease outbreaks from molecular data revealing antigenic drift and antigenic shift events

An **infectious disease** is a disease resulting from an infection by microbial agents such as viruses, bacteria, fungi, protozoa, and helminths. A **communicable disease** is an infectious disease that can be transmitted from person to person (not all infectious diseases are communicable; e.g., rabies is an infectious disease acquired only through contact with a rabid animal). An epidemiologist studying an infectious disease is concerned with the causative agent, the source or reservoir of the disease agent, how it is transmitted, what host and environmental factors can aid development of the disease within a defined population, and how best to control or eliminate the disease. These factors describe the natural history or cycle of an infectious disease. ⏮ *Pathogenicity drives infectious disease (section 35.1)*

Two major types of epidemics are recognized: common source (noncommunicable) and propagated (communicable). A **common-source epidemic** is characterized as having reached a peak level within a short period of time (1 to 2 weeks), followed by a moderately rapid decline in the number of infected patients (**figure 37.3*a***). This type of epidemic usually results from a single, common contaminated source such as food (food poisoning) or water (cholera). By contrast, a **propagated epidemic** is characterized by a relatively slow and prolonged rise, and then a gradual decline in the number of individuals infected (figure 37.3*b*). This type of epidemic usually results from the introduction of a single infected individual into a susceptible population. The initial infection is then propagated to others in a gradual fashion until many individuals within the population are infected. An example is the increase in influenza cases that coincides with the return of college students after their winter break. Droplet and contact transmission of flu virus spreads rapidly among susceptible, and unvaccinated students. Whereas one infected student is sufficient to initiate the epidemic, it is the person-to-person transmission of the flu virus that extends the epidemic. After an infectious disease has been recognized in a population, epidemiologists correlate the disease outbreak with a specific organism; its exact cause must be discovered (**Historical Highlights 37.4**). At this point, the clinical or diagnostic microbiology laboratory enters the investigation. Its purpose is to isolate and identify the organism responsible for the disease. ⏮ *Clinical microbiology and immunology (chapter 36)*

As mentioned, epidemiologists recognize an infectious disease in a population by using various surveillance methods. Surveillance is a dynamic activity that includes gathering information on the development and occurrence of a disease, collating and analyzing the data, summarizing the findings, and using the information to select control methods (**figure 37.4**). Surveillance may not always require the direct examination of cases. However, to accurately interpret

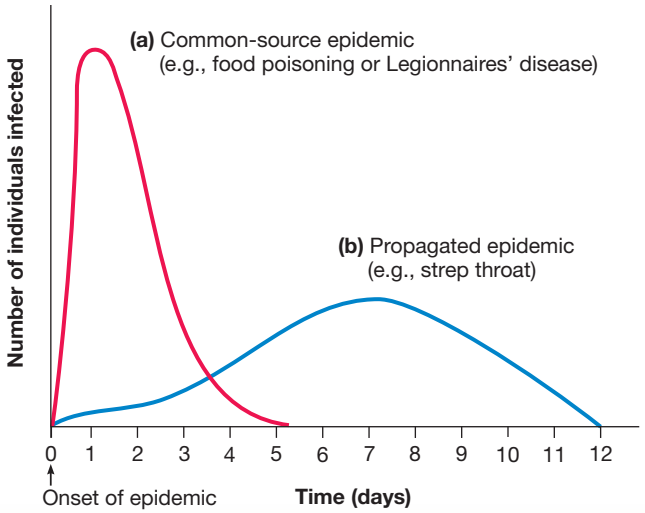

Figure 37.3 Epidemic Curves. (a) In a common-source epidemic, there is a rapid increase up to a peak in the number of individuals infected and then a rapid but more gradual decline. Cases usually are reported for a period that equals approximately one incubation period of the disease. (b) In a propagated epidemic, the curve has a gradual rise and then a gradual decline. Cases usually are reported over a time interval equivalent to several incubation periods of the disease.

MICRO INQUIRY *Is a flu epidemic an example of a common-source or a propagated epidemic? Explain your answer.*

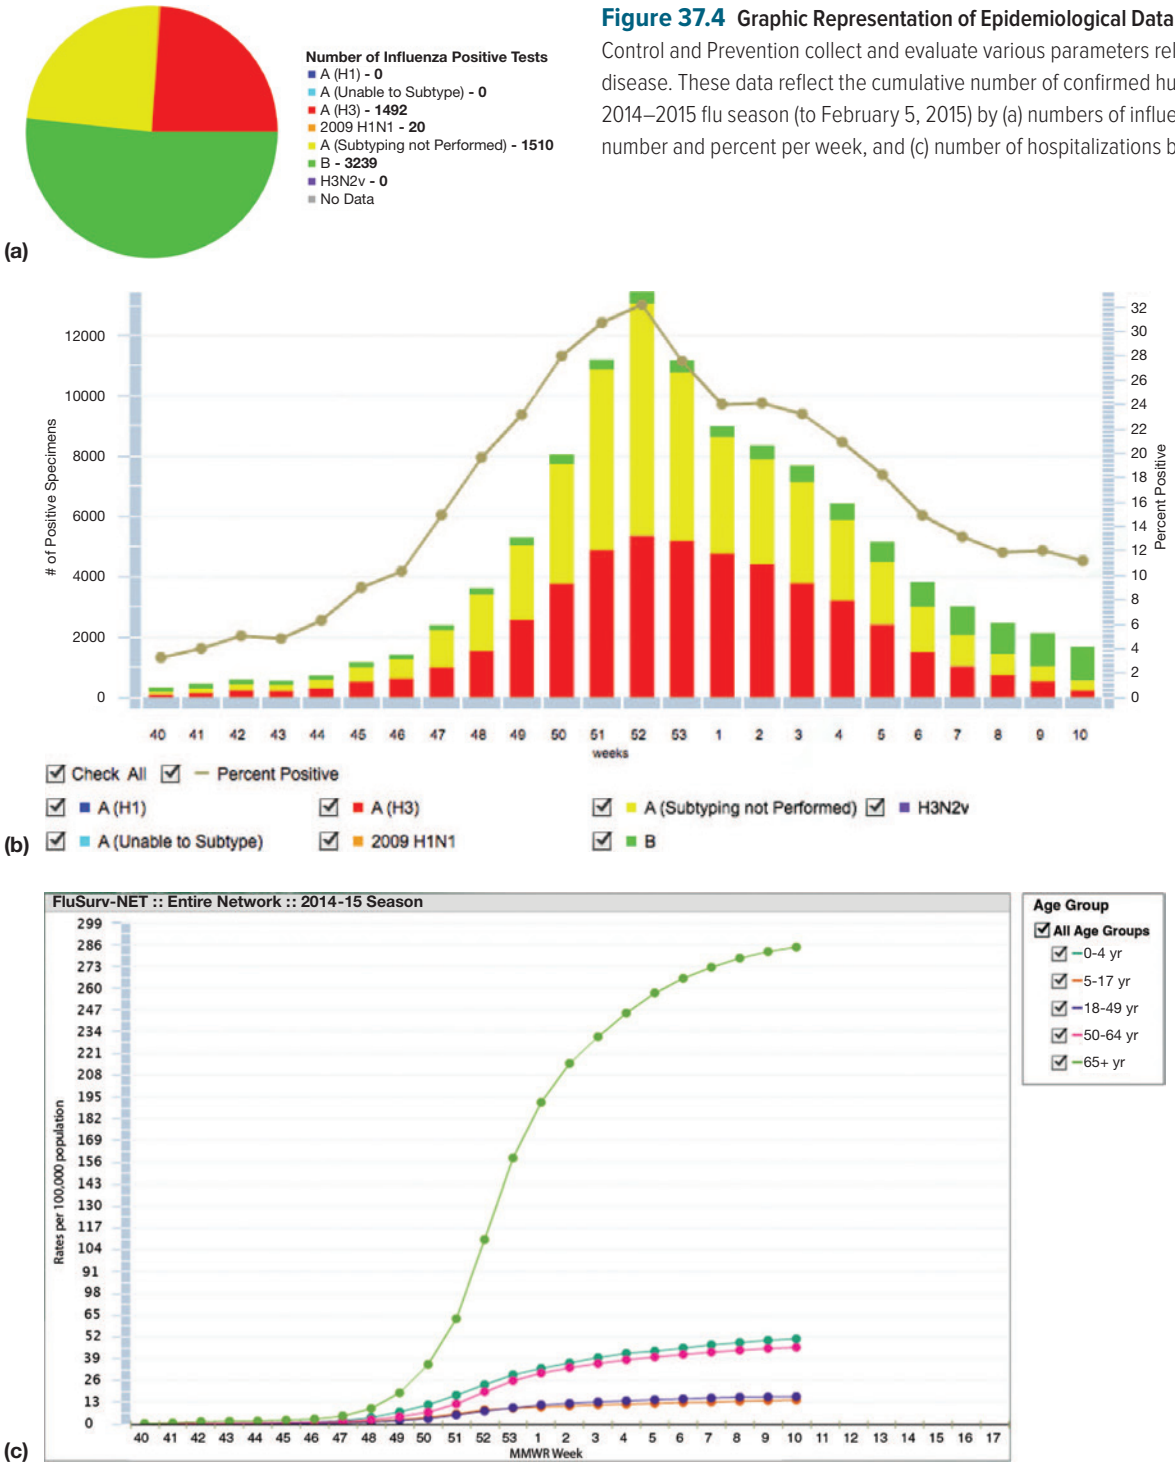

Figure 37.4 Graphic Representation of Epidemiological Data. The Centers for Disease Control and Prevention collect and evaluate various parameters related to human health and disease. These data reflect the cumulative number of confirmed human cases of influenza for the 2014–2015 flu season (to February 5, 2015) by (a) numbers of influenza subtypes, (b) strain number and percent per week, and (c) number of hospitalizations by age group and week.

surveillance data and study the course of a disease in individuals, epidemiologists and other medical professionals must be aware of the pattern of infectious diseases that reflects how the disease spreads through a population or at least to one person (*see figure 35.3*). Epidemiologists study disease patterns so they can rapidly identify new outbreaks before substantial morbidity and mortality occur.

◀◀ *Pathogenicity drives infectious disease (section 35.1)*

To understand how epidemics are propagated, consider **figure 37.5**. At time 0, all individuals in this population are susceptible to a hypothetical pathogen. The introduction of an infected individual initiates the epidemic outbreak (lower curve), which spreads to reach a peak by day 15. As individuals recover from the disease, they become immune and no longer transmit the pathogen (upper curve). The number of susceptible individuals

HISTORICAL HIGHLIGHTS

37.4 "Typhoid Mary"

In the early 1900s there were thousands of typhoid fever cases, and many people died of the disease. Most of these cases arose when people drank water contaminated with sewage or ate food handled by or prepared by individuals who were shedding the typhoid fever bacterium (*Salmonella enterica* serovar Typhi). The most famous carrier of the typhoid bacterium was Mary Mallon.

Between 1896 and 1906, Mallon worked as a cook in seven homes in New York City. Twenty-eight cases of typhoid fever occurred in these homes while she worked in them. As a result, the New York City Health Department had Mallon arrested and admitted to an isolation hospital on North Brother Island in New York's East River. Examination of her stools showed that she was shedding large numbers of typhoid bacteria, though she exhibited no external symptoms of the disease. An article published in 1908 in the *Journal of the American Medical Association* referred to Mallon as "Typhoid Mary," an epithet by which she is still known today. She was released when she pledged not to cook for others or serve food to them. Mallon changed her name and began to work as a cook again. For 5 years she managed to avoid capture while continuing to spread typhoid fever. Eventually the authorities tracked her down. She was held in custody for 23 years, until she died in 1938. As a lifetime carrier, Mary Mallon was positively linked with 10 outbreaks of typhoid fever, 53 cases, and 3 deaths.

therefore decreases. The decline in the number of susceptible individuals to the threshold density (the minimum number of individuals necessary to continue propagating the disease) coincides with the peak of the epidemic wave, and the incidence of new cases declines because the pathogen cannot propagate itself.

Herd immunity is the resistance of a population to infection and pathogen spread because of the immunity of a large percentage of the population. The larger the proportion of those immune, the smaller the probability of effective contact between infective and susceptible individuals; that is, many contacts will be immune, and thus the population will exhibit a group resistance. A susceptible member of such an immune population enjoys an immunity that is not of his or her own making but instead arises because of membership in the group.

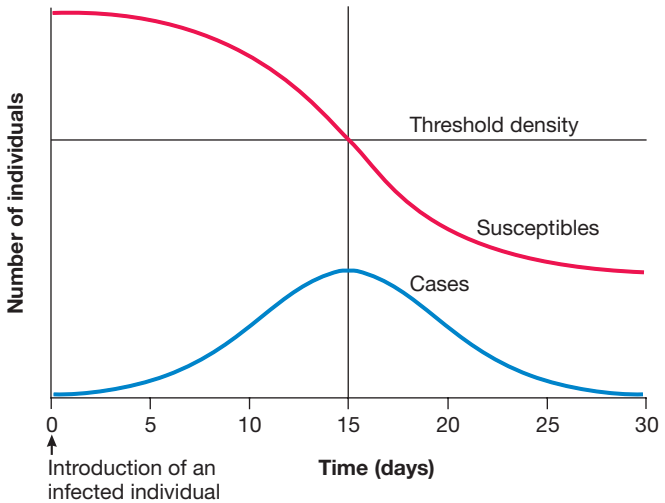

Figure 37.5 The Spread of an Imaginary Propagated Epidemic. The lower curve represents the number of cases, and the upper curve, the number of susceptible individuals. Notice the coincidence of the peak of the epidemic wave with the threshold density of susceptible people.

MICRO INQUIRY *Why does the number of susceptible individuals decline after the epidemic has reached its peak?*

At times public health officials immunize large portions of a susceptible population in an attempt to maintain a high level of herd immunity. Any increase in the number of susceptible individuals may result in an endemic disease becoming epidemic. The proportion of immune to susceptible individuals must be constantly monitored because new susceptible individuals continually enter a population through migration and birth.

Pathogens can cause endemic diseases because infected humans continually transfer them to others (e.g., sexually transmitted diseases) or because the pathogens continually reenter the human population from animal reservoirs (e.g., West Nile virus). Other pathogens continue to evolve and may produce epidemics (e.g., AIDS, influenza virus [A strain], and *Legionella* bacteria). As described in chapter 38, one way in which a pathogen changes is by **antigenic shift,** a major genetically determined change in the antigenic character of a pathogen *(see p. 830 and figure 38.3)*. Genetic changes introduced by an antigenic shift can be so extensive that the pathogen is no longer recognized by the host's immune system. For example, influenza viruses frequently change by recombination from one antigenic type to another. ⏮ *Minus-strand RNA viruses (section 27.6)* ⏭ *Influenza (flu) (section 38.1)*

Whenever antigenic shift or drift (*see p. 830*) occurs, the population of susceptible individuals increases because the immune system does not recognize the new or altered strains, respectively. Thus the need for annual flu vaccination. If the percentage of susceptible people is above the threshold density (figure 37.5), the level of protection provided by herd immunity will decrease and the morbidity rate will increase. For example, the morbidity rates

of influenza among schoolchildren may reach epidemic levels if the number of susceptible individuals rises above 30% for the whole population. One of the primary goals of public health is to ensure that the general public is sufficiently protected to withstand epidemics. This has resulted in the recommendation that at least 70% of the population be immunized against common infectious diseases, providing the herd immunity necessary for the protection of those who are not immunized. In other words, by keeping the population sufficiently immunized, the chain of infectious disease transmission is broken, limiting the reach of the disease (*see figure 35.1*). This is especially true for infectious diseases that quickly arise by antigenic shift, the 2014–2015 Influenza season's shift to an H3N2 viral strain being a great example.

37.4 Infectious Diseases and Pathogens Are Emerging and Reemerging

After reading this section, you should be able to:

- Report on recently emerged and reemerging global infectious diseases
- Organize geographic data to reveal changes in microbial drug resistance and vector spread of infection

Only a few decades ago, a grateful public trusted that science had triumphed over infectious diseases by building a fortress of health protection. Antibiotics, vaccines, and aggressive public health campaigns had yielded a string of victories over old enemies such as whooping cough, pneumonia, polio, and smallpox. In developed countries, people were lulled into believing that microbial threats were a thing of the past. Trends in the number of deaths caused by infectious diseases in the United States from 1900 through 2013 supported this conclusion (table 37.1). Sadly, despite this overall downward trend, the incidence of infectious disease resulting from emerging and reemerging microbial pathogens has claimed the lives of millions of people. The world has seen the global spread of AIDS, the resurgence of tuberculosis, the H1N1 influenza virus, and the appearance of new enemies such as Sin Nombre virus (also known as hantavirus pulmonary syndrome virus), hepatitis C and E viruses, pandemic emergence of SARS and MERS, pandemic Ebola virus, the Lyme disease spirochete, *Cryptosporidium* spp., and several strains of shiga toxin–producing *Escherichia coli*, not to mention the rise of extended-spectrum drug-resistant bacteria (**table 37.2**). In addition, during this same time period:

1. A "bird flu" virus that had never before attacked humans began to kill people in southeast Asia. ▶▶| *Influenza (flu) (section 38.1)*
2. A new variant of a fatal prion disease of the brain, Creutzfeldt-Jakob disease, was identified in the United Kingdom, transmitted by beef from animals with "mad cow disease." ▶▶| *Prion proteins transmit diseases (section 38.6)*
3. *Staphylococcus* spp. with resistance to methicillin and vancomycin, long the antibiotics of first choice and last resort, respectively, were seen for the first time. |◀◀ *Evolution in action (section 16.9)*
4. Several major multistate food-borne outbreaks occurred in the United States and Germany, including those caused by *Salmonella* spp. in peanut butter and sprouts, protists on raspberries, viruses on strawberries, and various bacteria in produce, ground beef, cold cuts, and breakfast cereal. ▶▶| *Food-borne disease outbreaks (section 41.3)*
5. A new strain of the tuberculosis bacterium that is resistant to many drugs and occurs most often in people infected with HIV arose in New York and other large cities. ▶▶| *Mycobacterium tuberculosis (section 39.1)*
6. The resurgence of vaccine-preventable, childhood diseases, most notably whooping cough, measles, and mumps, erupted in several cities and towns across the United States and Europe.

Table 37.2 National Institute of Allergy and Infectious Diseases List of Emerging and Reemerging Infectious Diseases

Pathogens Newly Recognized in the Past Two Decades	Reemerging Pathogens
BACTERIUM	BACTERIUM

Hepatitis E virus	Enterovirus A71
Human herpesvirus 8	Enterovirus D68
Human herpesvirus 6	Polio virus
Parvovirus B19	Dengue virus
MERS-CoV	
Avian influenza A (H7N9)	
Bourbon virus	
Chikungunya virus	

By the 1990s the idea that infectious diseases no longer posed a serious threat to human health was obsolete. In the twenty-first century, it is clear that humans will continually be faced with both new infectious diseases and the reemergence of older diseases once thought to be conquered. The CDC has defined these diseases as "new, reemerging, or drug-resistant infections whose incidence in humans has increased within the past three decades or whose incidence threatens to increase in the near future." Of note is the fact that while most emerging infectious diseases arise from the "Old World tropics," with today's capacity to travel anywhere in the world within 24 hours, infectious diseases can erupt just about anywhere in the world. In addition, newer data suggest that emergence and reemergence of infectious disease stem from zoonotic sources. Areas that are dense with livestock are highly correlated with disease eruption that then disseminates globally. The increased importance of emerging and reemerging infectious diseases has stimulated the establishment of a field called **systematic epidemiology,** which focuses on the ecological and social factors that influence the development of these diseases. Coupled with systematic epidemiology and remote sensing techniques, the growing field of public health informatics integrates surveillance activities, defines data elements, and disseminates information via the Internet so as to better track emerging and reemerging infectious diseases in real time.

Why are pathogens posing such a problem, despite dramatic advances in medical research, drug discovery, technology development, and sanitation? Many factors characteristic of the modern world undoubtedly favor the development and spread of these microorganisms and their diseases.

As population density increases in cities, the dynamics of microbial exposure and evolution increase in humans. Urbanization often crowds humans and increases exposure to microorganisms. Crowding leads to unsanitary conditions and hinders the effective implementation of adequate medical care, enabling more widespread transmission and propagation of pathogens. In modern societies, crowded workplaces, communal-living settings, day-care centers, large hospitals, and public transportation all facilitate microbial transmission. In this millennium, the speed and volume of international travel are major factors contributing to the global emergence of infectious diseases. The spread of a new disease often used to be limited by the travel time needed to reach a new host population. If the travel time was sufficiently long, as when a ship crossed the ocean, the infected travelers would either recover or die before reaching a new population. Because travel by air has essentially eliminated time between exposure and disease outbreak, a traveler can spread virtually any infectious disease in a matter of hours. The H1N1 influenza pandemic of 2009 is one example of how one virus-infected individual (in Mexico) can lead to a global pandemic as asymptomatic carriers transport the virus to others during normal activities (*see p. 831*).

When changes in climate or ecology occur, it should not be surprising to find changes in both beneficial and detrimental microorganisms. Global warming also affects microorganism survival. Mass migrations of refugees, workers, and displaced persons have led to a steady growth of urban centers at the expense of rural areas. Furthermore, land development and the exploration and destruction of natural habitats have increased the likelihood of human exposure to new pathogens and may select for pathogens better able to adapt to new hosts and changing environments. The introduction of pathogens to a new environment or host can alter transmission and exposure patterns, leading to sudden proliferation of disease. For example, the spread of Ebola virus disease in 2013–2015 across West Africa clearly resulted when a suspected bat pathogen jumped into the encroaching human population. Migration of infected persons along established roadways facilitated viral transmission. Here, a virus with a week-long incubation period quickly exploited cultural practices to reemerge as an insidious and deadly foe (Historical Highlights 37.3). ⏮ *Global climate change (section 28.2)*

Emerging and reemerging pathogens and their diseases are therefore the outcome of many different factors. Because the world is now so interconnected, we cannot isolate ourselves from other countries and continents. Changes in the disease status of one part of the world or the misuse of antibiotics in another part may well affect health around the planet. This was clearly understood after the arrival of an Ebola-exposed man in Dallas, Texas, in October 2014 ultimately resulted in the infection of two nurses with Ebola and a country on heightened alert anticipating its own epidemic. As Nobel laureate Joshua Lederberg so eloquently stated, "The microbe that felled one child in a distant continent yesterday can reach yours today and seed a global pandemic tomorrow."

Retrieve, Infer, Apply

2. What are some of the factors in your community that may lead to the emergence or reemergence of pathogens?
3. Describe how global climate change can lead to new human infectious diseases.

37.5 Health-Care Facilities Harbor Infectious Agents

After reading this section, you should be able to:

- Report the major causes of health-care–associated infection in the United States
- Distinguish community-acquired pathogens from health-care–associated pathogens, and explain why community-acquired pathogens are of concern to hospital personnel
- Recommend measures for preventing and controlling health-care–associated infections

Health-care–associated, sometimes called **health-care–acquired** or **nosocomial infections** (Greek *nosos*, disease, and *komeion*, to take care of), result from infections acquired by patients while in a hospital or other clinical care facility. Besides harming patients, health-care–associated infections (HAI) can affect nurses, physicians, aides, visitors, salespeople,

delivery personnel, custodians, and anyone else who has contact with the hospital. Most HAI become clinically apparent while patients are still hospitalized; however, disease onset can occur after patients have been discharged. Infections that are incubating when patients are admitted to a hospital are not health-care associated; they are community acquired. The CDC estimates that about 5% of all hospital patients (up to 2.5 million people) acquire some type of HAI. Thus health-care–associated infections represent a significant proportion of all infectious diseases acquired by humans, averaging approximately 1.87 million infections per year.

Health-care–associated diseases are usually caused by bacteria, most of which are noninvasive and part of the normal human microbiota. **Figure 37.6** summarizes the most common types of health-care–associated infections and pathogens. Interestingly, throughout most of the twentieth century, HAIs were dominated by penicillin-sensitive staphylococci. During subsequent years, the emergence of methicillin- and vancomycin-resistant *Staphylococcus aureus* (MRSA and VRSA, respectively) increased dramatically. First reported in the late 1980s, vancomycin-resistant enterococci (VRE) are now common in U.S. hospitals. Similar patterns are emerging for penicillin-resistant *Streptococcus pneumoniae*.

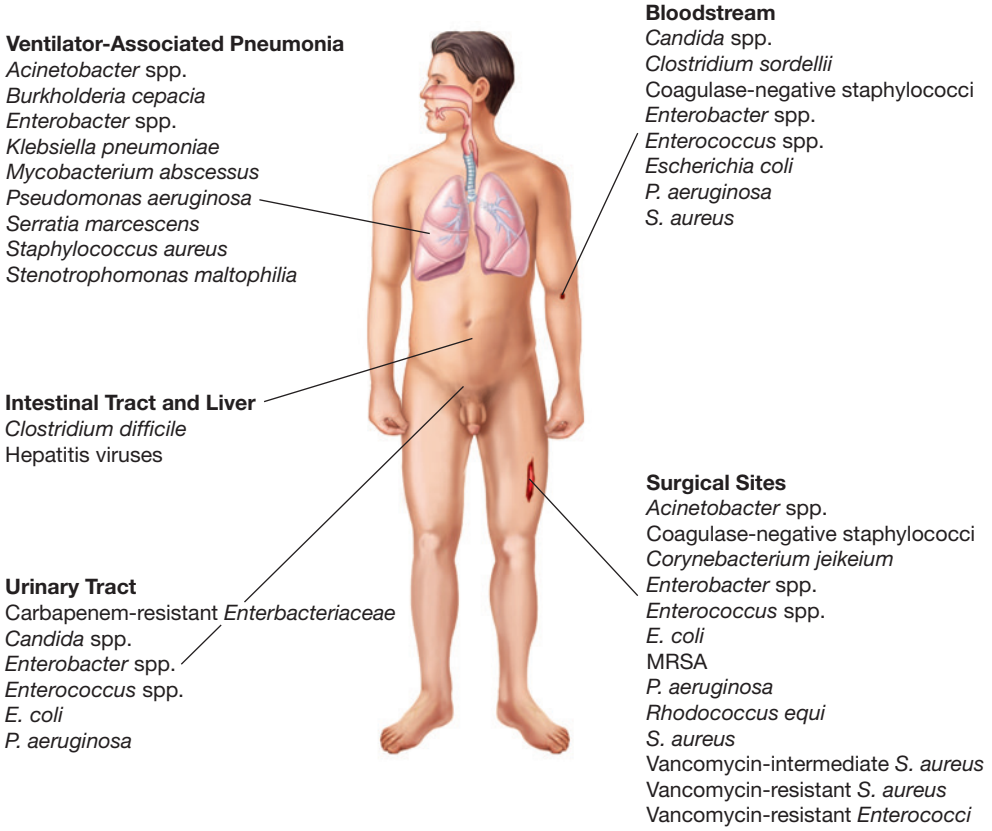

Figure 37.6 Health-Care–Associated Infections (HAIs). The most common HAIs are caused by bacteria, fungi, and viruses that are transferred to a patient from a health-care worker, contaminated instruments, plants and flowers, fresh foods, and so on.

Today the most common HAIs are (1) catheter-associated urinary tract infections, (2) surgical site infections, (3) central line (catheters)-associated bloodstream infections, and (4) ventilator-associated pneumonias (**figure 37.7**). Recently recognized health-care–associated, Gram-positive species include *Clostridium sordellii, Corynebacterium jeikeium* and *Rhodococcus equi*. The incidence of infections by the Gram-negative pathogens *Pseudomonas aeruginosa, Acinetobacter* spp., *Burkholderia cepacia,* and *Stenotrophomonas maltophilia* have also increased. Many Gram-negative bacilli are resistant to β-lactam antibiotics. These bacteria include *Klebsiella pneumoniae, E. coli,* other *Klebsiella* spp., *Proteus* spp., *Morganella* spp., *Citrobacter* spp., *Salmonella* spp., and *Serratia marcescens,* which are resistant to penicillins; many older cephalosporins; and even some newer cephalosporins such as cefotaxime, ceftriaxone, ceftazidime, and aztreonam. The β-lactamase-resistant members of **Enterobacteriaceae** are collectively referred to as extended spectrum β-lactamase (producing) *Enterobacteriaceae*. ⏮ *Evolution in action (section 16.9)*

Many potential exogenous sources of infection exist in a hospital. Animate sources are the hospital staff, other patients, and visitors. Some examples of inanimate exogenous sources are food, plants and flowers, computer keyboards, intravenous and respiratory therapy equipment, and water systems (e.g., softeners, dialysis units, and hydrotherapy equipment).

In the United States, HAIs prolong hospital stays by 4 to 14 days, result in an additional $28 billion to $33 billion per year to overall direct health-care costs, and lead to approximately 99,000 deaths annually. The enormity of this problem has led most hospitals to allocate substantial resources to developing methods and programs for the surveillance, prevention, and control of health-care–associated infections.

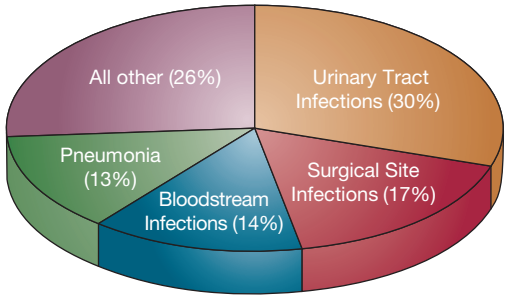

Figure 37.7 Leading Types of Health-Care–Associated Infections in the United States. These data reflect national statistics as of March 2015.

Retrieve, Infer, Apply

1. Describe a health-care–associated infection, and explain why such infections are important.
2. What two general sources are responsible for health-care–associated infections? Give some specific examples of each.
3. What can an infection control practitioner do to control health-care-associated infections?

37.6 Coordinated Efforts Are Required to Prevent and Control Epidemics

After reading this section, you should be able to:

- Assemble communicable disease linkages to create a chain of infection
- Reveal the weakest link in the chain of infection
- Advise vaccine use to prevent infectious disease transmission in a population
- Explain the role of disinfection, sanitation, and chemotherapy to control infectious disease transmission in a population

The control of an infectious disease relies heavily on a well-defined network of clinical microbiologists, nurses, physicians, epidemiologists, and infection control personnel who supply epidemiological information to a network of local, state, national, and international organizations. These individuals and organizations comprise the public health system. For example, each state has a public health laboratory that is involved in infection surveillance and control. The communicable disease section of a state laboratory includes specialized laboratory services for the examination of specimens or cultures submitted by physicians, local health departments, hospital laboratories, sanitarians, epidemiologists, and others. These groups share their findings with other health agencies in the state, the Centers for Disease Control and Prevention, and the World Health Organization.

Control Starts with Breaking the Chain of Infection

Just as the development of an infectious disease is a complex process involving many factors, so too is the design of specific epidemiological control measures. Epidemiologists must consider available resources and time constraints, adverse effects of potential control measures, and human activities that might influence the spread of the infection. Often control activities reflect compromises among alternatives. To proceed intelligently, one must identify components of the infectious disease chain that are primarily responsible for a particular epidemic. Control measures should be directed toward that part of the chain that is most susceptible to control—the weakest link in the chain (*see figure 35.1*).

There are three types of control measures. The first type is directed toward reducing or eliminating the source or reservoir of infection: social distancing and isolation of carriers, destruction of an animal reservoir of infection, treatment of water and sewage to reduce contamination (*see chapter 43*), and therapy that reduces or eliminates infectivity of the individual.

The second type of control measure is designed to break the connection between the source of the infection and susceptible individuals. Examples include general sanitation measures: chlorination of water supplies, pasteurization of milk and other beverages, supervision and inspection of food and food handlers, and destruction of vectors (e.g., spraying to eliminate mosquitoes).

The third type of control measure reduces the number of susceptible individuals and raises the general level of herd immunity by immunization. Examples include passive immunization (*see figure 34.3*) to give temporary immunity following exposure to a pathogen or when a disease threatens to become an epidemic, active immunization to protect the host population, and prophylactic treatment to prevent infection (e.g., use of chloroquine when traveling to malaria-endemic countries). Antimicrobial chemotherapy is discussed in chapter 9. We discuss the use of vaccines and the subsequent immunization in the next section.

Vaccines Immunize Susceptible Populations

A **vaccine** (Latin *vacca,* cow) is a preparation of one or more microbial antigens that induces protective immunity in the host. **Immunization** occurs when a vaccine has been successfully delivered. The specific goal of vaccination is to induce antibodies and activated T cells to protect a host from future infection. Many epidemics have been stayed by mass prophylactic immunization (**table 37.3**). Vaccines have eradicated smallpox, pushed polio to the brink of extinction, and spared countless individuals from hepatitis A and B, influenza, measles, rotavirus disease, tetanus, typhus, and other dangerous diseases. **Vaccinomics,** the application of genomics and bioinformatics to vaccine development, is bringing a fresh approach to the Herculean problem of making vaccines against various microorganisms and helminths.

▶▶| *Vaccines (section 42.1)*

To promote a more efficient immune response, antigens in vaccines can be mixed with an **adjuvant** (Latin *adjuvans,* aiding), which enhances the rate and degree of immunization. Adjuvants can be any nontoxic material that prolongs antigen interaction with immune cells, assists in processing of antigens by antigen-presenting cell (APC), or otherwise nonspecifically stimulates the immune response to the antigen. Several types of adjuvants can be used, including oil in water emulsions (Freund's incomplete adjuvant), aluminum hydroxide salts (alum), beeswax, and various combinations of bacteria (live or killed). In most cases, the adjuvant materials trap the antigen, thereby promoting a sustained release as APCs digest and degrade the preparation. In other cases, the adjuvant activates APCs so that antigen recognition, processing, and presentation are more efficient.

Table 37.3 Examples of Vaccines to Prevent Viral and Bacterial Diseases in Humans

Disease	Vaccine	Booster*	Recommendation
Viral Diseases			
Chickenpox	Attenuated Oka strain	None	Children 12–18 months: older children who have not had chickenpox
Hepatitis A	Inactivated virus	6–12 months	International travelers
Hepatitis B	Viral antigen	1–4 months 6–18 months	High-risk medical personnel: children, birth to 18 months and 11–12 years of age
Human papillomavirus infections	Recombinant protein subunits	2–3 months 6 months	Girls and boys 11–12 years of age
Influenza A/B	Inactivated virus or live attenuated	Yearly	All persons
Measles, Mumps, Rubella	Attenuated viruses (combination MMR vaccine)	None	First dose 12–15 months, 2nd dose 4–6 years
Poliomyelitis	Attenuated (oral poliomyelitis vaccine, OPV) or inactivated virus (inactivated polio vaccine, IPV)	Adults as needed	First dose at 2 months, 2nd at 4 months, 3rd at 16–18 months, 4th at 4–6 years
Rabies	Inactivated virus	None	For individuals in contact with wildlife, animal control personnel, veterinarians
Respiratory disease	Live attenuated adenovirus	None	Military personnel
Smallpox	Live attenuated vaccinia virus	None	Laboratory, health-care, and military personnel
Yellow fever	Attenuated virus	10 years	Military personnel and individuals traveling to endemic areas
Bacterial Diseases			
Anthrax	Extracellular components of unencapsulated *Bacillus anthracis*	None	Agricultural workers, veterinary, and military personnel
Cholera	Fraction of *Vibrio cholerae*	6 months	Individuals in endemic areas, travelers
Diphtheria, Pertussis, Tetanus	Diphtheria and tetanus toxoids, and acellular *Bordetella pertussis* vaccine (DTap) or tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap)	10 years	Children from 2–3 months old to 12 years, and adults; children 10–18 years, at least 5 years after DPT series, should receive Tdap
Haemophilus influenzae type b	Polysaccharide-protein conjugate (HbCV) or bacterial polysaccharide (HbPV)	None	First dose at 2 months, 2nd at 4 months, 3rd at 6 months, 4th at 12–15 months
Meningococcal infections	*Neisseria meningitidis* polysaccharides of serotypes A/C/Y/W-135	None	Military; high-risk individuals; college students living in dormitories; elderly in nursing homes
Plague	Fraction of *Yersinia pestis*	Yearly	Individuals in contact with rodents in endemic areas
Pneumococcal pneumonia	Purified *S. pneumoniae* polysaccharide of 23 pneumococcal types or pneumococcal conjugate of 13 strains	None	Adults over 50 with chronic disease
Q fever	Killed *Coxiella burnetii*	None	Workers in slaughterhouses and meat-processing plants
Tuberculosis	Attenuated *Mycobacterium bovis* (BCG vaccine)	3–4 years	Individuals exposed to TB for prolonged periods of time; used in some countries, not licensed in the U.S.
Typhoid fever	*Salmonella enterica* Typhi Ty21a (live attenuated or polysaccharide)	None	Residents of and travelers to areas of endemic disease
Typhus fever	Killed *Rickettsia prowazekii*	Yearly	Scientists and medical personnel in areas where typhus is endemic

* Subsequent immunization dose(s) after the initial immunization.

HISTORICAL HIGHLIGHTS

37.5 The First Immunizations

Since the time of the ancient Greeks, it has been recognized that people who have recovered from plague, smallpox, yellow fever, and various other infectious diseases rarely contract the diseases again. The first scientific attempts at artificial immunizations were made in the late eighteenth century by Edward Jenner (1749–1823), who was a country doctor from Berkeley, Gloucestershire, England. Jenner investigated the basis for the widespread belief of the English peasants that anyone who had vaccinia (cowpox) never contracted smallpox. Smallpox was often fatal—10 to 40% of the victims died—and those who recovered had disfiguring pockmarks. Yet most English milkmaids, who were readily infected with cowpox, had clear skin because cowpox was a relatively mild infection that left no scars.

On May 14, 1796, Jenner extracted the contents of a pustule from the arm of a cowpox-infected milkmaid, Sarah Nelmes, and injected it into the arm of eight-year-old James Phipps. As Jenner expected, immunization with the cowpox virus caused only mild symptoms in the boy. When he subsequently inoculated the boy with smallpox virus (an act now considered completely unethical), the boy showed no symptoms of the disease. Jenner then inoculated large numbers of his patients with cowpox pus, as did other physicians in England and on the European continent (**box figure**). By 1800 the practice known as variolation had begun in America, and by 1805 Napoleon Bonaparte had ordered all French soldiers to be vaccinated.

Further work on immunization was carried out by Louis Pasteur (1822–1895). Pasteur discovered that if cultures of chicken cholera bacteria were allowed to age for 2 or 3 months, the bacteria produced only a mild attack of cholera when inoculated into chickens. Somehow the old cultures had become less pathogenic (attenuated) for the chickens. He then found that fresh cultures of the bacteria failed to produce cholera in chickens that had been previously inoculated with old, attenuated cultures. To honor Jenner's work with cowpox, Pasteur gave the name *vaccine* to any preparation of a weakened pathogen that was used (as was Jenner's "vaccine virus") to immunize against infectious disease.

Nineteenth-Century Physicians Performing Vaccinations on Children.

The modern era of vaccines and immunization began in 1798 with Edward Jenner's use of cowpox as a vaccine against smallpox (**Historical Highlights 37.5**) and in 1881 with Louis Pasteur's rabies vaccine. Vaccines for other diseases did not emerge until later in the nineteenth century when, largely through a process of trial and error, methods for inactivating and attenuating microorganisms were improved and vaccines were produced. Vaccines were eventually developed against most of the epidemic diseases that plagued Western Europe and North America (e.g., diphtheria, measles, mumps, pertussis, German measles, and polio). Indeed, by the late twentieth century, it seemed that the combination of vaccines and antibiotics had solved the problem of microbial infections in developed nations. Such optimism was cut short by the emergence of new and previously unrecognized pathogens and antibiotic resistance among existing pathogens. Nevertheless, vaccination is still the most cost-effective weapon for preventing microbial disease (see table 37.2).

Vaccination of most children should begin at birth, initiating protection against the blood-borne hepatitis B virus. Other vaccines should be given at about age two months; a complete schedule of childhood vaccines is available on the Centers for Disease Control and Prevention (CDC) website. Before that age, children are protected by passive natural immunity from maternal antibodies. Vaccination of teens and most adults depends on their risk for exposure to infectious disease. Individuals living in close quarters (e.g., college students in residence halls, military personnel) and those living with infants, the elderly, and individuals with reduced immunity (e.g., those with chronic and metabolic diseases) should be vaccinated to prevent bacterial meningitis from *Neisseria meningitidis*. Additionally, they should confirm that they have received childhood vaccinations and, where necessary, be revaccinated with newer vaccine formulations. Adults (over 50 years) should also be vaccinated/revaccinated for influenza, measles/mumps/rubella, streptococcal pneumonia, whooping cough, and shingles, as determined by a physician.

Additional or booster vaccines are suggested for many. For instance, international travelers may need to be immunized against cholera, hepatitis A, plague, polio, typhoid, typhus, and yellow

Table 37.4 A Comparison of Vaccine Types[1]

Major Characteristic	Whole Cell Vaccines		Acellular or Subunit Vaccines	Recombinant or DNA Vaccines	
	Live, Attenuated	Inactivated		Recombinant	DNA
Typical Immunogen	Virus	Bacteria	1–20 antigens from microorganism	Virus or bacterial vector	Antigen(s) encoded by DNA
T Response	Strong	Weak	Very strong	Very strong	Very strong
B cell Response	Strong	Strong	Very strong	Very strong	Very strong
Stability	Decreased without refrigeration	Longer shelf life, freeze-dried	Longer shelf life, freeze-dried	Longer shelf life, freeze-dried	
Potential problems	Reversion to pathogen possible, not given to immuno- compromised	Weaker response, requires booster doses	Identification of antigens is costly and research intensive	Identification of genes is costly and research intensive	

[1]Source: http://www.vaccines.gov/more_info/types/

fever, depending on the public health policies of the country visited. Immunization is the most inexpensive method to prevent some infectious diseases; however, good hand hygiene and food/water cautions are still advised as some countries lack public health basics such as clean water. Veterinarians, forest rangers, and others whose jobs involve contact with animals may be vaccinated against rabies, plague, and anthrax. Health-care workers are typically immunized against hepatitis B virus. Vaccine recommendations for U.S. citizens are updated annually; travelers, veterinarians, and health-care providers should consult the CDC website, which lists vaccine and booster recommendations for all countries outside the United States, as well as recommendations for at-risk individuals. The role of immunization as a protective measure cannot be overstated: immunizations save lives.

Whole-Cell Vaccines

Many of the current vaccines used for humans that are effective against viral and bacterial diseases consist of whole microorganisms, termed **whole-cell vaccines.** These are either inactivated (killed) or attenuated (live but avirulent). The major characteristics of these vaccines are compared in **table 37.4**. **Inactivated vaccines** are effective, but they are less immunogenic, so they often require several boosters and normally do not adequately stimulate cell-mediated immunity or secretory IgA production. In contrast, **attenuated vaccines** usually are given in a single dose and stimulate both humoral and cell-mediated immunity. ⏮ *Innate host resistance (chapter 33); Adaptive immunity (chapter 34)*

Even though whole-cell vaccines are considered the "gold standard" of vaccines, they can be problematic. For example, whole-organism vaccines fail to shield against some diseases. Attenuated vaccines can also cause full-blown illness in an individual whose immune system is compromised (e.g., AIDS patients, cancer patients undergoing chemotherapy, the elderly). These same individuals may also contract the disease from healthy people who have been vaccinated recently. Moreover, attenuated viruses can at times mutate in ways that restore virulence, as happens when the live polio vaccine given in developing nations recombines with Coxsackie virus, leading to vaccine-derived polio. Children in the United States and other developed nations receive the killed polio vaccine, which is incapable of such genetic effects.

Acellular or Subunit Vaccines

A few of the common risks associated with whole-cell vaccines can be avoided by using only specific, purified macromolecules derived from pathogenic microorganisms. There are three general forms of **subunit vaccines:** (1) capsular polysaccharides, (2) recombinant surface antigens, and (3) inactivated exotoxins called **toxoids.** The purified microbial subunits or their secreted products can be prepared as nontoxic antigens to be used in the formulation of vaccines (**table 37.5**).

Recombinant-Vector and DNA Vaccines

Genes isolated from a pathogen that encode major antigens can be inserted into nonvirulent viruses or bacteria. Such recombinant microorganisms serve as vectors, replicating within the host and expressing the gene product of the pathogen-encoded antigenic proteins. The antigens elicit humoral immunity (i.e., antibody production) when they escape from the vector, and they also elicit cellular immunity when they are broken down and properly displayed on the cell surface (just as occurs when host cells harbor an active pathogen). Several microorganisms, such as rotavirus and attenuated *Salmonella enterica,* have been used in the production of these **recombinant-vector vaccines.**

On the other hand, **DNA vaccines** introduce fragments of pathogen DNA directly into the host cell. When injected into muscle cells, the DNA is taken into the nucleus and the pathogen's

Table 37.5 Subunit Vaccines Currently Available for Human Use

Microorganism or Toxin	Vaccine Subunit
Capsular polysaccharide	
Haemophilus influenzae type b	Polysaccharide-protein conjugate (HbCV) or bacterial polysaccharide (HbPV)
Neisseria meningitidis	Polysaccharides of serotypes A/C/Y/W-135
Streptococcus pneumoniae	23 distinct capsular polysaccharides
Surface antigen	
Hepatitis B virus	Recombinant surface antigen (HbsAg)
Human papillomavirus	Recombinant protein subunits
Toxoids	
Corynebacterium diphtheriae toxin	Inactivated exotoxin
Clostridium tetani toxin	Inactivated exotoxin

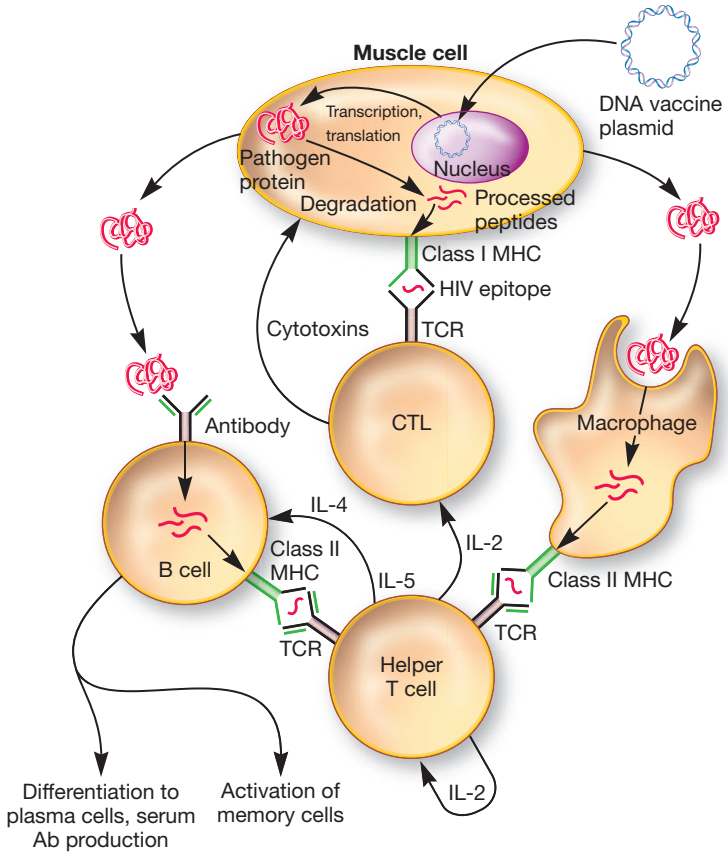

Figure 37.8 DNA Vaccine. DNA coding for a pathogen's proteins is inserted into host cells and expressed. The foreign proteins elicit both cell-mediated and antibody (Ab) responses.

DNA is transiently expressed, generating foreign proteins to which the host's immune system responds (**figure 37.8**). DNA vaccines are very stable; refrigeration is often unnecessary. At present, human trials are underway with several different DNA vaccines against malaria, AIDS, influenza, hepatitis B, and herpes. *Constructing Vaccines*

37.7 Bioterrorism Readiness Is an integral Component of Public Health Microbiology

After reading this section, you should be able to:

- Discuss the readiness efforts necessary to be prepared for a bioterrorism attack
- Prioritize microorganisms based on public health threat
- Construct tables of prevention and control information relative to an infectious agent
- Alert appropriate authorities in response to suspected acts of bioterrorism

Bioterrorism is defined as "the intentional or threatened use of viruses, bacteria, fungi, or toxins from living organisms to produce death or disease in humans, animals, and plants." The use of biological agents to effect personal or political outcomes is not new, and the modern use of biological agents is a reality (**Historical Highlights 37.6**). The most notable intentional uses of biological agents for criminal or terror intent are (1) the use of *Salmonella enterica* serovar Typhimurium in 10 restaurant salad bars (by the Rajneeshee religious cult in The Dalles, Oregon, 1984); (2) the intentional release of *Shigella dysenteriae* in a hospital laboratory break room (perpetrator[s] unknown; Texas, 1996); and (3) the use of *Bacillus anthracis* spores delivered through the U.S. postal system (perpetrator[s] unknown, although the FBI named Bruce Ivins, now deceased, as the likely suspect; five eastern U.S. states, 2001). The *S. enterica*–contaminated salads resulted in 751 documented cases and 45 hospitalizations due to salmonellosis. The *S. dysenteriae* release resulted in eight confirmed cases and four hospitalizations for shigellosis. The *B. anthracis* spores infected 22 people (11 cases of inhalation anthrax and 11 cases of cutaneous anthrax) and caused five deaths. The list of biological agents that could pose the greatest public health risk in the event of a bioterrorism attack is relatively short and includes viruses, bacteria, and toxins that, if acquired and properly disseminated, could become a difficult public health challenge in terms of limiting the numbers of casualties and controlling panic (**table 37.6**).

Among weapons of mass destruction, biological weapons can be as destructive as chemical weapons, including nerve gas. In certain circumstances, biological weapons can be as devastating as a nuclear explosion: a few kilograms of anthrax spores could kill as many people as a Hiroshima-size nuclear bomb. Biological agents are likely to be chosen as a means of localized attack (biocrime) or mass casualty (bioterrorism) for several reasons. They are mostly invisible, odorless, tasteless, and difficult

HISTORICAL HIGHLIGHTS

37.6 1346—The First Recorded Biological Warfare Attack

The Black Death, which swept through Europe, Asia, and North Africa in the mid-fourteenth century, was probably the greatest public health disaster in recorded history. Europe, for example, lost an estimated quarter to a third of its population. This is not only of great historical interest but also relevant to current efforts to evaluate the threat of military or terrorist use of biological weapons. ▶▶| *Arthropods can transmit bacterial diseases (section 39.2)*

Some believe that evidence for the origin of the Black Death in Europe is found in a memoir by Gabriele de' Mussi of Genoa. According to this fourteenth-century memoir, the Black Death reached Europe from the Crimea (a region of the Ukraine) in 1346 as a result of a biological warfare attack. The Mongol army hurled plague-infected cadavers into the besieged Crimean city of Caffa (now Feodosija, Ukraine), thereby transmitting the disease to the inhabitants; fleeing survivors then spread the plague from Caffa to the Mediterranean Basin. Such transmission was especially likely at Caffa, where cadavers would have been badly mangled by being hurled and the defenders probably often had cut or abraded hands from coping with the bombardment. Because many cadavers were involved, the opportunity for disease transmission was greatly increased. Disposal of victims' bodies in a major disease outbreak is always a problem, and the Mongol army used their hurling machines as a solution to limited mortuary facilities. It is possible that thousands of cadavers were disposed of this way; de' Mussi's description of "mountains of dead" might have been quite literally true. Indeed, Caffa could be the site of the most spectacular incident of biological warfare ever, with the Black Death as its disastrous consequence. It is a powerful reminder of the horrific consequences that can result when disease is successfully used as a weapon.

to detect. Furthermore, perpetrators may escape undetected as it may take hours to days before signs and symptoms of their use become evident. Additionally, the general public is not likely to be protected immunologically against agents that might be used in bioterrorism. Ultimately the use of biological agents in terrorism results in fear, panic, and chaos.

In 1998 the U.S. government launched the first national effort to create a biological weapons defense. The initiatives included (1) the first-ever procurement of specialized vaccines and medicines for a national civilian protection stockpile; (2) invigoration of research and development in the science of biodefense; (3) investment of more time and money in genome sequencing, new vaccine research, and new therapeutic research; (4) development of improved detection and diagnostic systems; and (5) preparation of clinical microbiologists and clinical microbiology laboratories as members of first-responder teams to respond in a timely manner to acts of bioterrorism. In 2002 the Congress enacted the Public Health Security and Bioterrorism Preparedness and Response Act, which identified "select" agents whose use is now tightly regulated. A final rule that governs the possession,

Table 37.6 Some CDC-Defined Biological Select Agents and Toxins (BSATs)

Bacteria	Virus	Toxin
*Bacillus anthracis**	Crimean-Congo hemorrhagic fever virus	Abrin
Bacillus anthracis Pasteur	Eastern Equine Encephalitis virus	Botulinum toxins*
Brucella abortus	Ebola virus*	Conotoxins
Brucella melitensis	Lassa fever virus	Ricin
Brucella suis	Marburg virus*	Saxitoxin
*Burkholderia mallei**	Monkeypox virus	Staphylococcal enterotoxins A, B, C, D, & E
*Burkholderia pseudomallei**	Nipah virus	T-2 toxin
Coxiella burnetii	Reconstructed 1918 Influenza virus Rift Valley fever virus	Tetrodotoxin
*Clostridium botulinum**	SARS-associated coronavirus	
*Francisella tularensis**	Tick-borne encephalitis viruses	
Rickettsia prowazekii	Variola major virus*	
*Yersinia pestis**	Variola minor virus*	
	Venezuelan equine encephalitis virus	

* Tier 1 agents. The documented risk of causing a high-consequence event is greater for Tier 1 BSATs than for the other BSATs.

Table 37.7 Criteria for Presumptive Identification of Six Bacterial Select Agents

Pathogen	Gram Morphology	Colonial Morphology	Biochemical Results
Bacillus anthracis	Gram-positive, endospore-forming rod	Gray, flat, "Medusa head" irregularity, nonhemolytic on sheep's blood agar	Catalase positive, oxidase positive, urea negative, Voges-Proskauer (VP) positive, phenylalanine (Phe) deaminase negative, NO_3^- to NO_2^- positive
Brucella suis	Gram-negative rod (tiny)	Nonpigmented, convex-raised, pinpoint after 48 hr, nonhemolytic	Catalase positive, oxidase variable, urea positive, VP negative
Burkholderia mallei	Gram-negative, straight or slightly curved coccobacilli, bundles	Gray, smooth, translucent after 48 hr, nonhemolytic	Catalase positive, oxidase variable, indole negative, arginine dihydrolase positive, NO_3^- to NO_2^- positive
Clostridium botulinum	Gram-positive, endospore-forming rod	Creamy, irregular, rough, broad, nonhemolytic	Catalase negative, urea negative, gelatinase positive, indole negative, VP negative, Phe deaminase negative, NO_3^- to NO_2^- negative
Francisella tularensis	Gram-negative rod (tiny)	Gray-white, shiny, convex, pinpoint after 72 hr, nonhemolytic	Catalase positive (weak), oxidase negative, β-lactamase positive, urea negative
Yersinia pestis	Gram-negative rod (bipolar staining)	Gray-white, "fried-egg" irregularity, nonhemolytic, grows faster and larger at 28°C	Catalase positive, oxidase negative, urea negative, indole negative, VP negative, Phe deaminase negative

use, and transport of select agents was issued in 2005. The select agent definition, however, was revised in 2012 to identify a "Tier 1" subset that (1) could produce a mass casualty event or economic devastation, (2) were highly communicable, (3) had a low infectious dose, and (4) might be readily weaponized (table 37.6).

In 2003 Congress established the Department of Homeland Security to coordinate the defense of the United States against terrorist attacks. As one of many duties, the secretary of Homeland Security is responsible for maintaining the National Incident Management System to monitor large-scale hazardous events. Bioterrorism and other public health incidents are managed within this system. The Department of Health and Human Services will respond and deploy assets as needed within the areas of its statutory responsibility (e.g., the Public Health Service Act and the Federal Food, Drug, and Cosmetic Act), while appraising the secretary of Homeland Security of the nature of the response. The secretary of Health and Human Services directs the CDC to effect the necessary integration of public health activities.

The events of September and October 2001 in the United States changed the world. Global efforts to prevent terrorism, especially using biological agents, are evolving from cautious planning to proactive preparedness. In the United States, the CDC has partnered with academic institutions across the country to educate, train, and drill public health employees, first responders, and numerous environmental and health-care providers. Centers for Public Health Preparedness were established to bolster the overall response capability to bioterrorism. Another CDC-managed program that began in 1999, the Laboratory Response Network (LRN), serves to ensure an effective laboratory response to bioterrorism by helping to improve the nation's public health laboratory infrastructure through its partnership with the FBI and the Association of Public Health Laboratories (APHL). The LRN maintains an integrated network that links state and local public health, federal, military, and international laboratories so that a rapid and coordinated response to bioterrorism or other public health emergencies (including veterinary, agriculture, military, and water- and food-related) can occur.

In the absence of overt terrorist threats and without the ability to rapidly detect bioterrorism agents, it is likely that a bioterrorism act will be defined by a sudden spike in an unusual (nonendemic) disease reported to the public health system. Also, suddenly increased numbers of zoonoses, diseased animals, or vehicle-borne illnesses may indicate bioterrorism. Important guidelines and standardized protocols prepared for all sentinel (local hospital, contract, clinic, etc.) laboratories to assist in the management of clinical specimens containing select agents have been established by the American Society for Microbiology in coordination with the CDC and the APHL. A summary of the rule-out tests for six Tier 1 bacterial agents is presented in **table 37.7**. The diseases and microbiology associated with specific select agents are discussed in chapters 38–40.

Retrieve, Infer, Apply

1. In what three general ways can epidemics be controlled? Give one or two specific examples of each type of control measure.
2. Name some of the microorganisms that can be used to commit biocrimes. From this list, which pose the greatest risk for causing large numbers of casualties?
3. Why are biological weapons more destructive than chemical weapons?
4. What is the Public Health Security and Bioterrorism Preparedness and Response Act designed to do?

Key Concepts

37.1 Epidemiology Is an Evidence-based Science

- Epidemiology is the science that evaluates the determinants, occurrence, distribution, and control of health and disease in a defined population.
- Specific epidemiological terminology is used to communicate disease incidence in a given population. Frequently used terms include sporadic disease, endemic disease, hyperendemic disease, epidemic, index case, outbreak, and pandemic.

37.2 Epidemiology Is Rooted in Well-Tested Methods

- Public health surveillance is necessary for recognizing a specific infectious disease within a given population. This consists of gathering data on the occurrence of the disease, collating and analyzing the data, summarizing the findings, and applying the information to control measures.
- Population-based and case-based surveillance data are used to track infections within a population.
- Remote sensing and geographic information systems are used to digitally gather data from natural environments.
- Statistics is an important tool used in the study of modern epidemiology.
- Epidemiological data can be obtained from such factors as morbidity, prevalence, and mortality rates.

37.3 Infectious Disease Is Revealed Through Patterns Within a Population

- A common-source epidemic is characterized by a sharp rise to a peak and then a rapid but not as pronounced decline in the number of individuals infected (**figure 37.3**). A propagated epidemic is characterized by a relatively slow and prolonged rise and then a gradual decline in the number of individuals infected.
- Herd immunity is the resistance of a population to infection and pathogen spread because of the immunity of a large percentage of the individuals within the population.

37.4 Infectious Diseases and Pathogens Are Emerging and Reemerging

- Humans will continually be faced with both new infectious diseases and the reemergence of older diseases once thought to be conquered.
- The CDC has defined these diseases as "new, reemerging, or drug-resistant infections whose incidence in humans has increased within the past two decades or whose incidence threatens to increase in the near future."
- Many factors characteristic of the modern world undoubtedly favor the development and spread of these microorganisms and their diseases (such as transportation, commerce, housing development).

37.5 Health-Care Facilities Harbor Infectious Agents

- Health-care–associated (nosocomial) infections are infections acquired within a hospital or other clinical care facility and are produced by a pathogen acquired during a patient's stay. These infections come from either endogenous or exogenous sources (**figures 37.6** and **37.7**).
- Health-care-associated diseases are usually caused by bacteria, most of which are noninvasive and part of the normal human microbiota.

37.6 Coordinated Efforts Are Required to Prevent and Control Epidemics

- The public health system consists of individuals and organizations that function in the control of infectious diseases and epidemics.
- Vaccination is one of the most cost-effective weapons for preventing microbial disease, and vaccines constitute one of the greatest achievements of modern medicine.
- Many of the current vaccines in use for humans (**table 37.3**) consist of whole organisms that are either inactivated (killed) or attenuated (live but avirulent).
- Some of the risks associated with whole-cell vaccines can be avoided by using only specific purified macromolecules derived from pathogenic microorganisms. Currently there are three general forms of subunit or acellular vaccines: capsular polysaccharides, recombinant surface antigens, and inactivated exotoxins (toxoids) (**table 37.5**).
- A number of microorganisms have been used for recombinant-vector vaccines. The attenuated microorganism serves as a vector, replicating within the host and expressing the gene product of the pathogen-encoded antigenic proteins. The proteins can elicit humoral immunity when the proteins escape from the cells and cellular immunity when they are broken down and properly displayed on the cell surface.
- DNA vaccines elicit protective immunity against a pathogen by activating both branches of the immune system: humoral and cellular (**figure 37.8**).
- Epidemiological control measures can be directed toward reducing or eliminating infection sources, breaking the connection between sources and susceptible individuals, or isolating the susceptible individuals and raising the general level of herd immunity by immunization.

37.7 Bioterrorism Readiness Is an integral Component of Public Health Microbiology

- Among weapons of mass destruction, biological weapons can be more destructive than chemical weapons. The list of biological agents that could pose the greatest public health risk in the event of a bioterrorism attack is short and includes viruses, bacteria, parasites, and toxins (**table 37.6**).
- Specific laboratory tests define the process for hospital and other sentinel labs to rule out a select agent.

Compare, Hypothesize, Invent

1. Why is international cooperation a necessity in the field of epidemiology? What specific problems can you envision if there were no such cooperation?
2. What common sources of infectious disease are found in your community? How can the etiologic agents of such infectious diseases spread from their source or reservoir to members of your community?
3. How could you prove that an epidemic of a given infectious disease was occurring?
4. How can changes in herd immunity contribute to an outbreak of a disease on an island?
5. College dormitories are notorious for outbreaks of flu and other infectious diseases. These are particularly prevalent during final exam weeks. Using your knowledge of the immune response and epidemiology, suggest practices that could be adopted to minimize the risks at such a critical time.
6. Why does an inactivated vaccine induce only a humoral response, whereas an attenuated vaccine induces both humoral and cell-mediated responses?
7. Why is a DNA vaccine delivered intramuscularly and not by intravenous or oral routes?
8. Community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA) was an unexpected development. In the United States, CA-MRSA isolates are classified as USA300. It was unknown whether USA300 strains are clonal in origin (i.e., arising from a single, common parental strain), represent convergent evolution of multiple strains, or are some combination of the two. To differentiate between these possibilities, the entire genome sequence of 10 USA300 isolates from eight states was compared. There were very few single nucleotide polymorphisms in eight of the 10 isolates (*see figure 19.5 and related discussion*). Furthermore, the same eight were extremely virulent in a mouse model and produced the same exotoxins, whereas the other two were only modestly virulent and produced fewer exotoxins.

   Why do you think it was important to determine if USA300 was clonal in origin or if the strains arose from multiple parental strains? What would be the public health implication of each origin?

   Based on this evidence, what do you conclude about the origin of these 10 USA300 strains? Explain your answer.

Human Diseases Caused by Viruses and Prions

Mosquitoes, like this Anopheles female, transmit a number of viruses to humans.

Honest . . . It Was the Mosquito!

Exactly what happened when they returned from Bandafassi, Senegal, remains a mystery. All they knew for sure is that they had been bitten, a lot, while in Africa. Colorado State University researcher Brian Foy and his graduate assistant Kevin Kobylinski study malaria. They went to Senegal to trap mosquitoes. About 5 days after they returned to Colorado, both men became sick. They had headaches, rash, fatigue, and painfully swollen joints. Foy also had painful urination and bloody semen. Several days later, Foy's wife, Joy, began to complain of many of the same symptoms, along with chills, headache, malaise, and sensitivity to light. Their four children, however, had no signs or symptoms of illness.

About a week later, the symptoms abated. Intrigued by the pattern, Foy was sure he and Kobylinski had been infected in Senegal with one of the many mosquito-borne diseases transmitted through one or more of the bites. But Joy was not bitten; she was nowhere near Senegal. Foy and Kobylinski sought answers, but none were forthcoming. Laboratory tests on blood samples of the husband, wife, and student were finally performed at the U.S. Centers for Disease Control and Prevention's Division of Vector Borne Diseases, which happens to be in nearby Fort Collins, Colorado. As suspected, Foy and Kobylinski tested positive for dengue fever, a mosquito-borne viral disease. Dengue could explain most of the symptoms. But Joy's blood test was negative for dengue.

Kobylinski went back to Senegal a year later where he told his story to a colleague. Without hesitation, the scientist declared that the Americans had been infected with Zika virus. Zika is found primarily in Africa and usually misdiagnosed as dengue. Little is known about Zika other than it is a mosquito-borne flavivirus. Kobylinski relayed the information to Foy, who had the blood samples tested for Zika. Sure enough, all three blood samples had antibodies to Zika.

So how did Joy become infected? A little research revealed that Zika virus infects 50% more women than men. This hinted at sexual transmission. The species of mosquito and the Zika life cycle ruled out the possibility that Joy was infected by a mosquito in the United States There was no direct evidence of sexual transmission—except, coded in his case report, Foy noted having had vaginal sexual intercourse with his wife upon his return from Senegal and before he had symptoms. Excited by their discovery, the three published a scientific paper describing sexual transmission of Zika virus for the first time. The morals to this story include: Mosquitoes can harbor a number of human pathogens, a fortuitous mosquito bite can lead to a new discovery (e.g., the probable sexual transmission of Zika virus), and being part of a "natural experiment" can get you authorship on a scientific paper.

Chapters 6 and 27 review the general biology of viruses and introduce basic virology. In chapter 38, we continue this coverage by discussing some of the most important viruses that are human pathogens. We group viral diseases according to their mode of acquisition and transmission; viral diseases that occur in the United States are emphasized.

More than 400 different viruses can infect humans. Diseases caused by these viruses are particularly interesting, considering the small amount of viral genetic information introduced into a host cell. This apparent simplicity belies the severe pathological features and clinical consequences that result from many viral diseases. With few exceptions, only prophylactic or supportive treatment is available. Collectively these diseases are some of the most common and yet most puzzling of all infectious diseases. The resulting frustration is compounded when year after year, familiar diseases of unknown etiology or new diseases become linked to viral infections, while vaccines for a range of viral diseases are questioned by some and unavailable to many.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Review basic virology (sections 6.1–6.6) and prion biochemistry (section 6.7)
- ✔ List the major features of each group of viruses in the Baltimore system of viral classification (chapter 27)
- ✔ Explain pathogenicity and the infection process (chapter 35)

38.1 Viruses Can Be Transmitted by Airborne Routes

After reading this section, you should be able to:

- Report the common viral diseases spread by airborne transmission
- Identify typical signs and symptoms of viral diseases spread by airborne transmission
- Correlate airborne viral infection and disease severity with viral virulence factors

Because air does not support virus multiplication, any virus that is airborne must have originated from a living source. When humans are the source of the airborne virus, it usually is propelled from the respiratory tract by coughing, sneezing, or vocalizing.

Chickenpox (Varicella) and Shingles (Herpes Zoster)

Chickenpox (varicella) is a highly contagious skin disease primarily of children two to seven years of age. Humans are the reservoir and source for this virus, which is acquired by droplet inhalation into the respiratory system (**figure 38.1*a***). The virus is highly infectious, with secondary infection rates in susceptible household contacts of 65 to 86%. In the prevaccine era, about 4 million cases of chickenpox occurred annually in the United States, resulting in approximately 11,000 hospitalizations and 100 to 150 deaths.

The causative agent is the enveloped, double-stranded (ds) DNA varicella-zoster virus (VZV; species *Human herpesvirus 3*), a member of the family *Herpesviridae*. The virus produces at least six glycoproteins that play a role in viral attachment to specific receptors on respiratory epithelial cells. Following an incubation period of 10 to 23 days, small vesicles erupt on the face or upper trunk, fill with pus, rupture, and become covered by scabs (figure 38.1*b*). Healing of the vesicles occurs in about 10 days. During this time, intense itching often occurs.

Laboratory testing for VZV is not normally required, as the diagnosis of chickenpox is typically made by clinical assessment. Laboratory confirmation is recommended, though, to confirm the diagnosis of severe or unusual cases of chickenpox. The introduction of the attenuated varicella vaccine (*see table 37.3*) in the 1990s has drastically reduced the incidence of chickenpox. However because fewer cases are seen, the likelihood of misdiagnosis is increased. Furthermore, in persons who have previously received varicella vaccination, chickenpox is still possible, as immunity wanes. In these individuals, mild or atypical chickenpox symptoms may occur, posing particular challenges for clinical diagnosis. The vaccine is recommended for ages twelve months to twelve years and can be administered separately or as a combined measles, mumps, rubella (MMR) and varicella (MMVR) vaccine.

Individuals who recover from chickenpox are subsequently immune to this disease; however, they are not free of the virus, as viral DNA resides in a dormant (latent) state within the nuclei of cranial nerves and sensory neurons in the dorsal root ganglia. Although viral DNA is maintained in infected cells, virions cannot be detected (**figure 38.2*a***). When the infected person becomes immunocompromised by such factors as age, cancers,

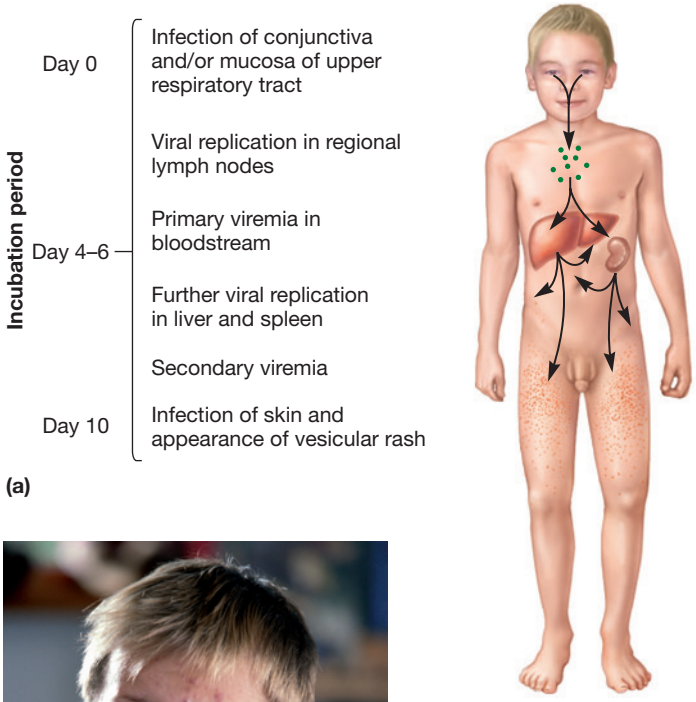

Figure 38.1 Chickenpox (Varicella). (a) Course of infection. (b) Typical vesicular skin rash. This rash occurs all over the body but is heaviest on the trunk and diminishes in intensity toward the periphery.

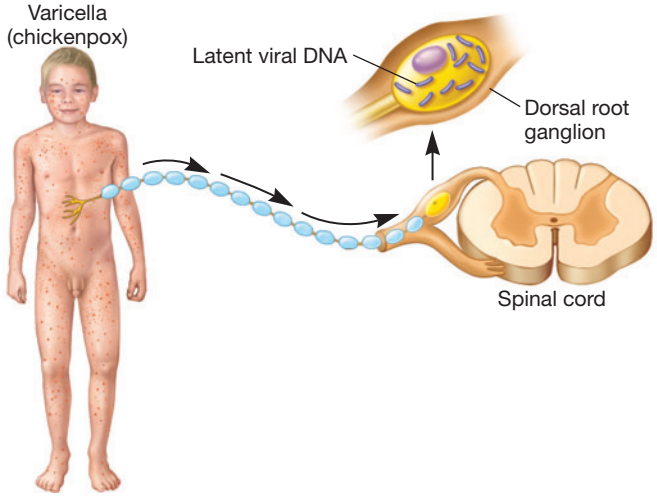
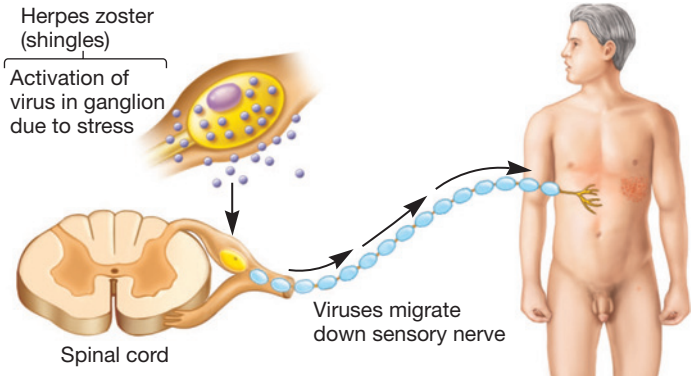
organ transplants, AIDS, or psychological or physiological stress, the viruses may become activated (figure 38.2*b*). They migrate down sensory nerves, initiate viral replication, and produce painful vesicles because of sensory nerve damage (figure 38.2*c*). In this reactivated form, the pain is called **postherpetic neuralgia.** To manage the intense pain, corticosteroids or the drug gabapentin can be prescribed. The antiviral drug acyclovir is used to shorten the infection in severe cases or in immunocompromised patients who develop chickenpox. Another reactivated form of chickenpox is called **shingles** (**herpes zoster**). Most cases occur in people over fifty years of age. Except for the pain of postherpetic neuralgia, shingles does not require specific therapy; however, in immunocompromised individuals, acyclovir, valacyclovir, or famciclovir are recommended. The U.S. Food and Drug Administration (FDA) has licensed a vaccine for shingles (Zostavax) for people fifty years and older. The Centers for Disease Control and Prevention (CDC) estimates that one in three people will get shingles, although the total number of cases



(a) Primary infection—Chickenpox



(b) Recurrence—Shingles

(c)

Figure 38.2 Pathogenesis of the Varicella-Zoster Virus. (a) After an initial infection with varicella (chickenpox), the viruses migrate up sensory peripheral nerves to their dorsal root ganglia, producing a latent infection. (b) When a person becomes immunocompromised or is under psychological or physiological stress, the viruses may be activated. (c) They migrate down sensory nerve axons, initiate viral replication, and produce painful vesicles. Since these vesicles usually appear around the trunk of the body, the name *zoster* (Greek for girdle) is used.

MICRO INQUIRY *Where does viral DNA reside during latent infection? Can virions be detected at this time?*

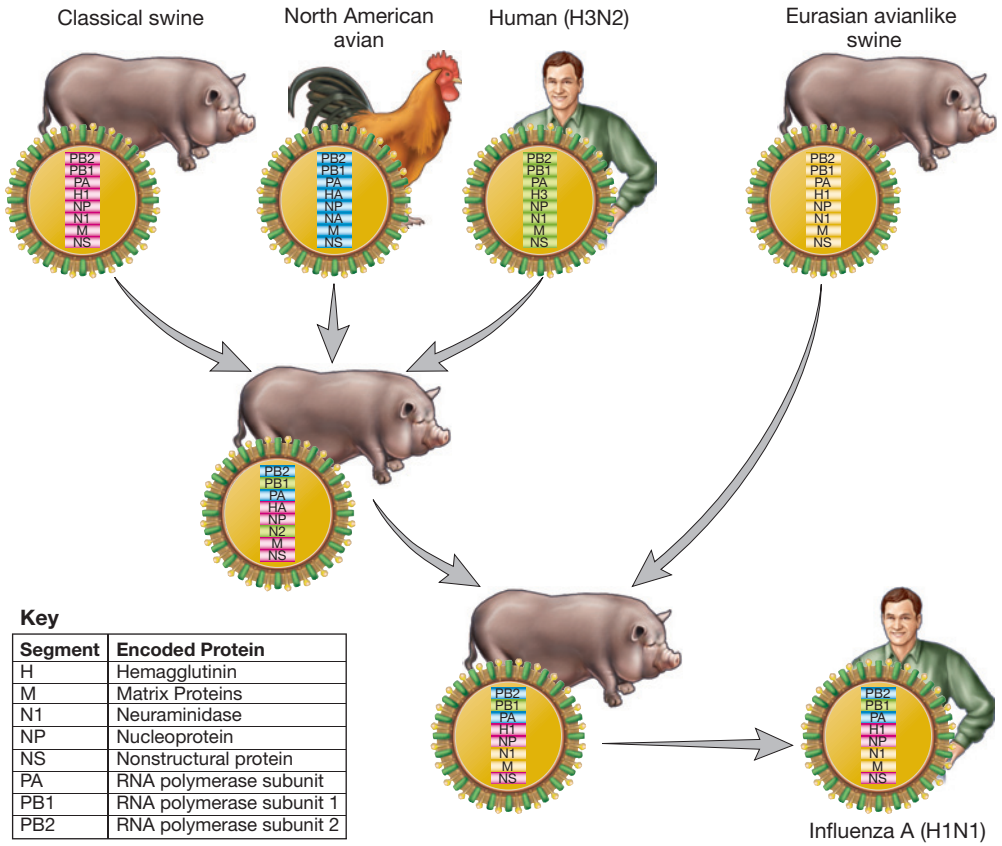
may decline as a shingles vaccine is now available. More than 1 million cases of herpes zoster occur annually in the United States, with 50% of these in people over the age of sixty. There are approximately 96 deaths from herpes zoster annually in the United States.

Influenza (Flu)

Influenza (Italian, *un influenza di freddo*—to be influenced by the cold), or the flu, was described by Hippocrates in 412 BCE. The first well-documented global epidemic of influenza-like disease occurred in 1580. Since then, 31 possible influenza pandemics have been documented, with four occurring in the twentieth century. The worst pandemic on record occurred in 1918 and killed approximately 50 million people around the world. This disaster, traced to the Spanish influenza virus, was followed by pandemics of Asian flu (1957), Hong Kong flu (1968), Russian flu (1977), and the novel swine flu (2009). (The names reflect popular impressions of where or from what the episodes began, although all are now thought to have originated in China.) Another new influenza strain erupted from pigs in 2011. It was the dominant strain of the 2014 flu season, for which that season's vaccine was only 23% effective. ⏮ *Minus-strand RNA viruses (section 27.7)*

Influenza is a respiratory system disease caused by negative-strand RNA viruses that belong to the family *Orthomyxoviridae (see figure 27.28)*. The three genera are *Influenzavirus A, Influenzavirus B,* and *Influenzavirus C*; only types A and B cause significant human disease. Influenza viruses are widely distributed in nature, infecting a variety of mammal and bird hosts. All influenza viruses are acquired by inhalation or ingestion of virus-contaminated respiratory secretions (thus the public health recommendation to "cover your cough and wash your hands frequently"). During an incubation period of 1 to 2 days, viral particles adhere to host respiratory epithelium and initiate the replication cycle (*see figure 27.28b*). Two envelope spikes, hemagglutinin (HA) and neuraminadase (NA) play critical roles. HA is the adherence factor that binds host cells and thereby triggers receptor-mediated endocytosis. This is facilitated by NA, which is thought to hydrolyze the mucus that covers the epithelium. Once within the cytoplasm enclosed in an endosome, HA again functions, this time to bring about release of the virus's 7–8 nucleocapsids into the cytosol. To do this, HA undergoes a dramatic conformational change when the endosomal pH decreases. The hydrophobic ends of the hemagglutinin spring outward and extend toward the endosomal membrane. After they contact the membrane, fusion occurs and the RNA nucleocapsids are released into the cytoplasm. Each influenza virus nucleocapsid consists of a single negative-strand RNA molecule associated with nucleoprotein (NP) and three subunits of the RNA-dependent RNA polymerase (PA, PB1, and PB2; **figure 38.3**). NA also has an additional role in the replication cycle. It aids in the release of newly assembled influenza virus virions from infected cells by cleaving sialic acid residues between virus and host membranes. ⏮ *Several cytoplasmic membranous organelles function in the secretory and endocytic pathways (section 5.4)*

Influenza viruses are classified into subtypes based on their HA and NA. There are 16 HA (H1–H16) and 9 NA (N1–N9)



Key

Segment	Encoded Protein
H	Hemagglutinin
M	Matrix Proteins
N1	Neuraminidase
NP	Nucleoprotein
NS	Nonstructural protein
PA	RNA polymerase subunit
PB1	RNA polymerase subunit 1
PB2	RNA polymerase subunit 2

Figure 38.3 Influenza Infection.
Influenza A viruses infect birds, pigs, and humans. Reassortment of viral RNA from more than one viral subtype results in novel subtypes, such as the H1N1 cause of the 2009–2010 influenza pandemic.

antigenic forms known; they recombine to produce the various HA/NA subtypes. Host specificity can be explained in part by the difference in receptor binding. Human influenza viruses preferentially attach by way of their HA protein to receptors on human tracheal epithelial cells. In contrast, avian influenza viruses preferentially bind receptors found on intestinal epithelial cells of waterfowl (the main viral replication site of avian influenza viruses), for the most part, restricting infection to birds.

Recall that the genomes of influenza viruses are linear RNA segments that change frequently due to point mutations and reassortment (figure 38.3). As RNA viruses, influenza viruses must use an RNA-dependent RNA polymerase (RdRp) to replicate their genomes. This gives rise to a high mutation rate because RdRps lack proofreading capabilities. These smaller genetic changes often result in subtle protein (antigen) changes, especially within the HA and NA structures. This is known as **antigenic drift.** Antigenic drift results from the accumulation of mutations of HA and NA in a single strain of flu virus within a geographic region and was responsible for the 2014–2015 mismatch between one vaccine flu strain and the circulating strain. This usually occurs every 2 to 3 years, causing local increases in the number of flu infections. **Antigenic shift,** however, is a larger protein sequence change made possible by the linear, segmented nature of the RNA genome. It occurs when two different strains of flu viruses (e.g., one from swine and one from humans) infect the same host cell and are incorporated into a single new capsid (figure 38.3). Because the new, recombinant virus contains segments from two different flu strains, there is a greater change with antigenic shift than with antigenic drift. Indeed, antigenic shifts are responsible for major epidemics and pandemics. Antigenic variation occurs almost yearly with influenza A virus, less frequently with the B virus, and thus the need for yearly influenza vaccination. Antigenic shift has not been demonstrated in the C virus. ⏮ *Infectious disease is revealed through patterns within a population (section 37.3)*

Animal reservoirs are critical to the epidemiology of human influenza. For example, rural China is one region of the world in which chickens, pigs, and humans live in close, crowded conditions. Influenza is widespread in birds, and although birds cannot usually transmit the virus to humans, they can transfer it to pigs. Pigs can transfer it to humans and humans back to pigs. Recombination between human and avian strains thus occurs in pigs, leading to novel HA/NA combinations causing major antigenic shifts. To track the various influenza subtypes, a standard nomenclature system was developed. It includes the following information: group (A, B, or C), host of origin, geographic location, strain number, and year of original isolation. Antigenic descriptions of the HA and NA surface proteins are given in parentheses for type A viruses only. The host of origin is indicated for viruses obtained from nonhuman hosts; for example, A/swine/Iowa/15/30 (H1N1). However, the host origin is not given for human isolates; for example, A/Hong Kong/03/68 (H3N2).

Influenza A viruses having H1, H2, and H3 HA antigens, along with N1 and N2 NA antigens, are predominant in nature, infecting humans since the early 1900s. H1N1 viruses appeared in 1918 and were replaced in 1957 by H2N2 viruses as the predominant subtype. The H2N2 viruses were subsequently replaced by H3N2 as the principle subtype in 1968. The H1N1 subtype reappeared in 1977 and cocirculates today with H2N1, H3N2, H5N2, H7N2, H7N3, H7N7, H9N2, H10N7, and H5N1 viruses. Importantly, the receptor-binding specificity of human and avian influenza viruses just discussed suggests that in order to infect humans, surface HA and NA proteins of avian influenza viruses must gain the capacity to recognize human-type receptors. Indeed, genome sequences of the earliest isolates of the 1918, 1957, and 1968 pandemics demonstrated that otherwise avian influenza A viruses possessed HAs that recognized specific receptors with a characteristic structure usually seen in human influenza strains.

The year 2009 brought another influenza A H1N1 pandemic. Although there was initially much concern, this H1N1 strain was much, much milder than its relative that caused the 1918 pandemic. The novel H1N1 influenza emerged in Veracruz, Mexico, as a new strain when a previous triple reassortment of bird, swine, and human influenza viruses further recombined with a Eurasian pig influenza virus. Within months this new H1N1 strain became pandemic: by the end of the 2010 flu season there were more than 622,000 cases in 122 countries, with over 18,000 deaths. In the United States there were over 113,500 cases and 3,400 deaths.

The novel H1N1 (swine) flu pandemic of 2009 diverted attention from the continuing threat of the highly pathogenic H5N1 (avian) flu. The threat of the H5N1 subtype was first recognized in 1997, when it was responsible for six deaths, although it had been sporadically detected prior to that. Between 2003 to 2014, however, H5N1 was responsible for several bird to human and human to human transmissions in Asia, along with a substantial number of bird infections, resulting in the culling of millions of birds. So far this virus seems to spread rarely from birds to humans and even more rarely between humans. Even so, millions of birds have been destroyed to help prevent transmission of the virus. Unfortunately, highly pathogenic avian influenza H5 viruses H5N8 and H5N2 and a novel H5N1 have been found in both domestic and wild birds in the United States in 2015. This has resulted in the culling of hundreds of thousands of U.S. chickens and turkeys, export restrictions, and soaring egg prices. Bird populations continue to be carefully monitored.

Because of potentially severe consequences of pandemic influenza infection in humans, an international effort coordinated by the World Health Organization (WHO) continues to monitor virus surveillance, epidemiology, and control efforts for each virus subtype, as well as for newly recombinant strains. For example, in 2013 another influenza strain, H7N9, erupted in Asia. As of mid-March 2015 there were 643 human cases of H7N9. H7N9 has caused serious human illness and is fatal in about 30% of its victims. Of note are the additional reports of H5N2, H5N3, H5N8 bird outbreaks in Taiwan, and an H5N1 bird outbreak in Nigeria.

As with many other viral diseases, only the symptoms of influenza usually are treated. The antiviral drugs amantadine and rimantadine are no longer recommended for treatment of influenza, as most strains have developed resistance. Instead the CDC now recommends oseltamivir, zanamivir, and the newly approved peramivir; these can reduce the duration and symptoms of type A influenza if administered during the first two days of illness. These drugs are chemically related antiviral agents known as neuraminidase inhibitors; they have activity against both influenza A and B viruses. Neuraminidase inhibitors prevent the release of newly formed virions from their host cell by blocking the catalytic site of the enzyme neuraminidase. With the neuraminidase blocked, virions do not detach from the host cell membrane and therefore cannot travel to infect another cell. Importantly, aspirin (salicylic acid) should be avoided in children younger than fourteen years to reduce the risk of Reye's syndrome. ⏮ *Antiviral drugs (section 9.6)*

The mainstay for prevention of influenza since the late 1940s has been inactivated virus vaccines, and the more recently approved live-attenuated, nasal spray vaccines (*see table 37.3*). Although the flu vaccine is recommended for all, it is particularly important that the chronically ill, individuals under five and over age sixty-five, and residents of nursing homes be immunized, as disease in these patients is most likely to be severe. Because of influenza's high genetic variability, efforts are made each year to incorporate new virus subtypes into the vaccine. Even when no new subtypes are identified in a given year, annual immunization is still recommended because immunity using the inactivated virus vaccine typically lasts only 1 to 2 years.

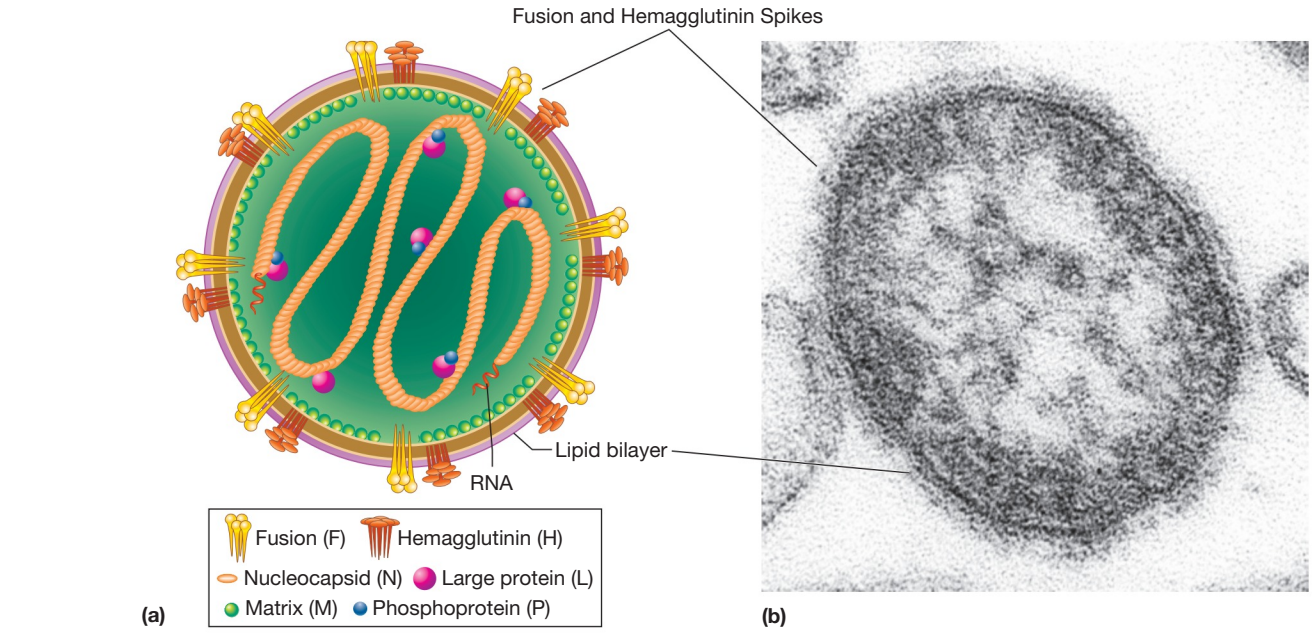
Measles (Rubeola)

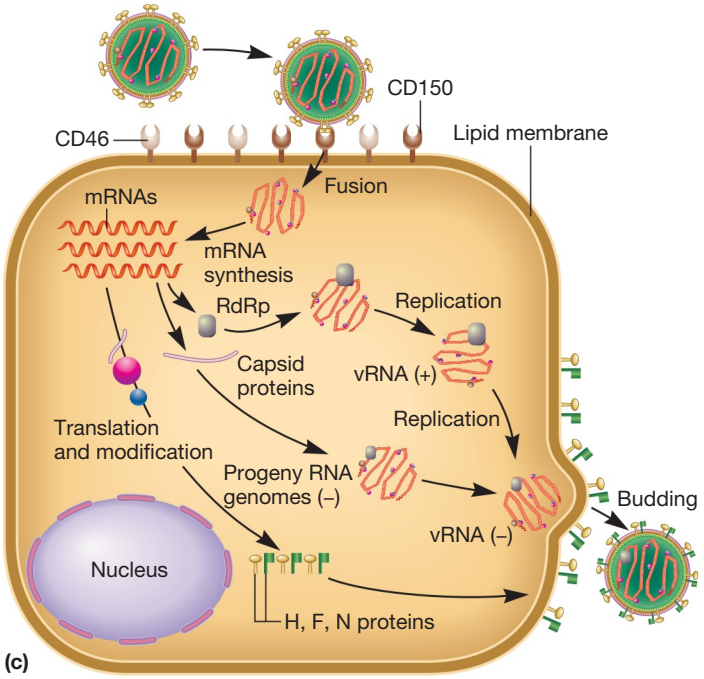
Measles (**rubeola:** Latin *rubeus,* red) is an extremely contagious disease that is endemic throughout most of the world. There were 145,700 cases of measles reported to WHO in 2013, with about 400 deaths every day. Fortunately, it is no longer endemic in the United States; thanks to an aggressive vaccination program, most U.S. cases of measles today are only those imported from other countries. There are approximately 18 measles-active countries as of 2015. Unfortunately, sporadic cases of measles in teens and young adults have been being reported in the United States since 2011. Notably, in 2014 there were 644 U.S. cases reported to the CDC. More than half of those were traced to an Amish man returning to Ohio from the Philippines. He gave the disease to unvaccinated community members, who passed it on to local college students whose vaccine protection had lapsed. Late in 2014 at Disneyland in California there erupted a second wave of measles cases, also believed to have had its origin in the Philippines. These progressed into the early weeks of 2015 where 141 new cases of measles were reported in 17 states and the District of Columbia. Aggressive public health measures were implemented to contain the epidemic.

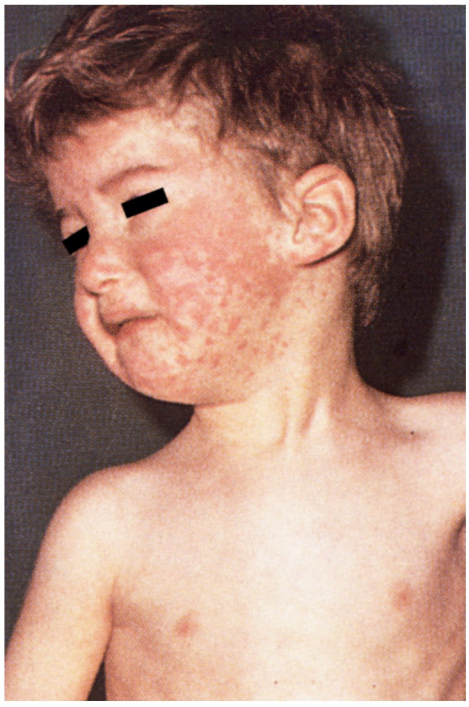
Measles virus (MeV) is a negative-strand, enveloped RNA virus in the genus *Morbillivirus* and the family *Paramyxoviridae* (**figure 38.4*a***). The MeV genome encodes eight proteins, six of which are structural.

MeV enters the body through the respiratory tract or the conjunctiva of the eyes. The receptors for MeV are found on activated B and T cells, as well as antigen-presenting cells. The hemagglutinin (H) and fusion (F) proteins mediate attachment of the viral envelope to the host cell membrane, facilitating entry by promoting fusion of the viral envelope and the host cell's plasma membrane. Two proteins, L and N, form the nucleocapsid. The remaining proteins (P, V, C, and M) are involved in viral replication.

The incubation period for measles is usually 10 to 14 days, and visible symptoms begin about the tenth day (figure 38.4*d*). The measles prodrome is characterized by nasal discharge, cough, fever, headache, and conjunctivitis, which intensify several days prior to the onset of rash. Within 3 to 5 days, skin eruptions occur as erythematous (red) maculopapular (discolored area of small bumps) lesions that are at first discrete but gradually become confluent (figure 38.4*e*). The rash normally lasts about 5 to 7 days. **Koplik's spots,** red lesions with a bluish-white speck in the center of each, are sometimes seen on the mucosal lining of the mouth in the early stages of disease. Recovery from measles begins soon







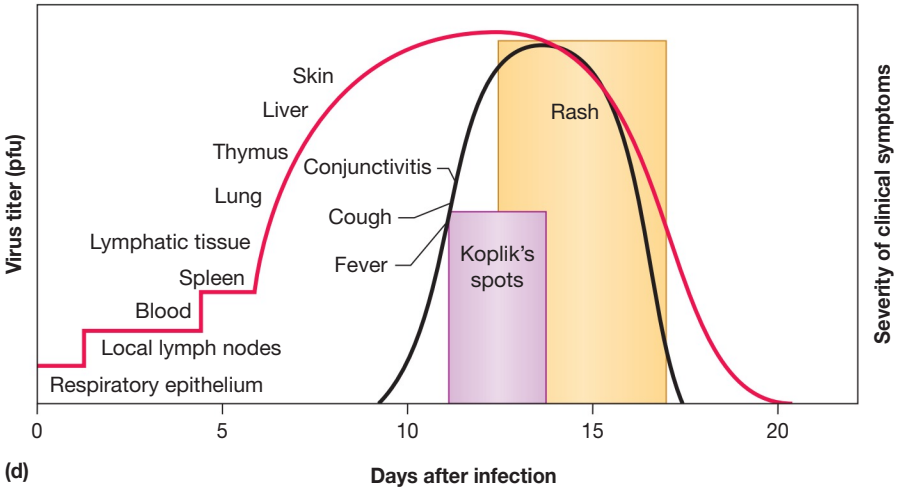


Figure 38.4 Measles (Rubeola). (a) Schematic of the spherical, RNA morbillivirus that causes measles. (b) Transmission electron micrograph of a measles virus (MeV) virion (virion is 100 to 200 nm in diameter). (c) Life cycle of MeV. MeV virions exit the host by budding. (d) Severity of measles symptoms (black line) corresponds to the viral load (red line) in the tissue sites. (e) The rash of small, raised spots is typical of measles. The rash usually begins on the face and moves downward to the trunk.

after the rash is reported. Although a progressive degeneration of the central nervous system called **subacute sclerosing panencephalitis** is a rare complication, it is devastating and can result in permanent cognitive deficits.

No specific treatment is available for measles. The use of attenuated measles vaccine in combination with mumps and rubella (MMR vaccine) or as a combined measles, mumps, rubella, and varicella vaccine is recommended for all children (*see table 37.3*). Serious outbreaks of measles are still reported in North America and Europe, especially among the unvaccinated. A measles infection, as well as immunization with measles vaccine, typically provides lifelong immunity against reinfection. Unfortunately, a now-disproven research report had linked (measles) vaccination to autism, convincing many to forgo immunization of their children. While no vaccine is without potential risk, it is very clear that the benefit of vaccination far outweighs that risk.

Mumps

Mumps is an acute, highly contagious disease. The annual mumps incidence in most parts of the unvaccinated world is approximately 1–10 per 10,000 population, with epidemics every 2 to 5 years. U.S. cases range from a total of several hundred to several thousand every year, the low rates largely due to the highly effective vaccine. In 2009–2010 an outbreak occurred in the New York metroplex. The index case was an eleven-year-old boy returning from a trip to the United Kingdom. This ultimately led to about 3,000 cases of mumps. There were also several smaller mumps outbreaks in 2011–2013, mostly on college campuses. However, there were 1,151 cases in 2014, several of which were attributed to members of professional hockey teams. As with measles resurgence, modern mumps cases are typically in those whose immunity has waned or who were never vaccinated.

Mumps virus (MuV) is a member of the genus *Rubulavirus* in the family *Paramyxoviridae*. MuV virions are pleomorphic, enveloped, and contain a helical nucleocapsid containing negative-strand RNA. Like the measles virus, MuV is transmitted in saliva and respiratory droplets, but it is less contagious than measles or chickenpox. The most prominent manifestations of mumps are swelling and tenderness of the salivary (parotid) glands 16 to 18 days after infection of the host by the virus. The swelling usually lasts for 1 to 2 weeks and is accompanied by a low-grade fever. Severe complications of mumps are rare; however, deafness, meningitis, encephalitis, and inflammation of the epididymis and testes (orchitis) leading to sterility can occur, especially in postpubescent males. Therapy is limited to symptomatic and supportive measures. A live, attenuated mumps virus vaccine is available. It usually is given as part of the trivalent or tetravalent MMR vaccine (*see table 37.3*).

Respiratory Syndromes and Viral Pneumonia

Acute viral infections of the respiratory system are among the most common causes of human disease. The infectious agents are called acute respiratory viruses, and they collectively produce a variety of clinical manifestations, including rhinitis (inflammation of the mucous membranes of the nose), tonsillitis, laryngitis, and bronchitis. Adenoviruses, coronaviruses, picornoviruses (rhinoviruses, coxsackieviruses A and B, echoviruses, and poliovirus), influenza viruses, parainfluenza viruses, respiratory syncytial virus, and human metapneumovirus are thought to be responsible. It should be emphasized that for most of these viruses, there is a lack of specific correlation between the agent and the clinical manifestation; hence the term syndrome. Most of these viruses have many strains, so immunity is not complete, and reinfection is common. The best treatment is rest with symptom management.

Some viral infections of the respiratory system culminate in pneumonia. However, viral pneumonia is typically only diagnosed when other causes, including mycoplasmal pneumonia, (*see p. 866*) have been ruled out. The clinical picture of viral pneumonia is nonspecific. Symptoms may be mild, or there may be severe illness and death. Importantly, secondary (subsequent) bacterial infections may also contribute to respiratory illness initiated by viruses. We highlight two coronaviruses and human respiratory syncytial virus as examples of these pathogens.

Coronaviruses are positive-strand RNA viruses named for the crownlike spikes on their surface. There are four main subtypes of coronaviruses; alpha, beta, gamma, and delta. Coronavirus virions are relatively large (120 to 150 nm), with a helical nucleocapsid surrounded by an envelope. Large spikes protrude from the envelope to aid in attachment and entry into host cells. The protruding envelope spikes extend from the oval-to-spherical virion to give the illusion of a halo, or corona, around the virus (**figure 38.5**). The spike proteins mediate viral attachment and fusion to the host cell membrane. There are many coronaviruses

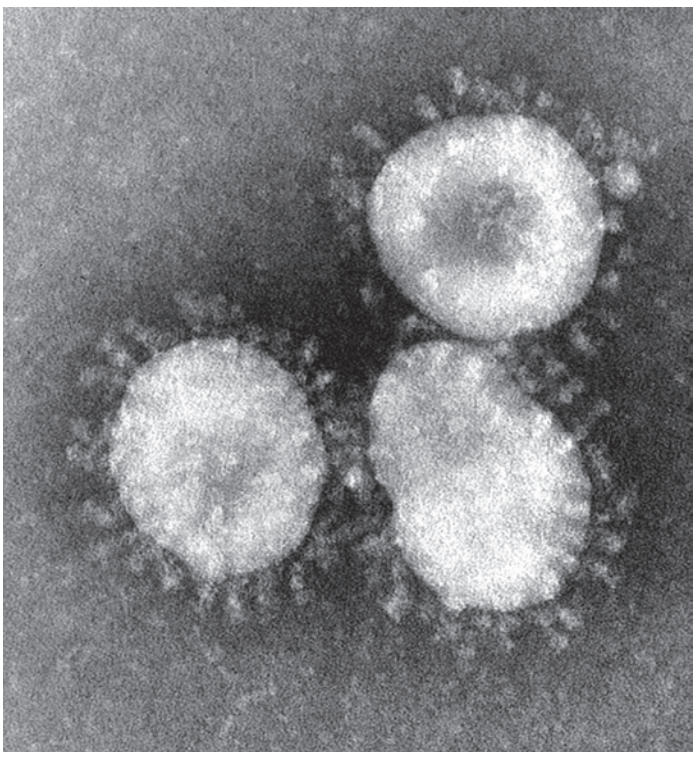

Figure 38.5 SARS Coronavirus (SARS-CoV). Coronaviruses are named for the crownlike (corona) appearance seen by electron microscopy.

that naturally infect animals, but most do not usually infect people. However, two relatively new coronaviruses do infect people: SARS-CoV and MERS-CoV. In addition to humans, SARS-CoV infects monkeys, Himalayan palm civets, raccoon dogs, cats, dogs, and rodents; and MERS-CoV also infects camels and bats.

Severe acute respiratory syndrome (**SARS**) is a highly contagious viral disease caused by the SARS coronavirus (SARS-CoV). SARS-CoV was first recognized in China in 2002, where it infected 8,098 people; it killed 774 worldwide in about one year. Since 2004 there have been no known cases of SARS-CoV. We report on it here as a great example of how a novel virus can emerge, wreak havoc on society, and burn itself out. The virus caused a febrile (100.4°F, 38°C) lower respiratory tract illness. Sudden, severe illness in otherwise healthy individuals was a hallmark of the disease. Other symptoms included headache, mild flulike discomfort, and body aches. SARS patients developed a dry cough after a few days, and most developed pneumonia. About 10 to 20% of patients had diarrhea. SARS was transmitted by close contact with respiratory secretions (droplet spread). No specific treatment is currently approved and no vaccine is licensed for preventative use. Molecular evidence suggests that substitutions in one or two amino acids within the receptor-binding domain of the human receptor were the likely the reason for reduced virulence of SARS-CoV infections late in 2004, indicating that mutations coding for these proteins may be responsible for the apparent eradication of the SARS virus.

Middle East respiratory syndrome (**MERS**) is a relatively new viral respiratory illness of humans caused by MERS-CoV. It was first reported in Saudi Arabia in 2012 and has since spread to several other countries. It has caused illness in hundreds of people from several countries in and near the Arabian Peninsula. In 2014 the first confirmed cases of MERS were reported in two travelers to the United States from Saudi Arabia; they were not linked. Most people infected with MERS-CoV developed severe acute respiratory illness, including fever, cough, and shortness of breath four to five days after exposure. Many of the infected also have gastrointestinal distress and diarrhea. MERS has a 30 to 40% mortality rate. There is no currently approved antiviral treatment. Prevention is through diligent respiratory protection and thorough hand hygiene when exposure is possible.

Human respiratory syncytial virus (**HRSV**) often is described as the most dangerous cause of lower respiratory infections in infants (less than one year of age) and the elderly (age 65 and older). The virus is found worldwide and causes seasonal (November to March) outbreaks lasting several months. In the United States, over 2.1 million children (under five years old) require outpatient visits, and between 100,000 and 126,000 infants are hospitalized each year for HRSV diagnoses. Additionally, there are 177,000 hospitalizations and 14,000 deaths among those 65 years or older.

HRSV is a member of the negative-strand RNA virus family *Paramyxoviridae*. The virion is variable in shape and size (average diameter 120–300 nm). It is enveloped with two virus-specific glycoproteins as part of the structure. One of the two glycoproteins, G, is responsible for binding the virus to the host cell; the other, the fusion or F protein, permits fusion of the viral envelope with the host cell plasma membrane, leading to entry of the virus. The F protein also induces fusion of the plasma membranes of infected cells. Thus, HRSV gets its name from the resulting formation of a syncytium or multinucleated mass of fused cells. The syncytia are responsible for inflammation, alveolar thickening, and fluid accumulation in alveolar spaces. HRSV is transmitted by direct contact with respiratory secretions of humans. Virions are unstable in the environment (surviving only a few hours on environmental surfaces) and are readily inactivated with soap and water, and disinfectants.

Clinical manifestations of HRSV infection include acute onset of fever, cough, rhinitis, and nasal congestion. In infants and young children, this often progresses to severe bronchitis and viral pneumonia. Diagnosis is by either RSV rapid antigen test kit or RSV detection by reverse transcriptase (rt) PCR. Treatment of uncomplicated cases is with fluid replacement and fever reducers. In more serious cases, oxygen therapy with inhaled ribavirin is used. A series of monoclonal antibody (palivizumab) injections has been shown to reduce the severity of this disease in premature infants and babies who are immunosuppressed. Prevention and control consist of isolation of RSV-infected individuals and strict attention to good hand-washing practices.

Rubella (German Measles)

Rubella (Latin *rubellus*, little red) was first described in Germany in the 1800s as a variant of measles ("first disease"), and then scarlet fever ("second disease"); next it was called "third disease" and then rubella or German measles. It is a moderately contagious disease that occurs primarily in children five to nine years of age. It is caused by rubella virus, an enveloped, positive-strand RNA virus that is a member of the family *Togaviridae*. Rubella is worldwide in distribution, being spread in droplets shed from the respiratory secretions of infected individuals. Once the virus is inside the body, the incubation period ranges from 12 to 23 days. A rash of small red spots (**figure 38.6**),

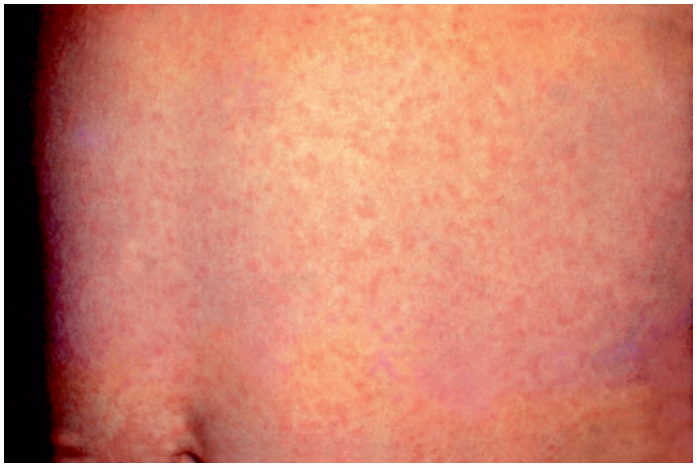

Figure 38.6 German Measles (Rubella). This disease is characterized by a rash of red spots. Spots are not raised above the surrounding skin as in measles (rubeola; see figure 38.4e).

MICRO INQUIRY *Why is it thought that the characteristic rash is not caused by viral infection of skin cells?*

usually lasting no more than 3 days, and a light fever are the normal symptoms. The rash appears as immunity develops and the virus disappears from the blood, suggesting that the rash is immunologically mediated and not caused by the virus infecting skin cells. Because rubella tends to be such a mild infection, usually no treatment is indicated.

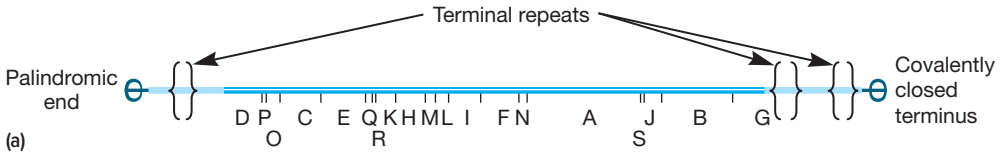
However, rubella can be disastrous if contracted by a woman who is in her first trimester of pregnancy. It can lead to fetal death, premature delivery, or a wide array of congenital defects called **congenital rubella syndrome.** These defects include damage to the heart, eyes, and ears, and brain damage that leads to cognitive disabilities. All children and women of childbearing age who have not been previously exposed to rubella should be vaccinated. The United States was declared rubella free in 2009; there have been no endemic cases reported since then. The live attenuated rubella vaccine (part of MMR or MMRV, *see table 37.3*) continues to be recommended.

Smallpox (Variola)

Smallpox (**variola**) is a highly contagious disease of antiquity. We highlight it for two reasons: it is the only example of vaccine eradication of disease; and it continues to instill concern should it be used in bioterrorism. Both eradication and bioterrorism are linked to the fact that smallpox is uniquely an illness of humans. It is caused by orthopoxviruses belonging to the species *Variola virus*. Variola viruses (VARVs) belong to the family *Poxviridae*, which also includes the species *Monkeypox virus*, *Molluscum contagiosum virus*, and *Vaccinia virus.* Vaccinia virus (VACV) is the virus that causes cowpox and serves as the antigen in the smallpox vaccine. Poxviruses are large, brick-shaped, and contain a dumbbell-shaped core (*see figure 6.6*). The genome consists of a single, linear molecule of double-stranded DNA that is replicated in the host cell's cytoplasm. The genome is composed of approximately 186 kilobase (kb) pairs with covalently closed ends (**figure 38.7*a***). Variola virus isolates have approximately 200 open reading frames that are closely spaced and nonoverlapping. Interestingly, the size of the virion (300 by 250 to 200 nm) is slightly larger than that of some of the smallest bacteria (e.g., *Chlamydia* spp.).

Smallpox was once one of the most prevalent of all diseases. It was a universally dreaded scourge for more than 3 millennia, with case fatality rates of 20 to 50%; it disabled and disfigured those who survived. The disease begins with a prodrome of systemic aches. Characteristic symptoms of infection also include acute onset of fever 101°F (38.3°C), followed by a rash that features firm, deep-seated vesicles or pustules in the same stage of development (figure 38.7*b*). First subjected to some control in tenth-century India and China, it was gradually suppressed in the industrialized world after Edward Jenner's 1796 landmark discovery that infection with the harmless cowpox (vaccinia) virus renders humans immune to the smallpox virus (*Historical Highlights 37.5*).

Protection from smallpox is through vaccination. The smallpox vaccine contains live vaccinia virus. Since the advent of immunization and because of concerted efforts by WHO, smallpox was eradicated throughout the world—the greatest public health achievement ever. The last case from a natural infection occurred in Somalia in 1977. The Somali man was part of the vaccination program, but his vaccine did not take. Fortunately he survived the disease and only recently died. Eradication was possible because smallpox has obvious clinical features, very few asymptomatic carriers, only human hosts as reservoirs, and a short period of infectivity (3 to 4 weeks). Furthermore, variola virus is generally transmitted by direct and fairly prolonged face-to-face contact. It also can be spread through direct contact with infected bodily fluids or contaminated objects such as bedding or



(b)

MICRO INQUIRY *What specific clinical and biological features of smallpox made its eradication possible?*

clothing. Smallpox has been reported to spread through the air in enclosed settings such as buildings, buses, and trains.

Variola virus enters the respiratory tract, seeding the mucous membranes, passing rapidly into regional lymph nodes. The average incubation period is 12 to 14 days but can range from 7 to 17 days. During this time, the virus multiplies in the host, but the host is not contagious. Another brief period of viremia precedes the prodromal phase. The prodromal phase lasts for 2 to 4 days and is characterized by malaise, severe head and body aches, occasional vomiting, and fever (over 104°F, 40°C), all beginning abruptly. During the prodromal phase, the mucous membranes in the mouth and pharynx become infected, resulting in a rash of small, red spots. These spots develop into open sores that spread large amounts of the virus into the mouth and throat. At this time, the person is highly contagious. The virus then invades the capillary epithelium of the skin, leading to the development of the following sequence of lesions in or on the skin: eruptions, papules, vesicles, pustules, crusts, and desquamation (figure 38.7*b*). The rash appears on the face, spreads to the arms and legs, and then the hands and feet. Usually the rash spreads over the body within 24 hours. By the third day of the rash, it forms raised bumps. By the fourth day, the bumps fill with a thick, opaque fluid and often have a depression in the center that looks like a bellybutton. This is a major distinguishing characteristic of smallpox, as compared to other diseases that exhibit rashes. The fever usually declines as the rash appears but rises and is sustained from the time the vesicles form until they crust over. Oropharyngeal and skin lesions contain abundant virus particles, particularly early in the disease process. Death from smallpox is due to toxemia associated with immune-mediated blood clots and elevated blood pressure.

Routine immunization for smallpox was discontinued in the United States once global eradication was confirmed. An accidental or deliberate release of the virus would be catastrophic in an unimmunized population and could cause a major pandemic. Thus if an outbreak occurred, prompt recognition and institution of control measures would be paramount as there is no FDA-approved treatment for smallpox, even though several antiviral agents have been suggested as adjunct therapies. ⏮ *Bioterrorism readiness is an integral component of public health microbiology (section 37.7)*

8. What factors inherent in the variola virus and the disease smallpox made it possible to eradicate them?

38.2 Arthropods Can Transmit Viral Diseases

After reading this section, you should be able to:

- Report the two common arthropod-borne viral diseases
- Identify typical signs and symptoms of two arthropod-borne viral diseases
- Correlate arthropod-borne virus infection with geography and time of year

Arthropod-borne viruses (arboviruses) are transmitted by blood-sucking arthropods from one vertebrate host to another. They multiply in the tissues of the arthropod without producing disease, although the arthropod vector acquires a lifelong infection. Approximately 150 of the recognized arboviruses cause illness in humans. Diseases produced by the *ar*thropod-*bo*rne viruses (arboviruses) can be divided into three clinical syndromes: (1) fevers of an undifferentiated type with or without a rash; (2) encephalitis (inflammation of the brain), often with a high fatality rate; and (3) hemorrhagic fevers, also frequently severe and fatal. No antiviral therapy is effective in treating arbovirus diseases, although supportive treatment is beneficial.

Chikungunya

Chikungunya virus, a member of *Togaviridae*, is a positive-strand, enveloped RNA virus. We highlight it here as an emerging infectious disease. In late 2013 it was found on the Caribbean Islands, and by July 7, 2015, a total of 207 chikungunya virus disease cases had been reported to the CDC from 32 states. All of these cases were in travelers returning from affected areas. At the same time the virus was detected as locally transmitted cases in Puerto Rico and the U.S. Virgin Islands. The virus is transmitted to humans by *Aedes aegypti* and *Aedes albopictus* mosquitoes.

Acute chikungunya virus infection in humans often includes fever and joint pain. Other symptoms may include headache, muscle pain, joint swelling, or rash. These symptoms often resolve in 7 to 10 days. However, many patients report prolonged joint pain persisting for months to years. Rare complications include eye inflammation, myocarditis, hepatitis, nephritis, hemorrhage, encephalitis, and Guillain-Barré syndrome.

Chikungunya virus detection is by tissue culture, viral RNA amplified by RT-PCR within eight days of infection, and antiviral antibodies five days post infection. There is no medicine to treat, or vaccine to prevent, chikungunya virus infection. Travelers to endemic areas should follow guidelines to prevent mosquito-borne infectious disease; they should use insect repellent, wear light-colored clothes with long sleeves and pants, and stay in places with mosquito netting, window and door screens, and fans. ⏮ *The polymerase chain reaction amplifies targeted DNA (section 17.2)*

Equine Encephalitis

Equine encephalitis is caused by viruses in the genus *Alphavirus,* family *Togaviridae*. They are positive-strand, enveloped RNA

viruses. As the name implies, this is a disease of horses, where it can be fatal. However, in humans, the disease can present as a spectrum from fever and headache to (aseptic) meningitis and encephalitis. Human disease can progress to include seizures, paralysis, coma, and death. The virus is transmitted to humans by *Aedes* and *Culex* spp. mosquitoes. Various geographic descriptors are used to define the disease caused by genetically distinct strains of these arboviruses: eastern equine encephalitis (EEE) occurs along the eastern Atlantic coast from Canada to South America; western equine encephalitis (WEE) occurs from Canada to South America along the western coast; and Venezuelan equine encephalitis occurs in central and southern parts of the United States into South America. Reservoir hosts are important in the replication, maintenance, and dissemination of these arboviruses. Treatment consists of the supportive care of symptoms. Currently no vaccine is available to prevent disease. Preventative measures rely on common mosquito precautions.

Heartland Virus

Heartland virus is a member of the genus *Phlebovirus*, in the family *Bunyaviridae*. Heartland virus is yet another emerging virus, this one infecting eight people in Missouri and Tennessee (in the U.S. heartland), between 2012 and 2014. Early data suggest that heartland virus is transmitted by the Lone Star tick, although other ticks may also transmit the virus.

Patients infected with heartland virus presented with fever and overwhelming fatigue. Some also complained of headaches, muscle aches, diarrhea, anorexia, or nausea. They all had laboratory findings found in patients with other tick-borne viral diseases, low leukocytes and platelets. Most patients required hospitalization but fully recovered. One patient died. There is no drug to treat, or vaccine to prevent, the disease caused by heartland virus. Supportive care and treatment of symptoms are recommended. Prevention of heartland virus infection is through standard tick precautions: use of tick repellants, wearing light-colored clothing having long sleeves and pants, and tick checks.

West Nile Fever (Encephalitis)

West Nile fever (encephalitis) is caused by a positive-strand RNA flavivirus (West Nile virus) that occurred primarily in the Middle East, Africa, and Southwest Asia, where the disease was first discovered in 1937 in the West Nile district of Uganda. In 1999 the virus appeared unexpectedly in the United States (New York), causing seven deaths among 62 confirmed human encephalitis cases and extensive mortality in a variety of domestic and exotic birds. Epidemiological data suggest that the virus crossed the Atlantic in an infected bird, mosquito, or human traveler.

By 2015, 47 U.S. states and the District of Columbia reported West Nile virus (WNV) infections in over 41,679 people, resulting in 1,753 deaths. WNV is transmitted to humans predominantly by *Culex* spp. mosquitoes that feed on infected birds (crows and sparrows). Mosquitoes harbor the greatest concentration of virus in the late summer and early fall, and corresponding to this, there is a peak of disease in late August to early September. The risk of disease then decreases as the mosquitoes die when the weather becomes colder. Although many people are bitten by WNV-infected mosquitoes, most do not know they have been exposed and remain asymptomatic or exhibit only mild, flulike symptoms.

Human-to-human transmission has been reported through blood and organ donation; however, the risk of acquiring WNV infection from donated blood or organs has greatly diminished since the introduction of a PCR-based detection assay in 2003. There are no data to suggest that WNV transmission to humans occurs from handling infected birds (live or dead), but barrier protection is suggested in handling potentially infected animals. The virus can be recovered from *Culex* mosquitoes, birds, and blood taken in the acute stage of a human infection. Diagnosis is by a rise in neutralizing antibody in a patient's serum. Only one antigenic type exists and immunity is presumed permanent. An enzyme-linked immunosorbent assay (ELISA) test for IgM anti-WNV antibody is the FDA-approved diagnostic test. Other immunological and molecular testing is available at state health department laboratories or at the CDC. There is no treatment other than hospitalization and intravenous fluids. There is no human vaccine to prevent WNV. Mosquito abatement and the use of repellents such as DEET are currently the only control measures. ⏮ *Enzyme-linked immunosorbant assay (section 36.4)*

38.3 Direct Contact Diseases Can Be Caused by Viruses

After reading this section, you should be able to:

- Report the common viral diseases spread by direct contact
- Identify typical signs and symptoms of common viral diseases spread by direct contact
- Correlate direct contact virus infection and disease severity with viral virulence factors

Recall that each microorganism has an optimal portal of entry into the host. In addition to air- and vector-borne transmission, viruses can be exchanged between people. Transmission of disease from one person to another often requires close personal contact. For example, transfer of microorganisms between people occurs by direct contact with the infected person through touching, kissing, sexual contact, contact with body fluids and secretions, or contact with open wounds. We now consider several viral diseases that are transmitted by direct contact.

Acquired Immune Deficiency Syndrome (AIDS)

AIDS (acquired immune deficiency syndrome) was the great pandemic of the second half of the twentieth century. Fortunately the 2011 report issued by the Joint United Nations Programme on HIV/AIDS and the WHO indicates that the number of new HIV infections has decreased 21% since 1997, when the epidemic began to peak globally. Today 35 million people are infected and living with HIV/AIDS worldwide (**figure 38.8**). First described in 1981, AIDS is the result of an infection by the **human immunodeficiency virus** (**HIV**), a positive-strand, enveloped RNA virus within the family *Retroviridae*. In the United States, AIDS is caused primarily by HIV-1 (some cases result from HIV-2 infection); the HIV-2 strain predominantly causes AIDS in West Africa.

HIV is acquired and may be passed from one person to another when infected blood, semen, or vaginal secretions come in contact with an uninfected person's broken skin or mucous membranes. In the developing world, AIDS affects as many women as men, with many women getting AIDS from men who have multiple sex partners. In the United States, the groups most at risk for acquiring AIDS are (in descending order) men who have unprotected sex with other men; intravenous drug users; heterosexuals who have unprotected sex with infected partners; children born of infected mothers, as well as their breast-fed infants; transfusion patients; and transplant recipients. Transmission of HIV in the latter two risk groups is exceedingly rare due to extensive testing of blood products. Transmission through semen increases HIV virulence as much as 100,000-fold relative to transmission by other routes. The mortality rate from AIDS is almost 100% within 9 to 11 years post infection, if it is not treated. The use of combined antiviral medications has significantly reduced the morbidity and mortality of AIDS in developed nations. Modern medications can provide good quality of life and extended life expectancy, making HIV infection essentially a chronic, yet controllable, disease.

HIV-1 virions are approximately 110 nm in diameter, have a cylindrical core capsid, and their membrane envelopes are peppered with viral spike proteins (**figure 38.9*a***). The core contains two copies of its RNA genome and several enzymes. Ten virus-specific proteins have been discovered. One of them, the gp120 envelope protein, facilitates attachment to a susceptible host cell (e.g., T-helper cell). Electron cryotomography imaging reveals that the gp120 spikes are approximately 14 nm long and are randomly distributed around the virion. The gp120 proteins form trimeric spikes; that is, three lobes form the final three-dimensional spike structure, which sits on three membrane-bound feet (figure 38.9*c*). ◀◀ *Electron cryotomography (section 2.4)*

Once inside the body, the virus's gp120 envelope protein (figure 38.9*b*) binds the CD4 glycoprotein in the plasma membranes of $CD4^+$ T cells, macrophages, dendritic cells, and monocytes. Because dendritic cells are present throughout the body's mucosal surfaces and bear the CD4 protein, it is possible that these are the first cells infected by HIV in sexual transmission. The virus requires a coreceptor in addition to CD4. Macrophage-tropic strains, which seem to predominate early in the disease

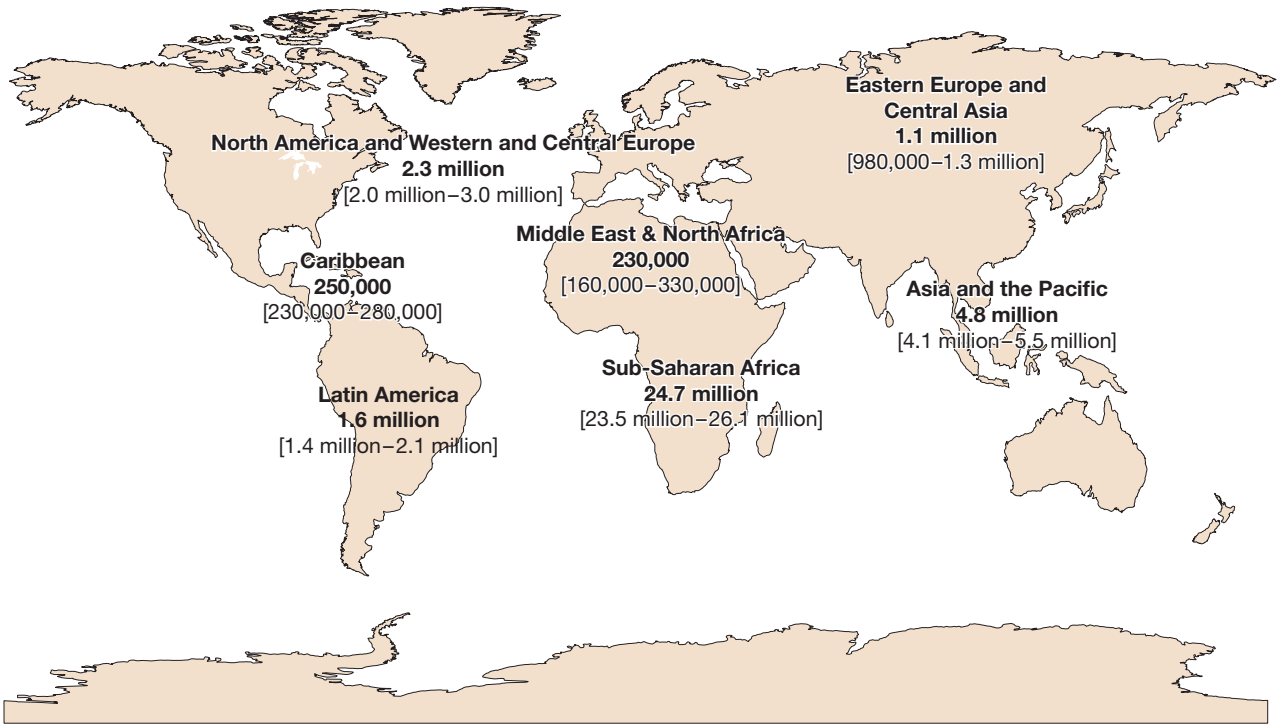

Figure 38.8 The Global HIV/AIDS View. This figure shows data from the 2013 UNAIDS report on the global AIDS epidemic. The report estimates that 35 million people are living with HIV/AIDS. Latest official data available, July 2015.

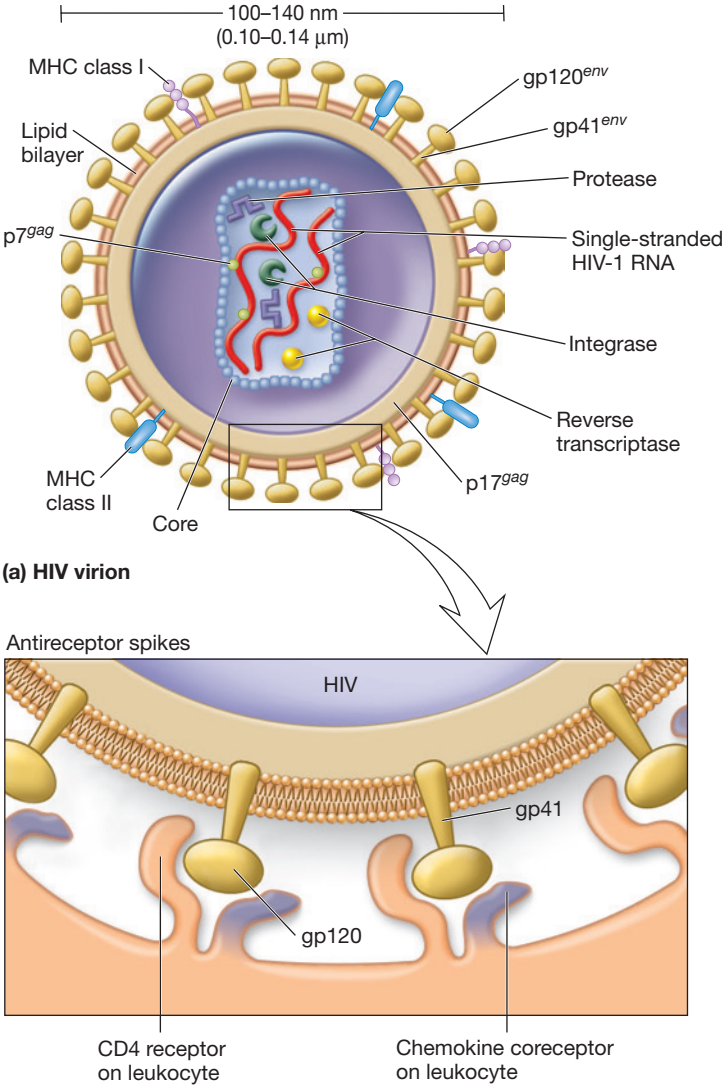

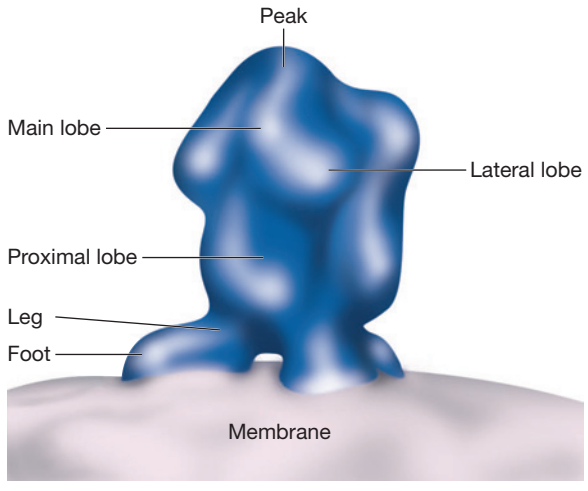

Figure 38.9 Schematic Diagram of the HIV-1 Virion. (a) The HIV-1 virion is enveloped and contains 72 external spikes. These spikes are formed by the two major viral envelope proteins, gp120 and gp41 (gp stands for glycoprotein—proteins linked to sugars—and the number refers to the mass of the protein, in kilodaltons). The HIV-1 lipid bilayer is also studded with various host proteins, including class I and class II major histocompatibility complex molecules, acquired during virion budding. The cone-shaped core of HIV-1 contains four nucleocapsid proteins (p24, p17, p9, p7), each of which is proteolytically cleaved from a 53 kDa Gag precursor by the HIV-1 protease. The phosphorylated p24 polypeptide forms the chief component of the inner shell of the nucleocapsid, whereas the p17 protein is associated with the inner surface of the lipid bilayer and stabilizes the exterior and interior components of the virion. The p7 protein binds directly to genomic RNA through a zinc finger structural motif and together with p9 forms the core. The retroviral core contains two copies of the single-stranded HIV-1 genomic RNA to which preformed viral reverse transcriptase, integrase, and protease enzymes are attached. (b) The snug attachment of HIV glycoprotein molecules (gp41 and gp120) to their specific receptors on a human cell membrane. These receptors are CD4 and chemokine coreceptors CCR5 and CXCR4 (fusin) that permit docking with the host cell and fusion with the cell membrane. (c) Surface-rendered model of the gp120 ENV protein spike of human and simian immunodeficiency viruses.

and infect both macrophages and T cells, require CCR5 (a chemokine coreceptor) as well as CD4. A second chemokine coreceptor, called CXCR-4, is used by T-cell–tropic strains that are active at later stages of infection. These strains induce the formation of syncytia (multinucleated masses of fused cells). There are rare individuals with two defective copies of the CCR5 gene who do not develop AIDS because the virus cannot infect their macrophages and T cells. People with one good copy of the CCR5 gene do get AIDS but have an altered disease presentation than those with no mutation. ◀◀ *Retroviruses (section 27.8); T-cell receptors (section 34.5)*

The virus can enter host cells by endocytosis. Infection of the host cell begins when the gp120 protein binds to the CD4 and coreceptor. Elegant studies using membrane tracking dyes show that the virus uncoats from within the endocytic compartment as the viral envelope fuses with the endosome membrane, releasing the virion contents into the cytosol (**figure 38.10*a***). Another entry method is endocytosis-independent; on the binding of the virus to some host cells, a conformational change in gp120 permits gp41 to extend, coil, and insert into the host cellular membrane. This process pulls the viral and cellular membranes together, allowing them to fuse. Inside the infected cell, the core protein remains associated with the RNA as it is copied into a single strand of DNA by the RNA-dependent DNA polymerase activity of the reverse transcriptase enzyme (*see figure 27.3*). The RNA template is next degraded by another reverse transcriptase component, ribonuclease H, and the newly synthesized DNA strand now serves as template to form a double-stranded DNA

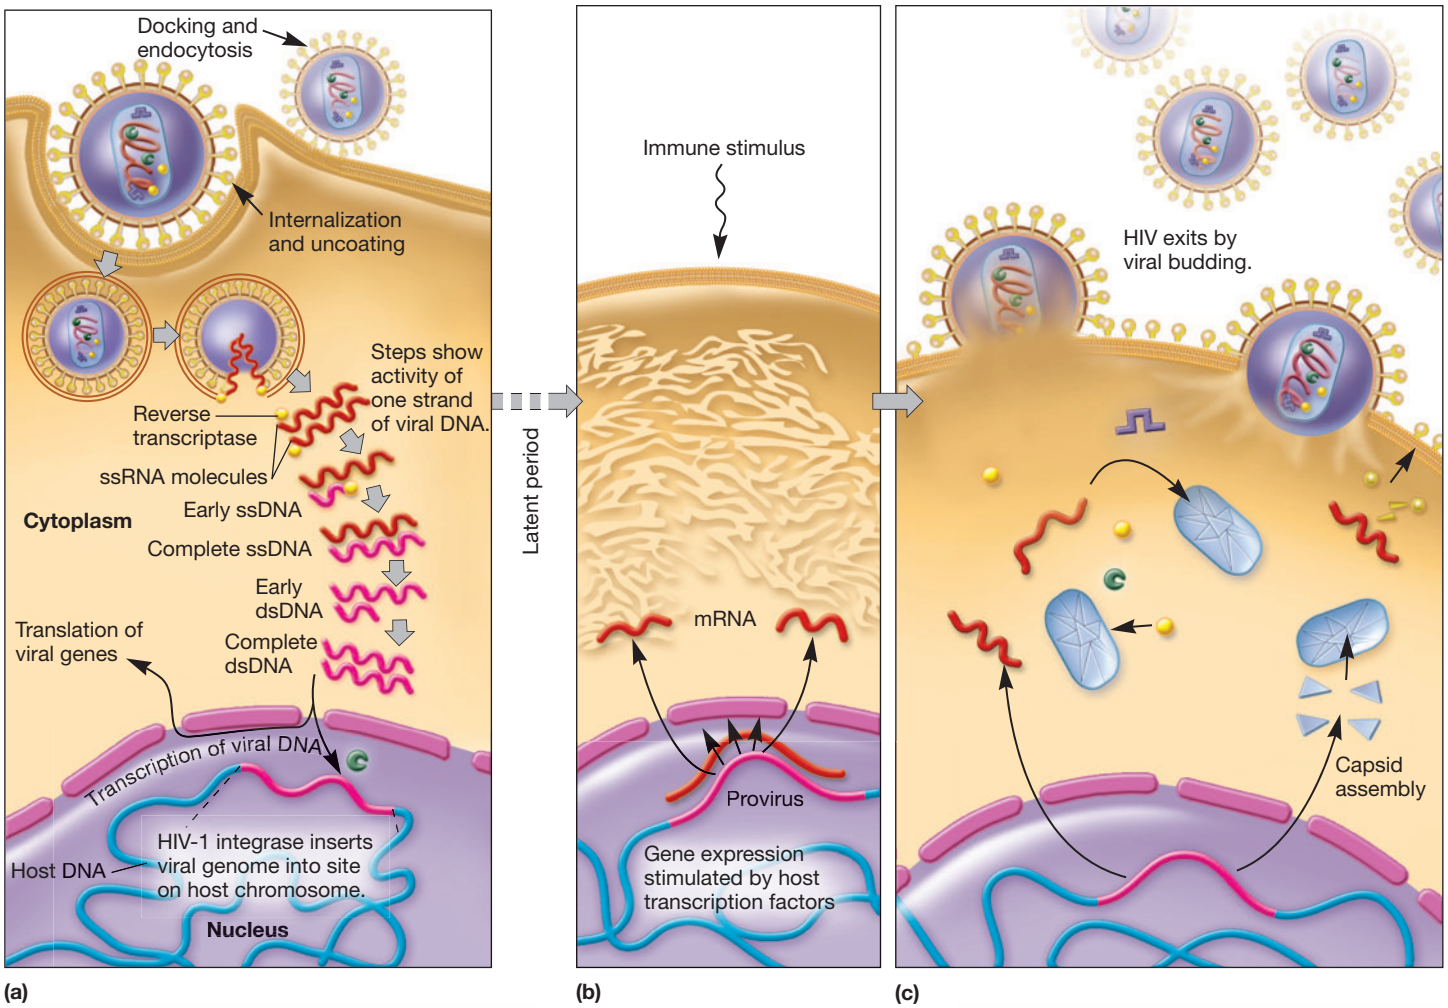

Figure 38.10 **HIV Life Cycle.** (a) The HIV virion binds to the $CD4^+$ host cell and enters the host cell by endocytosis. Membrane labeling studies show that the viral envelope fuses with the endocytic compartment releasing the virion contents into the cytosol. Reverse transcriptase catalyzes the synthesis of a single complementary strand of DNA from each of the twin RNA molecules. This DNA serves as a template for synthesis of double-stranded (ds) DNA. The dsDNA is inserted into the host chromosome as a provirus (latency). (b) The provirus genes are transcribed. (c) Viral mRNA is translated into virion components (capsid, reverse transcriptase, spike proteins), and the virion is assembled. Mature virus particles bud from the host cell, taking host membrane as their envelope.

MICRO INQUIRY *What is the function of integrase and how is its activity related to latency?*

copy of the original RNA genome. A complex of the double-stranded DNA (provirus) and integrase enzyme moves into the nucleus. Then proviral DNA is integrated into the cell's DNA through a complex sequence of reactions catalyzed by integrase. The integrated provirus can remain latent, giving no clinical sign of its presence. Alternatively the provirus can force the cell to synthesize viral mRNA (figure 38.10*b*). Some of the RNA is translated to produce viral proteins by host cell ribosomes. Viral proteins and the complete HIV-1 RNA genome are then assembled into new virions that bud from the infected host cell (figure 38.10*c*). Eventually the host cell lyses. ◀◀ *The major histocompatibility complex (section 34.4)*

Once a person becomes infected with HIV, the course of disease may vary greatly. The acute infection stage occurs 2 to 8 weeks after HIV infection. About 70% of individuals in this stage experience a brief illness referred to as acute retroviral syndrome, with symptoms that may include fever, malaise, headache, macular (small, red, spotty) rash, weight loss, lymph node enlargement (lymphadenopathy), and oral candidiasis. During this stage, the virus multiplies rapidly and disseminates to lymphoid tissues throughout the body, until an acquired immune response (antibodies and cytotoxic T cells) can be generated to bring virus multiplication under control **(figure 38.11)**. During the acute infection stage, levels of HIV increase rapidly, with 10^5 to 10^6 copies of viral RNA per milliliter of plasma being detected. It is believed that the extent to which the immune response is able to control this initial burst of virus multiplication may determine the amount of time required for progression to the next clinical stage.

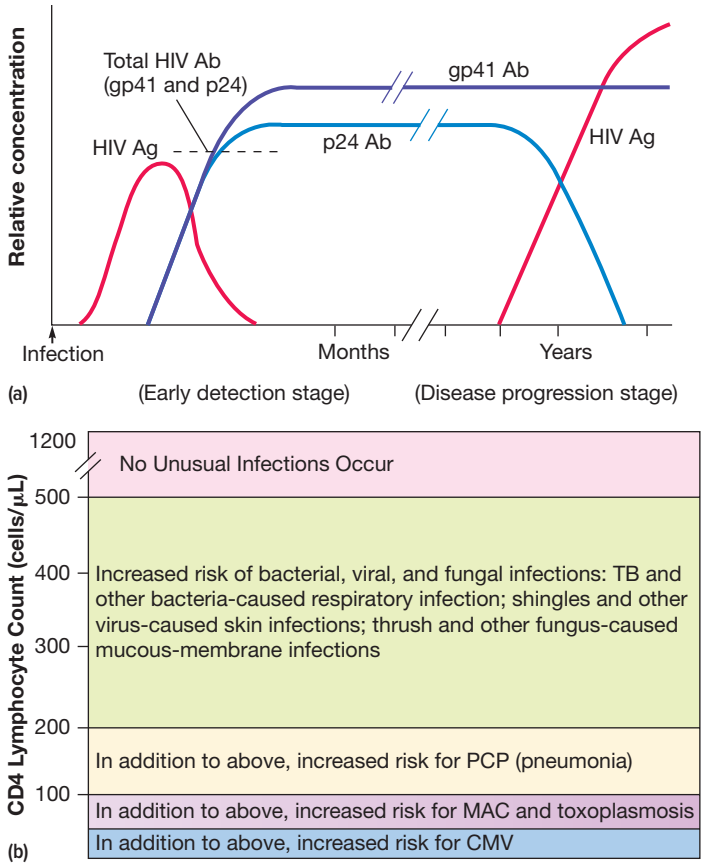

Figure 38.11 The Typical Immunological Pattern in an HIV-1 Infection. (a) HIV-1 antigen (HIV Ag) is detectable as early as 2 weeks after infection and typically occurs before IgG antibodies against gp41 and p24 develop. Seroconversion occurs when HIV-1 antibodies have risen to detectable levels. This usually takes place several weeks to months after infection. The period between HIV-1 infection and seroconversion often is associated with an acute flulike illness. HIV-1 antigen usually disappears following seroconversion but reappears in later stages of the disease. The reappearance of antigen usually indicates impending clinical deterioration. An asymptomatic HIV-1 antigen-positive individual is six times more likely to develop AIDS within 3 years than a similar individual who is HIV-1 antigen negative. Thus testing for the presence of HIV-1 antigens assists clinicians in monitoring progression of the disease. (b) As CD4 lymphocytes are destroyed by HIV, their declining numbers result in increased host susceptibility to specific infections.

The asymptomatic stage of HIV infection may last from 6 months to 10 years (or longer in some individuals). During this stage, the levels of detectable HIV in the blood decrease, but the virus continues to replicate, particularly in lymphoid tissues. Even before any changes in $CD4^+$ T cells can be detected, the virus may affect certain immune functions; for example, memory cell responses to common antigens such as tetanus toxoid or *Candida albicans*.

During the chronic symptomatic stage, which can last for months to years, virus multiplication continues and the number of $CD4^+$ T cells in the blood begins to significantly decrease. Because these T-helper cells are critically important in the generation of acquired immunity, individuals at this stage develop a variety of symptoms including fever, weight loss, malaise, fatigue, anorexia, abdominal pain, diarrhea, headaches, and lymphadenopathy. Paradoxically, some patients develop increased serum antibody production during this stage, perhaps as a result of generalized immune dysfunction. These antibodies, however, do little to protect the host from infection. As $CD4^+$ T-cell numbers continue to decline, some patients develop opportunistic infections, such as oral candidiasis (thrush), tuberculosis, and infections rarely seen in other patients, including *Mycobacterium avium* complex (MAC), cryptococcal pneumonia, cytomegalovirus (CMV) infections, acute toxoplasmosis, or *Pneumocystis* pneumonia (PCP) (figure 38.11*b*).

In order to simplify a diagnosis of HIV/AIDS disease, the CDC has recently created a revised algorithm on which HIV disease criteria are based. This was necessary to interpret often mixed results of rapid tests. Thus, a confirmed HIV case is now classified in one of five HIV infection stages (0, 1, 2, 3, or "unknown"). Stage 0 defines a diagnosis of acute (primary) HIV, where HIV tests may be equivocal within 6 months of an initial HIV diagnosis (i.e., a sequence of positive and negative HIV tests is reported after an initial positive HIV test, resulting from either the use of an older, less-sensitive test or patient antibody production that is not fully developed). If the criteria for stage 0 are not met, the stage is classified as 1, 2, 3, or unknown, depending on $CD4^+$ T-lymphocyte numbers (**table 38.1**) or whether an opportunistic illness is present (**table 38.2**). If the criteria for a stage of 0, 1, 2, or 3 cannot be met (e.g., because of missing information on CD4 test results), the stage is "unknown."

In addition to its devastating effects on the immune system, HIV infection can also lead to disease of the central nervous system when virus-infected macrophages cross the blood-brain barrier. The classical symptoms of central nervous system disease in AIDS patients are headaches, fevers, subtle cognitive changes, abnormal reflexes, and ataxia (irregularity of muscular action). Dementia and severe sensory and motor changes characterize more advanced stages of the disease. Another potential complication of HIV infection is cancer. Individuals infected with HIV-1 have an increased risk of three types of tumors: (1) the human herpesvirus 8–induced Kaposi's sarcoma (**figure 38.12**), (2) carcinomas of the mouth and rectum, and (3) B-cell lymphomas or lymphoproliferative disorders. It seems likely that the depression of the initial immune response enables other tumor-causing agents to initiate the cancers.

Laboratory diagnosis of HIV infection can be by isolation and culture of the virus or by using assays for viral reverse transcriptase activity or viral antigens. However, diagnosis is most commonly accomplished through the detection of specific anti-HIV antibodies in the blood. A number of newer antibody-based rapid tests have decreased reports of false results. The most sensitive HIV assay employs the polymerase chain reaction (PCR). PCR can be used to amplify and detect tiny amounts of viral RNA and proviral DNA in infected host cells. Quantitative PCR assays provide an estimate of a patient's viral load. This is

Table 38.1 HIV Infection Stages 1-3, Based on Age-Specific $CD4^+$ T-Lymphocyte Count or $CD4^+$ T-Lymphocyte Percentage of Total Lymphocytes*

HIV Stage*	Age at date of $CD4^+$ T-lymphocyte test					
	<1 year		1–5 years		6+ years	
	Cells/μL	%	Cells/μL	%	Cells/μL	%
1	≥1,500#	≥34#	≥1,000#	≥30#	500–1200#	≥26#
2	750–1,499	26–33	500–999	22–29	200–499	14–25
3	<750	<26	<500	<22	<200	<14

*The stage is based primarily on the $CD4^+$ T-lymphocyte count; the $CD4^+$ T-lymphocyte count takes precedence over the CD4 T-lymphocyte percentage, and the percentage is considered only if the count is missing (see www.cdc.gov).

#Normal CD4 (cell count and percent) for this age group.

Table 38.2 Disease Processes Associated with AIDS

Bacterial infection, multiple or recurrent
Candidiasis of bronchi, trachea, or lungs
Candidiasis, esophageal
Cervical cancer, invasive
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month's duration)
Cytomegalovirus disease (other than liver, spleen, or lymph nodes)
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy, HIV-related
Herpes: chronic ulcer(s) (>1 month's duration); or bronchitis, pneumonitis, or esophagitis
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month's duration)
Kaposi's sarcoma
Lymphoma, Burkitt's
Lymphoma, immunoblastic
Lymphoma, primary, of brain
Mycobacterium avium complex or *M. kansasii*
Mycobacterium tuberculosis infection, any site
Mycobacterium infection, other species or unidentified species
Pneumocystis pneumonia
Pneumonia, recurrent
Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
Toxoplasmosis of brain
Wasting syndrome

particularly significant because the level of virions in the blood, as well as the concentration of $CD4^+$ cells, is very predictive of the clinical course of the infection. The probable time to development of AIDS can be estimated from the patient's blood virion level and $CD4^+$ cell count. ◀◀ *Polymerase chain reaction amplifies targeted DNA (section 17.2)*

At present there is no cure for AIDS. Primary treatment is directed at reducing the viral load and disease symptoms, and treating opportunistic infections and malignancies. The antiviral drugs currently approved for use in HIV disease are described in detail in chapter 9. An overview of their mechanisms of action are presented in figure 9.16*b*. Briefly, there are five types. (1) Nucleoside reverse transcriptase inhibitors (NRTIs) are nucleoside analogues that inhibit the enzyme reverse transcriptase as it synthesizes viral DNA. (2) Nonnucleoside reverse transcriptase inhibitors (NNRTIs) prevent HIV DNA synthesis by selectively binding to and inhibiting the reverse transcriptase enzyme. (3) Protease inhibitors (PIs) work by blocking the activity of the HIV protease, which is responsible for generating mature viral proteins, and thus interferes with

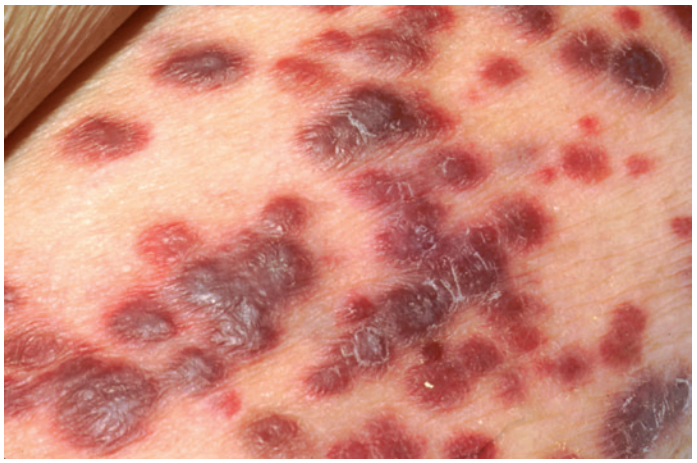

Figure 38.12 **Kaposi's Sarcoma on the Arm of an AIDS Patient.** The flat purple tumors can occur in almost any tissue.

virion assembly. (4) Integrase inhibitors (IIs) prevent the incorporation of the HIV genome into the host's chromosomes. (5) Fusion inhibitors (FIs) prevent HIV entry into cells or release of viral RNA from endosomes. The most successful treatment approach in combating HIV/AIDS is to use drug combinations. An effective combination is a cocktail of an NRTI, NNRTI, and a PI or II. The use of such drug combination use is referred to as HAART (highly active antiretroviral therapy).

The development of a vaccine for AIDS has been a long-sought goal. Among the many problems encountered in developing an HIV vaccine is the fact that the viral envelope proteins continually change their antigenic properties; HIV has a high mutation rate because reverse transcriptase lacks proofreading capabilities. One new experimental approach has been to synthesize hybrid antibodies to block the highly conserved gp120 protein from docking with host cells.

Many HIV researchers continue to take great interest in HIV-infected persons who do not develop AIDS; these individuals maintain $CD4^+$ T-cell counts of at least 600 per microliter of blood, have less than 5,000 copies of HIV RNA per milliliter of blood, and have remained this way for more than 10 years after documented infection even in the absence of antiviral agents. Other researchers are actively studying HIV patients who undergo radiation and bone marrow transplants with stem cells that lack the CCR5 co-receptor as a possible means of overcoming the disease.

Prevention and control of AIDS are achieved primarily through education. Understanding risk factors and practicing strategies to reduce risk are essential in the fight against AIDS. Barrier protection from blood and body fluids greatly limits risk of HIV infection. Education to prevent the sharing of intravenous needles and syringes is also very important. Additionally, prevention includes the continued screening of blood and blood products.

Cold Sores

A cold sore, also known as a fever blister, is a fluid-filled lesion typically found on the lips or inside the nostrils. They usually cause pain, itching, or a burning sensation, because they reside on or near nerve endings. They are caused by infection with the double-stranded DNA viruses commonly called herpes simplex viruses (genus *Simplexvirus*). Herpes simplex viruses have icosahedral capsids and are enveloped. The genome encodes approximately 100 proteins. The term herpes is derived from the Greek word meaning "to creep."

Clinical descriptions of herpes lesions date back to the time of Hippocrates (circa 400 BCE). Transmission is through direct contact of epithelial tissue surfaces with the virus. Herpes simplex virus type 1 (HSV-1; species *Human herpesvirus 1*) was initially thought to infect oral mucosal epithelium to cause cold sores or fever blisters, and herpes simplex virus type 2 (HSV-2; species *Human herpesvirus 2*) was thought to infect genital epithelium to cause genital herpes. However, both viruses can infect either tissue site. The herpesvirus genome must first enter an epithelial cell for the initiation of infection. The initial association is between proteoglycans of the epithelial cell surface and viral glycoproteins. This is followed by a specific interaction with one of several cellular receptors collectively termed HVEMs for *h*erpes*v*irus *e*ntry *m*ediators. The capsid, along with some associated proteins, then migrates along the cellular microtubule transport machinery to nuclear envelope pores. This "docking" is thought to result in the viral DNA being injected through nuclear envelope pores while the capsid remains in the cytoplasm.

Active and latent phases have been identified within an infected host. After an incubation period of about a week, the active phase begins. During the active phase, the virus multiplies explosively; between 50,000 and 200,000 new virions are produced from each infected cell. During this replication cycle, herpesvirus inhibits its host cell's metabolism and degrades host DNA, inducing apoptosis. As a result, the cell dies, releasing viral progeny to infect other cells. Such an active infection may be symptom-free, or painful blisters, containing fluid and infectious virions, may occur in the infected tissue. Indeed, apparently healthy people can transmit HSV to other hosts. This is especially true of HSV-2; it can be passed to sexual contacts even when there are no clinical signs of infection. Blisters involving the epidermis and surface mucous membranes of the lips, mouth, and gums (**gingivostomatitis**) are referred to as herpes labialis (**figure 38.13**). Primary and recurring HSV infections also may occur in the eyes, causing **herpetic keratitis** (inflammation of the cornea)—currently a major cause of blindness in the United States. Blisters involving the epidermis and surface mucous membranes of the genitals and perianal region are referred to as genital herpes. In all cases, the blisters are the result of cell lysis and development of a local inflammatory response. Fever, headache, muscle aches and pains, a burning sensation, and general soreness are frequently present during the active phase.

Although blisters usually heal within a week, after a primary infection, a very interesting virulence factor initiates the long-term survival of HSV-1–infected neurons, inducing the

Figure 38.13 Cold Sores. Herpes simplex fever blisters on the lip, caused by herpes simplex type 1 virus.

latent phase of infection. As the active infection is curtailed by a vigorous cellular immune response, viruses released from infected oral epithelia travel to the trigeminal nerve ganglion. The retreat to the nerve ganglion (cells) results in a latent state for the lifetime of the infected host, apparently to prevent further detection by the host immune system. With time, however, HSV-1 occasionally emerges from latency to grow productively, potentially attracting the wrath of the immune system. Stressful stimuli such as excessive sunlight, fever, trauma, chilling, emotional stress, and hormonal changes can reactivate the virus. Once reactivated, the virus moves from the nerve ganglion down a peripheral nerve and back to epithelial cells to produce the active phase. Interestingly, not all infected neurons die from a productive infection. Latently infected neurons and some neurons with productive HSV infection survive. How is this? It turns out that a small HSV gene can protect the infected neuron from host immune cells. The gene encodes the latency-associated transcript (LAT), an 8.5-kb RNA. LAT is spliced out of a transcript similar to that of an mRNA precursor, but no consistently expressed protein has been found to be translated from it. Instead, a long-lived 2-kb microRNA (miR-LAT) remaining in the nucleus appears to promote degradation of two proteins that inhibit cell proliferation and initiate apoptosis. In other words, miR-LAT prevents the infected cell from self-destruction, ensures neuron survival, and provides a hiding place for the virus. ⏮ *Eukaryotes use several other regulatory mechanisms (section 15.5)*

The drugs acyclovir, valacyclovir, and famciclovir are effective against cold sores. Idoxuridine and trifluridine are used to treat herpes infections of the eye. By adulthood, 70 to 90% of all people in the United States have been infected and have type 1 herpes antibodies. Diagnosis of HSV-1 infection is by ELISA and direct fluorescent antibody screening of tissue (*see figure 36.7*). Diagnosis may also be made through the recovery of viral DNA by PCR. These tests are especially useful in individuals who are particularly susceptible to severe infections.

Common Cold

The **common cold** (**coryza:** Greek *koryza*, discharge from the nostrils) is one of the most frequent infections experienced by humans. The incidence of infection is greater during the winter months, likely due to increased indoor population density, the effect of dry winter air on mucous membranes, and the decreased immune function that results from the direct effect of cold temperatures. About 50% of the cases are caused by rhinoviruses (Greek *rhinos*, nose), which are nonenveloped, positive-strand RNA viruses in the family *Picornaviridae*. There are over 115 distinct serotypes, and each of these antigenic types has a varying capacity to infect the nasal mucosa and cause a cold. In addition, immunity to many of them is transitory. Several other respiratory viruses are also associated with colds (e.g., coronaviruses and parainfluenza viruses). Thus colds are common because of the diversity of rhinoviruses, the involvement of other respiratory viruses, and the lack of a durable immunity. ⏮ *Plus-strand RNA viruses (section 27.5)*

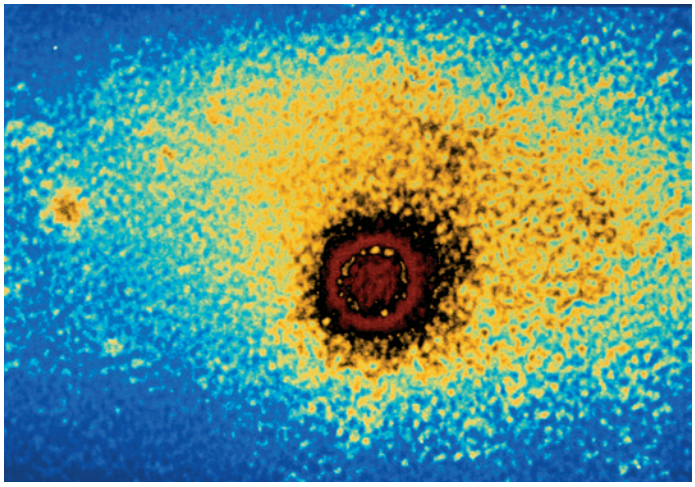

Figure 38.14 Rhinovirus Virion. One of over 100 types of virus that cause the common cold.

Rhinoviruses provide an excellent example of the medical relevance of research on virion morphology (**figure 38.14**). The complete rhinovirus capsid structure has been elucidated with the use of X-ray diffraction techniques. The results help explain rhinovirus resistance to human immune defenses. The capsid protein that recognizes and binds to host cell surface molecules during infection lies at the bottom of a surface cleft (sometimes called a "canyon") about 12 Å deep and 15 Å wide. Thus the binding site is well protected from the immune system while it carries out its functions. Moreover, with greater than 100 serotypes of human rhinoviruses, immunity to one strain may not protect against another strain, making vaccine development problematic. Possibly drugs that could fit in the cleft and interfere with virus attachment can be designed.

Viral invasion of the upper respiratory tract is the basic mechanism in the pathogenesis of a cold. The virus enters the body's cells by binding to cellular adhesion molecules. The clinical manifestations include the familiar nasal stuffiness, sneezing, scratchy throat, and watery discharge from the nose. The discharge becomes thicker and assumes a yellowish appearance over several days. General malaise is commonly present. Fever is usually absent in uncomplicated colds, although a low-grade (100 to 102°F, 37.8 to 38.9°C) fever may occur in infants and children. The disease usually runs its course in about a week. Diagnosis of the common cold is made from observations of clinical symptoms. There are no procedures for direct examination of clinical specimens or for serological diagnosis.

Sources of the cold viruses include infected individuals excreting viruses in nasal secretions, airborne transmission over short distances by way of moisture droplets, and transmission on contaminated hands or fomites. Epidemiological studies of rhinovirus colds have shown that the familiar explosive, noncontained sneeze may not play an important role in virus spread. Rather, hand-to-hand contact between a rhinovirus "donor" and a susceptible "recipient" is more likely. The common cold occurs worldwide with two main seasonal peaks, spring and early autumn. Infection is most common early in

life and generally decreases with an increase in age. Treatment for the common cold is mainly rest, extra fluids, and the use of anti-inflammatory agents for alleviating local and systemic discomfort.

Cytomegalovirus Inclusion Disease

Cytomegalovirus inclusion disease is caused by human cytomegalovirus (HCMV), a member of the family *Herpesviridae* (species *Human herpesvirus 5*). HCMV is an enveloped, double-stranded DNA virus with an icosahedral capsid. Most people become infected with this virus at some time during their life; in the United States, as many as 80% of individuals older than thirty-five years have been exposed and carry a lifelong infection. Although most HCMV infections are asymptomatic, certain groups are at risk for serious illness and long-term effects. For example, HCMV remains the leading cause of congenital virus infection in the United States, a significant cause of transfusion-acquired infections, and a frequent contributor to morbidity and mortality among organ transplant recipients and immunocompromised individuals (especially AIDS patients). Because the virus persists in the body, it is shed for several years in saliva, urine, semen, and cervical secretions.

HCMV can infect any cell of the body, where it multiplies slowly and causes the host cell to swell in size; hence the prefix "cytomegalo-," which means "enlarged cell." Cytomegaloviruses are well known for their ability to interfere with many host immune functions, such as antigen presentation, cytokine production, and natural killer cell activity. Infected cells contain unique **intranuclear inclusion bodies** and cytoplasmic inclusions (**figure 38.15**). In fatal cases, cell damage is seen in the gastrointestinal tract, lungs, liver, spleen, and kidneys. In less-severe cases, cytomegalovirus inclusion disease symptoms resemble those of infectious mononucleosis.

Laboratory diagnosis is by virus isolation and culture from urine, blood, semen, and lung or other infected tissue. Serological tests for anti-HCMV IgM and IgG or by rapid test kits also are available. Detection of HCMV nucleic acid by PCR is also used.

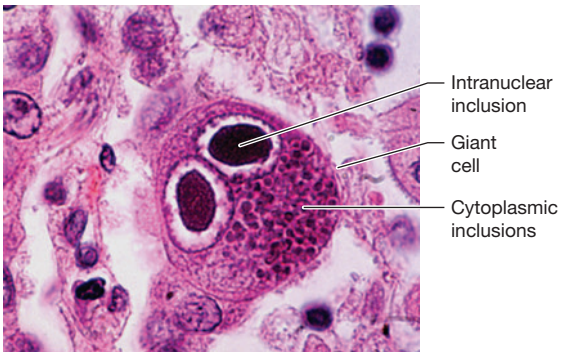

Figure 38.15 Cytomegalovirus Inclusion Disease. Light micrograph of a giant cell in a lung section infected with cytomegalovirus (×480). Cells containing intranuclear inclusion bodies have a typical "owl-eyed" appearance because of the clear halo that surrounds the inclusion. Sometimes inclusions also are visible in the cytoplasm.

The virus has a worldwide distribution, especially in developing countries, where infection is universal by childhood. The prevalence of this disease increases with poor hygiene or as socioeconomic status declines. The antivirals ganciclovir, valganciclovir, foscavir, and cidofovir are used only for high-risk patients. Infection can be prevented by avoiding close personal contact (including sexual) with an actively infected individual. Transmission by blood transfusion or organ transplantation can be avoided by using blood or organs from seronegative donors.

Genital Herpes

Genital herpes is a lifelong infection caused by herpes simplex virus, predominantly type 2 (HSV-2). (**figure 38.16*a***). These viruses have a very short replication cycle. The core DNA is linear

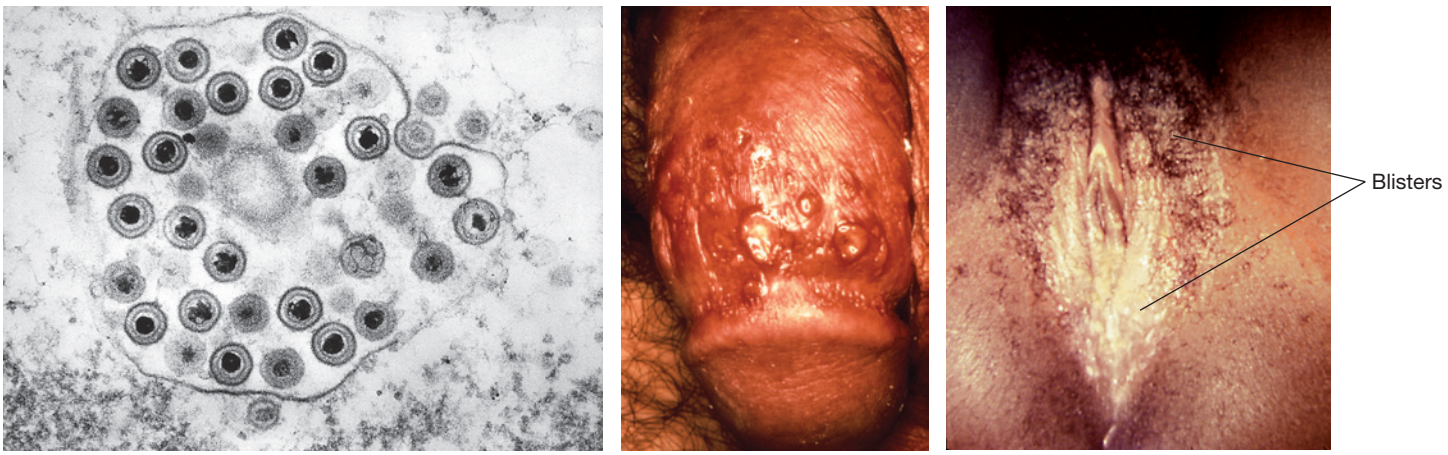

Figure 38.16 Genital Herpes. (a) Herpes simplex virus virions inside an infected cell. (b) Herpes vesicles on the penis. The vesicles contain fluid that is infectious. (c) Herpes blistering around the vaginal opening.

MICRO INQUIRY *Where does HSV-2 reside during latency?*

and double stranded. The HSV-2 envelope contains at least eight glycoproteins. HSV-2 is most frequently transmitted by sexual contact. Infection begins when the virus is introduced into a break in the skin or mucous membranes. The virus infects the epithelial cells of the external genitalia, the urethra, and the cervix (figure 38.16*b,c*). Rectal and pharyngeal herpes are also transmitted by sexual contact.

The details of HSV-2 infection are very similar to those of HSV-1. In the case of HSV-2, the viruses retreat to nerve cells in the sacral plexus of the spinal cord, where they remain in a latent form. As described for HSV-1, during the latent phase, the host cell does not die. Because viral genes are not expressed, the infected person is symptom-free. It should be noted that both primary infection and reactivation can occur without any symptoms, and apparently healthy people can transmit HSV-2 to their sexual partners or their newborns during vaginal delivery, the latter leading to **congenital** (**neonatal**) **herpes.** Congenital herpes is one of the most life-threatening of all infections in newborns, affecting approximately 30 out of every 100,000 babies per year in the United States. It can result in neurological involvement, as well as blindness. As a result, any pregnant female who has active or new genital herpes should have a cesarian section instead of delivering vaginally. For unknown reasons, HSV-2 is also associated with a higher-than-normal rate of cervical cancer and miscarriages.

Diagnosis of HSV-2 infection is by ELISA screening of blood or serum, direct fluorescent antibody testing of tissue, and/or PCR. Although there is no cure for genital herpes, oral use of the antiviral drugs acyclovir, valacyclovir, or famciclovir has proven to be effective in ameliorating the recurring blister outbreaks. However, famciclovir seems somewhat less effective for suppression of viral shedding. Topical acyclovir is also effective in reducing virus shedding, the time until the crusting of blisters occurs, and new lesion formation.

In the United States, the incidence of genital herpes has increased so much during the past several decades that it is now a very common sexually transmitted disease. It is estimated that 776,000 people in the United States get new herpes infections each year. That's 15.5% of individuals aged fourteen to forty-nine infected with the HSV-2, annually.

Human Herpesvirus 6 Infection

Human herpesvirus 6 (HHV-6) is the etiologic agent of **exanthem subitum** (Greek *exanthema*, rash) in infants. HHV-6 is a unique member of the family *Herpesviridae* that is distinct serologically and genetically from the other herpesviruses. The virus envelope encloses an icosahedral capsid and a core containing double-stranded DNA. The disease caused by HHV-6 was originally termed **roseola infantum** and then given the ordinal designation **sixth disease** to differentiate it from other exanthems and roseolas. Exanthem subitum is a short-lived disease characterized by a high fever of 3 to 4 days' duration, after which the temperature suddenly drops to normal and a macular rash appears on the trunk and then spreads to other areas of the body. HHV-6 infects over 95% of the U.S. infant population, and most children are seropositive for HHV-6 by three years of age. $CD4^+$ T-cells are the main site of viral replication, whereas monocytes are in an infected, latent state. In adults, HHV-6 is commonly found in peripheral-blood mononuclear cells and saliva, suggesting that the infection is lifelong. Since the salivary glands are the major site of latent infection, transmission is probably by way of saliva.

Because HHV-6 produces latent infections, it occasionally reactivates in immunocompromised hosts, leading to pneumonitis. Furthermore, HHV-6 has been implicated in several other diseases (lymphadenitis and multiple sclerosis) in immunocompetent adults. Diagnosis is by immunofluorescence or enzyme immunoassay, or PCR. To date, there is no antiviral therapy or prevention.

Human Parvovirus B19 Infection

Since its discovery in 1974, **human parvovirus B19** (family *Parvoviridae*, genus *Erythrovirus*) has emerged as a significant human pathogen. B19 virions are uniform, icosahedral, naked particles approximately 23 nm in diameter. Parvoviruses have a genome composed of one ssDNA molecule of about 5,000 bases. Parvoviruses are among the simplest of the DNA viruses. The genome is so small that it must resort to the use of overlapping genes to encode the very few proteins it encodes. The genome does not code for any enzymes, and the virus must use host cell enzymes for all biosynthetic processes. Thus viral DNA can only be replicated in the nucleus during the S phase of the cell cycle, when the host cell replicates its own DNA. Because the viral genome is single stranded and linear, the host DNA polymerase must be tricked into copying it. By using a self-complementary sequence at the ends of the viral DNA, the parvovirus genome folds back on itself to form a primer for replication (*see figure 27.19*). This is recognized by the host DNA polymerase and DNA replication ensues. ⏮ *Parvoviruses (section 27.3)*

A spectrum of disease is caused by parvovirus B19 infection, ranging from mild symptoms (fever, headache, chills, malaise) in normal persons and **erythema infectiosum** (**figure 38.17**) in children (also called **fifth disease**), to a joint disease syndrome in

Figure 38.17 Erythema infectiosum. The facial rash of fifth disease, sometimes called "slapped face syndrome."

adults. More serious diseases include aplastic crisis in persons with sickle cell disease and autoimmune hemolytic anemia, and pure red cell aplasia due to persistent B19 virus infection in immunocompromised individuals. The B19 parvovirus can also infect a fetus, resulting in anemia, fetal hydrops (the accumulation of fluid in tissues), and spontaneous abortion. This has prompted a grass-roots awareness of B19 complications among school teachers who may be pregnant. It is assumed that the natural mode of infection is by the respiratory route. The average incubation period is 4 to 14 days. Approximately 20% of infected individuals are asymptomatic, and a smaller percentage of infected individuals have symptoms for up to 3 weeks. Infection typically results in a lifelong immunity to B19.

B19 infection is typically detected by serology (presence of anti-B19 antibodies) and/or PCR. Antiviral antibodies appear to represent the principal means of defense against infection and disease. The treatment of individuals suffering from acute and persistent B19 infections with commercial immunoglobulins containing anti-B19 and human monoclonal antibodies to B19 is an effective therapy. As with other diseases spread by contact with respiratory secretions, frequent hand-washing is the best prevention of the disease.

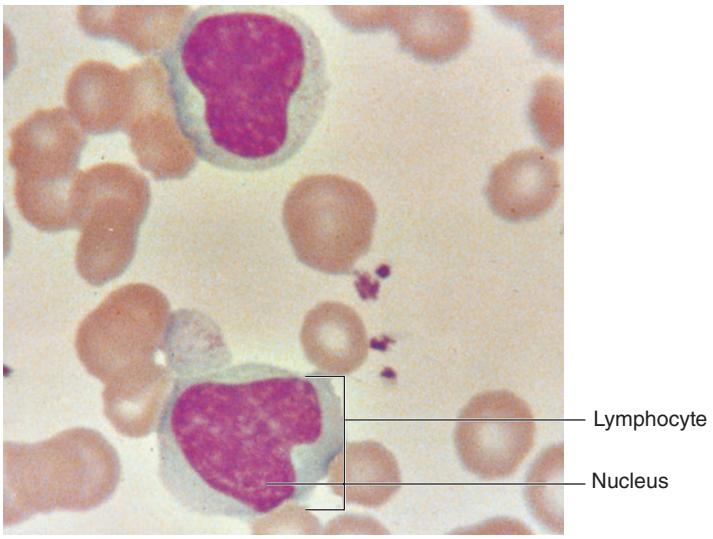

Figure 38.18 Evidence of Epstein-Barr Virus Infection in the Blood Smear of a Patient with Infectious Mononucleosis. Note the abnormally large lymphocytes (sometimes called Downey cells) containing indented nuclei with light discolorations.

Mononucleosis (Infectious)

Epstein-Barr virus (EBV; species *Human herpesvirus 4*) is a member of the family *Herpesviridae*. EBV exhibits the characteristic herpesvirus morphology: all herpesviruses consist of an icosahedral capsid (approximately 125 nm in diameter) surrounded by an envelope. The capsid contains double-stranded (ds) DNA. Its dsDNA exists as a linear form in the mature virion and a circular episomal form in latently infected host cells. EBV is the etiologic agent of **infectious mononucleosis** (mono), a disease whose symptoms closely resemble those of cytomegalovirus-induced mononucleosis. Because EBV occurs in oropharyngeal secretions, it can be spread by mouth-to-mouth contact (hence the terminology infectious and kissing disease) or shared drinking bottles and glasses. A person gets infected when the virus from someone else's saliva makes its way into epithelial cells lining the throat. After a brief bout of multiplication in the epithelial cells, the new virions are shed and infect memory B cells. Infected B cells rapidly proliferate and take on an atypical appearance (Downey cells) that is useful in diagnosis (**figure 38.18**). The disease is manifested by enlargement of lymph nodes and spleen, sore throat, headache, nausea, general weakness and tiredness, and a mild fever that usually peaks in the early evening. The disease lasts for 1 to 6 weeks and is self-limited. Like other herpesviruses, EBV becomes latent in its host.

Treatment of infectious mononucleosis is largely supportive and includes plenty of rest. Diagnosis is usually confirmed by demonstration of an increase in circulating mononuclear cells, along with a serological test for nonspecific (cross-reactive) antibodies, specific anti-viral antibodies, or identification of viral nucleic acid. Several rapid tests are available.

The peak incidence of mononucleosis occurs in people fifteen to twenty-five years of age. Collegiate populations, particularly those in upper socioeconomic classes, have a high incidence of the disease. About 50% of college students have no immunity, and approximately 15% of these can be expected to contract mononucleosis. People in lower socioeconomic classes tend to acquire immunity to the disease because of early childhood infection. EBV may well be the most common virus in humans, as it infects 80 to 90% of all adults worldwide. EBV infections are associated with the cancers Burkitt lymphoma in tropical Africa and nasopharyngeal carcinoma in Southeast Asia, East and North Africa, and in Inuit populations.

Viral Hepatitides

Inflammation of the liver is called **hepatitis** (pl., hepatitides; Greek *hepaticus*, liver). Currently 11 viruses are recognized as causing hepatitis. Two are herpesviruses (cytomegalovirus [CMV] and Epstein-Barr virus [EBV]) and nine are hepatotropic viruses that specifically target liver hepatocytes. EBV and CMV cause mild, self-resolving forms of hepatitis with no permanent hepatic damage. Both viruses cause the typical infectious mononucleosis syndrome of fatigue, nausea, and malaise. Of the nine human hepatotropic viruses, only five are well characterized; hepatitis G (**table 38.3**) and TTV (transfusion-transmitted virus) were only recently discovered. Hepatitis A (sometimes called infectious hepatitis) and hepatitis E are transmitted by fecal-oral contamination and discussed in the section on food-borne and waterborne diseases (section 38.4). The other major types include hepatitis B (sometimes called serum hepatitis), hepatitis C, and hepatitis D.

Table 38.3 Characteristics of Hepatitides Caused by Hepatotropic Viruses

Disease	Genome	Classification	Transmission	Characteristic	Prevention
Hepatitis A	RNA	*Picornaviridae, Hepatovirus*	Fecal-oral	Subclinical, acute infection	Killed HAV (Havrix vaccine)
Hepatitis B	DNA	*Hepadnaviridae, Orthohepadnavirus*	Blood, needles, body secretions, placenta, sexually	Subclinical, acute chronic infection; cirrhosis; primary hepatocarcinoma	Recombinant HBV vaccines
Hepatitis C	RNA	*Flaviviridae, Hepacivirus*	Blood, sexually	Subclinical, acute chronic infection; primary hepatocarcinoma	Routine screening of blood
Hepatitis D	RNA	Satellite	Blood, sexually	Coinfection with HBV required for satellite replication	HBV vaccine
Hepatitis E	RNA	*Hepeviridae, Hepevirus*	Fecal-oral	Subclinical, acute infection (but high mortality in pregnant women)	Improve sanitary conditions

Hepatitis B (serum hepatitis) is caused by **hepatitis B virus** (HBV), an enveloped virus with a partially double-stranded circular DNA genome of complex structure. HBV is classified as an *Orthohepadnavirus* within the family *Hepadnaviridae*. Members of this family are reverse-transcribing DNA viruses, so named because they encode a reverse transcriptase enzyme that is used to generate their genomes. ◀◀ *Reverse transcribing DNA viruses (section 27.8)*

Serum from individuals infected with HBV contains three distinct antigenic particles: a spherical 22 nm particle, a 42 nm spherical particle (containing DNA and a polymerase) called the **Dane particle,** and tubular or filamentous particles that vary in length (**figure 38.19**). The viral genome is 3.2 kb in length, consisting of four partially overlapping, open-reading frames that encode viral proteins. Viral multiplication takes place predominantly in hepatocytes. The infecting virus encases its double-shelled Dane particles within membrane envelopes coated with hepatitis B surface antigen (HBsAg). The inner nucleocapsid core antigen (HBcAg) encloses a single molecule of double-stranded HBV DNA and polymerase. HBsAg in body fluids is (1) an indicator of active hepatitis B infection, (2) used in the large-scale screening of blood for HBV, and (3) the basis for the first vaccine for human use developed by recombinant DNA technology. Diagnosis of HBV is made by detection of HBsAg in unimmunized individuals or HBcAg antibody. Viral load is determined using PCR to measure HBV nucleic acid.

Hepatitis B virus is normally transmitted through blood or other body fluids (saliva, sweat, semen, breast milk, urine, feces) and body-fluid–contaminated equipment (including shared intravenous needles). The virus can also pass through the placenta to the fetus of an infected mother. It is estimated that there have been 2 billion persons worldwide infected with HBV, and more than 400 million persons with chronic, lifelong HBV infection. In the United States, there are currently 40,000 new cases annually and one million chronically infected Americans. Additionally, 5,000 persons die yearly from HBV-related complications.

The clinical signs of hepatitis B vary widely. Most cases are asymptomatic. However, sometimes fever, loss of appetite, abdominal discomfort, nausea, fatigue, and other symptoms gradually appear following an incubation period of 1 to 3 months. The virus infects hepatic cells and causes liver tissue degeneration and the release of liver-associated enzymes (transaminases) into the bloodstream. This is followed by jaundice, the accumulation

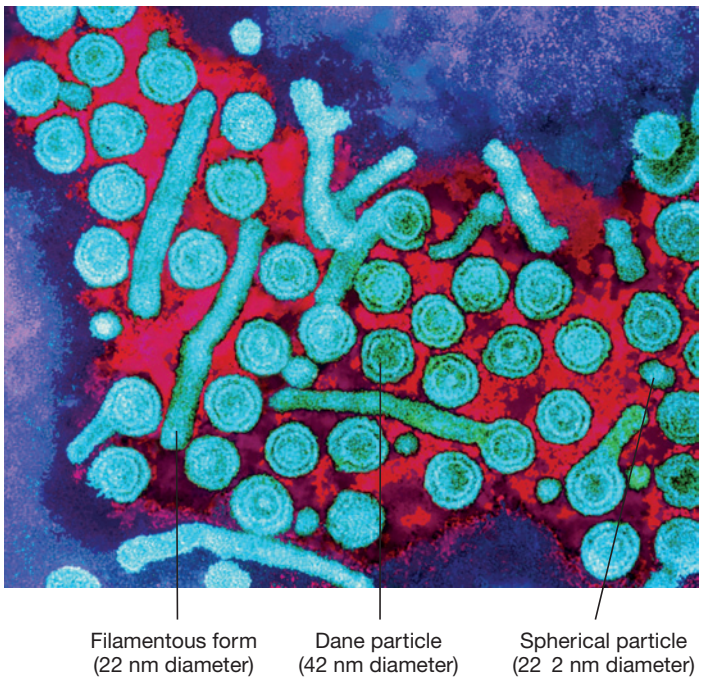

Figure 38.19 Hepatitis B Virus in Serum. Electron micrograph (×210,000) showing the three distinct types of hepatitis B antigenic particles. The spherical particles and filamentous forms are small spheres or long filaments without an internal structure, and only two of the three characteristic viral envelope proteins appear on their surface. Dane particles are the complete, infectious virion.

of bilirubin (a breakdown product of hemoglobin) in the skin and other tissues with a resulting yellow appearance. Chronic hepatitis B infection also causes the development of primary liver cancer, known as hepatocellular carcinoma. HBV is second only to tobacco as a known cause of human cancer.

General measures for prevention and control involve (1) excluding contact with HBV-infected blood and secretions, and minimizing accidental needlesticks; (2) passive prophylaxis with intramuscular injection of hepatitis B immune globulin within 7 days of exposure; and (3) active prophylaxis with a recombinant vaccines that contains S antigen (envelope protein, HBsAg). The vaccine is widely used and recommended for routine prevention of HBV in infants to eighteen-year-olds and risk groups of all ages (e.g., household contacts of HBV carriers, health-care and public safety professionals, men who have sex with other men, international travelers, hemodialysis patients). Recommended treatments for HBV include pegylated interferon-α (IFN-α), entecavir (ETV), and tenofovir disoproxil fumarate (TDF) as the first-line antiviral chemotherapy.

Hepatitis C is caused by **hepatitis C virus** (HCV), which has a 50-nm enveloped virion that contains a single strand of linear RNA. HCV is a member of the family *Flaviviridae* and is classified into multiple genotypes. It is transmitted by contact with virus-contaminated blood, by the fecal-oral route, by in utero transmission from mother to fetus, sexually, or through organ transplantation. Diagnosis is made by ELISA, which detects serum antibody to a recombinant antigen of HCV, and nucleic acid detection by PCR. HCV is found worldwide. Prior to routine screening, HCV accounted for more than 90% of hepatitis cases developed after a blood transfusion. Worldwide, hepatitis C has reached epidemic proportions, 2 million new cases reported annually. In the United States, HCV is the most common chronic blood-borne infection; approximately 3.2 million persons are chronically infected and 16,500 new cases occur annually. Currently HCV has a 48% annual fatality rate in the United States. Furthermore, HCV is the leading reason for liver transplantation in the United States. According to the U.S. Department of Veterans Affairs, 75 percent of people in the United States infected with HCV have genotype 1. Treatment for genotype 1 disease is now with the 2014 FDA-approved drug combination of sofosbuvir (a nucleotide analog polymerase inhibitor) and ledipasvir (an HCV replication inhibitor). A 12-week treatment with this drug combination results in complete cure of the virus from the host. Other genotypes continue to be treated with various combinations of antiviral drugs, including ribavirin and sofosbuvir for at least 12 weeks. This therapy can rid the virus in up to 80% of those infected with genotype 2. For genotype 3 infection, ribovirin and sofosbuvir are also recommended except for rare occasions where they are combined with pegylated (coupled to polyethylene glycol) recombinant IFN-α to effect cure.

In 1977 a cytopathic hepatitis agent termed the **delta agent** was discovered. Later it was called the hepatitis D virus (HDV) and the disease hepatitis D was designated. It is now named hepatitis delta virus. There are three known genotypes of HDV: genotype 1 has a worldwide distribution; genotype 2 exists in Taiwan, Japan, and northern Asia; and genotype 3 is found in South America. HDV is a satellite virus that is dependent on hepatitis B virus to provide the envelope protein (HBsAg) for its own replication. HDV's dependence on HBV means that HDV only replicates in liver cells coinfected with actively replicating HBV. HDV is spread only to persons who are already infected with HBV (superinfection) or to individuals who get HBV and the satellite at once (coinfection). Thus, the negative-strand RNA of HDV is smaller than the RNA of the smallest picornaviruses, and its circular conformation differs from the linear structure typical of animal negative-strand RNA viruses.

The primary laboratory tools for diagnosis of an HDV infection are serological tests for antidelta antibodies. Treatment of patients with chronic HDV infection remains difficult. There is no FDA-approved treatment for HDV. Some positive results have been obtained with interferon-α treatment for 3 months to 1 year. Liver transplantation is the only alternative to chemotherapy. Worldwide, there are approximately 15 million individuals infected with HDV. Thus because of the propensity of HDV to cause acute as well as chronic liver disease, continued incursion of HDV into areas of the world where persistent hepatitis B infection is endemic has serious implications. Prevention and control involve the widespread use of the hepatitis B vaccine.

Warts

Warts, or verrucae (Latin *verruca*, wart), are horny projections on the skin caused by human papillomaviruses. Human papillomavirus (HPV) is the name given to a group of DNA viruses that includes more than 100 different strains, some of which are oncogenic (cancer-associated) (**figure 38.20*a***). They differ in the types of epithelium they infect; some infect cutaneous sites, whereas others infect mucous membranes. More than 30 of these viruses are sexually transmitted; they can cause genital warts—soft, pink cauliflower-like growths that occur on the genital area of women (figure 38.20*b*) and men, as well as on the anal region (figure 38.20*c*). Genital warts are the most common sexually transmitted disease in the United States today.

Papillomaviruses are placed in the family *Papillomaviridae*. These viruses have nonenveloped icosahedral capsids with a double-stranded, supercoiled, circular DNA genome. At least eight distinct genotypes produce benign epithelial tumors that vary in respect to their location, clinical appearance, and histopathologic features. Warts occur principally in children and young adults, and are limited to the skin and mucous membranes. The viruses are spread between people by direct contact; autoinoculation occurs through scratching. Four major kinds of warts are **plantar warts, verrucae vulgaris, flat** or **plane warts,** and **anogenital condylomata (venereal warts).** Treatment includes physical destruction of the wart by electrosurgery, cryosurgery with liquid nitrogen or solid CO_2, laser fulguration (drying), direct application of the drug podophyllum to the wart, or injection of IFN-α.

Anogenital condylomata are sexually transmitted. Once HPV enters the body, the incubation period is 1 to 6 months.

(b)

(c)

Figure 38.20 **Human Papillomavirus (HPV).** (a) Transmission electron micrograph of HPV virions. (b) Genital warts of the vaginal labia. (c) Genital warts in the anal region.

Genital infection with HPV is of considerable importance because specific types of genital HPV play a major role in the pathogenesis of epithelial cancers of the male and female genital tracts. HPV strains are designated by numbers and can be divided into "high-risk" (oncogenic or cancer causing) and "low-risk" (nononcogenic) strains. Four high-risk strains (6, 11, 16, and 18) are responsible for 70% of cervical cancers and 90% of genital warts. Specifically they have been found in association with invasive cancers of the cervix, vulva, penis, or anus (and other sites). Other high-risk strains have been found to be associated with cancers no more than 1% of the time. These other strains cause benign or low-grade cervical cell changes and genital warts but are rarely, if ever, associated with invasive cancer.

About 79 million Americans are currently infected with HPV. About 14 million become newly infected annually. Frequent sexual contact is the most consistent predictor of HPV infection; the number of sexual partners is proportionately linked to the risk of HPV infection. About half of the infected individuals are sexually active teens and young adults (fifteen to twenty-four years of age). HPV is typically transmitted through direct contact, especially during vaginal or anal sex. Other types of genital contact in the absence of penetration (oral-genital, manual-genital, and genital-genital contact) can also lead to infection with HPV, but infection by these routes is less common. Most HPV infections are asymptomatic, transient, and clear on their own without treatment. However, in some individuals, HPV infections result in genital warts weeks or months after infection.

A quadrivalent vaccine against four strains of HPV (6, 11, 16, and 18) was licensed in the United States in 2006. The vaccine is made from noninfectious HPV-like particles and was recommended by the U.S. Advisory Committee on Immunization It is recommended for prophylactic use in females eleven to twenty-six years of age and males eleven to twenty-one years of age. The vaccine has been found to be safe and to

cause no serious side effects. Clinical trials have demonstrated 100% efficacy in preventing cervical precancers caused by the four HPV strains and nearly 100% efficacy in preventing vulvar and vaginal precancers and genital warts caused by the same four strains.

38.4 Food and Water Are Vehicles for Viral Diseases

After reading this section, you should be able to:

- Report the common food-borne and waterborne viral diseases
- Identify typical signs and symptoms of common food-borne and waterborne viral diseases
- Correlate food-borne and waterborne virus infection and disease severity with viral virulence factors

Food and water have been recognized as potential carriers (vehicles) of disease since the beginning of recorded history. Collectively more infectious diseases are transmitted by these two routes than any other. A few of the many human viral diseases that are food- and waterborne are now discussed. ▶▶| *Purification and sanitary analysis ensure safe drinking water (section 43.1)*

Gastroenteritis (Viral)

Acute viral gastroenteritis, inflammation of the stomach or intestines, is caused by six major categories of viruses: adenoviruses, astroviruses, bocaparvoviruses (bocaviruses and parvoviruses), caliciviruses (noroviruses and sapoviruses), parechoviruses, and rotaviruses (**figure 38.21**). The medical importance of these viruses is summarized in **table 38.4**. Acute viral gastroenteritis is a common illness, with a global incidence of 3 to 5 billion cases and 1.4 million deaths annually. Viral diarrhea is an especially common cause of mortality among children less than five years of age in developing countries, with 1.7 billion episodes and 700,000 deaths estimated to occur annually. In the United States, acute diarrhea in children accounts for more than 3.5 million cases, resulting in more than 500,000 office visits, 55,000 hospitalizations, and 30 deaths per year. The viruses responsible for gastroenteritis are transmitted by the fecal-oral route.

Noroviruses are estimated to cause about 20 million U.S. cases of acute gastroenteritis (at least 50% of all food-borne outbreaks of gastroenteritis). Furthermore, noroviruses are responsible for 1.9 million outpatient visits, 400,000 emergency department visits (primarily in young children), about 56,000 to 71,000 hospitalizations and 570–800 deaths (mostly of young children and the elderly). At least another 20% of global cases and the majority of severe cases of diarrhea in children under age 5 are due to rotaviruses, which are the leading cause of severe diarrhea in infants and children worldwide. Prior to the widespread use of vaccine to counter rotavirus in the U.S., there were more than 400,000 doctor visits, more than 200,000 emergency room visits, 55,000 to 70,000 hospitalizations, and 20 to 60 deaths, annually. Vaccination has reduced yearly rotavirus hospitalizations to fewer than 20,000, and deaths to single digits. Adenoviruses, sapoviruses, and astroviruses are the other major viral agents responsible for gastroenteritis. Genomic testing of patients with gastroenteritis has revealed two additional viral causes: human bocavirus 2 and parechoviruses (table 38.4).

The average incubation period for most of these viral diseases is 1 to 2 days. Viral gastroenteritis is seen most frequently in infants one to eleven months of age, where the virus attacks the epithelial cells of the upper intestinal villi, causing malabsorption, impairment of sodium transport, and diarrhea. The clinical manifestations typically range from asymptomatic to a relatively mild diarrhea with headache and fever, to a severe, watery, nonbloody diarrhea with abdominal cramps. Fatal dehydration is most common in young children. Vomiting is almost always present, especially in children. Viral gastroenteritis can be self-limiting. Treatment is designed to provide relief through the use

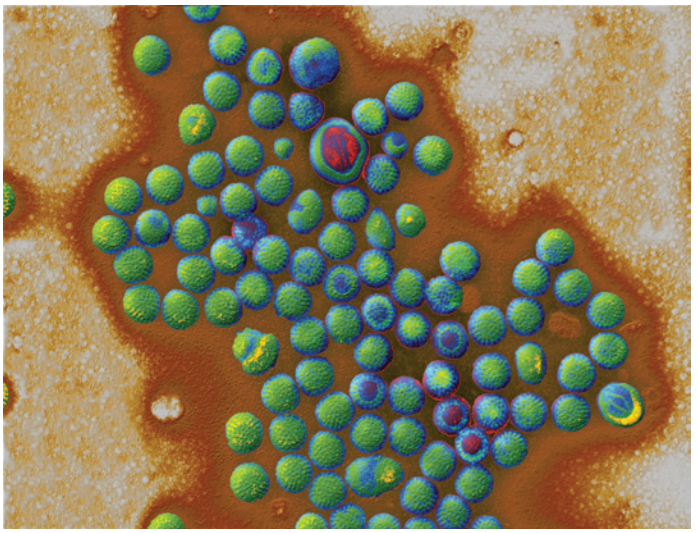

Figure 38.21 Rotavirus Virions. Electron micrograph of rotavirus virions (family *Reoviridae*) in a human gastroenteritis stool filtrate (×90,000).

Table 38.4 Medically Important Gastroenteritis Viruses

Family	Virus	Characteristics
Adenoviridae	Adenoviruses (subgroup F, serotypes 40 & 41)	Primarily pediatric cases, outbreaks on military bases, more severe in the immunocompromised
Astroviridae	Human Astroviruses	Primarily pediatric cases and outbreaks in nursing homes, lasts 1–3 days
Caliciviridae	Noroviruses (genotypes I and II)	Pediatric epidemics, outbreaks common in older children and adults (families, communities, social events); often associated with shellfish, food handlers with poor hand hygiene, and cruise ships
	Sapoviruses (genogroups 1, 2, 4, & 5)	Primarily pediatric cases with mild diarrhea, rarely adult cases associated with shellfish and other foods
Parvoviridae	Human bocavirus 2	Primarily pediatric cases; mild to severe diarrhea, rarely with acute flaccid paralysis
Picornaviridae	Human parechoviruses	Primarily pediatric cases; mild diarrhea, rarely with myocarditis and encephalitis complications
Reoviridae	Rotaviruses (Groups A-C)	Primarily pediatric cases, large outbreaks in adults; dehydrating diarrhea (5–7 days) with cramps, fever, nausea, and vomiting in pediatric cases, 3–5 days diarrhea in adult cases

of oral fluid replacement with isotonic liquids, analgesics, and antiperistaltic agents. Symptoms usually last for 1 to 5 days, and recovery often results in protective immunity to subsequent infection.

Hepatitis A

Hepatitis A (infectious hepatitis) usually is transmitted by fecal contamination of food or drink, or shellfish that live in contaminated water. The disease is caused by hepatitis A virus (HAV) of the genus *Hepatovirus* in the family *Picornaviridae*. Recall that while all hepatitis viruses can cause liver disease, not all are taxonomically related (table 38.3). HAV is an icosahedral, linear, positive-strand RNA virus that lacks an envelope. Once in the digestive system, the viruses multiply within the intestinal epithelium. Usually only mild intestinal symptoms result. Occasionally viruses are found in the blood (viremia) and may spread to the liver. The viruses reproduce in the liver, enter the bile, and are released into the small intestine. This explains why feces are so infectious. After about a 4-week incubation period, symptoms develop that include anorexia, general malaise, nausea, diarrhea, fever, and chills. If the liver becomes infected, jaundice ensues. Most cases resolve in 4 to 6 weeks and yield a strong immunity, although some patients relapse, exhibiting symptoms for 6 months or more. Fortunately the mortality rate is low (less than 1%). Approximately 40 to 80% of the U.S. population has antibodies, though few are aware of having had the disease. Control of infection is by simple hygienic measures, the sanitary disposal of excreta, and the HAV vaccine. The number of new cases has been dramatically reduced since the introduction of the hepatitis A vaccine in the 1990s. This vaccine is recommended for travelers (*see table 37.3*) going to regions with high rates of hepatitis A.

Hepatitis E

Hepatitis E is implicated in many epidemics in certain developing countries in Asia, Africa, and Central and South America. It is uncommon in the United States but is occasionally imported by infected travelers. The single, positive-strand RNA viral genome (7,900 nucleotides) is linear. The virion is spherical, nonenveloped, and 32 to 34 nm in diameter.

Infection usually is associated with feces-contaminated drinking water. Presumably HEV enters the blood from the gastrointestinal tract, replicates in the liver, is released from hepatocytes into the bile, and is subsequently excreted in the feces. Like hepatitis A, an HEV infection usually runs a benign course and is self-limiting. The incubation period varies from 15 to 60 days, with an average of 40 days. The disease is most often recorded in patients who are fifteen to forty years of age. Children are typically asymptomatic or present mild signs and symptoms, including abdominal pain, anorexia, dark urine, fever, hepatomegaly, jaundice, malaise, nausea, and vomiting. Case fatality rates are low (1 to 3%), except for pregnant women (15 to 25%), who risk death from fulminant hepatic failure. Diagnosis of HEV infection is by ELISA (IgM or IgG to recombinant HEV) or reverse transcriptase PCR. There are no specific measures for preventing HEV infections, other than those aimed at improving the level of health and sanitation in affected areas.

Poliomyelitis

Poliomyelitis (Greek *polios*, gray, and *myelos*, marrow or spinal cord), **polio,** or **infantile paralysis** is caused by poliovirus (species *Human enterovirus C*) and was first described in England in 1789 as a "leg-wasting" disease of children, although a pictograph from ancient Egypt clearly depicts a man with what appears to be polio (**Historical Highlights 38.1**). The virus is an

HISTORICAL HIGHLIGHTS

38.1 A Brief History of Polio

Like many other infectious diseases, polio is probably of ancient origin. Various Egyptian hieroglyphics dated approximately 2000 BCE depict individuals with wasting, withered legs and arms (**box figure**). In 1840 the German orthopedist Jacob von Heine described the clinical features of poliomyelitis and identified the spinal cord as the problem area. Little further progress was made until 1890, when Oskar Medin, a Swedish pediatrician, portrayed the natural history of the disease as epidemic in form. He also recognized that a systemic phase, characterized by minor symptoms and fever, occurred early and was complicated by paralysis only occasionally. Major progress occurred in 1908, when Karl Landsteiner and William Popper successfully transmitted the disease to monkeys. In the 1930s much public interest in polio occurred because of the polio experienced by U.S. President Franklin D. Roosevelt. This led to the founding of the March of Dimes campaign in 1938; the sole purpose of the March of Dimes was to collect money for research on polio. In 1949 John Enders, Thomas Weller, and Frederick Robbins discovered that poliovirus could be propagated in vitro in cultures of human embryonic tissues of nonneural origin. This was the keystone that later led to the development of vaccines.

In 1952 David Bodian recognized that there were three distinct serotypes of poliovirus. Jonas Salk successfully immunized humans with formalin-inactivated poliovirus in 1952, and this vaccine (IPV) was licensed in 1955. The live attenuated poliovirus vaccine (oral polio vaccine, OPV) developed by Albert Sabin and others had been employed in Europe since 1960 and was licensed for U.S. use in 1962. Both the Salk and Sabin vaccines led to a dramatic decline of paralytic poliomyelitis in most developed countries and, as such, have been rightfully hailed as two of the great accomplishments of medical science.

Ancient Egyptian with Polio. Note the withered leg.

enterovirus—a transient inhabitant of the gastrointestinal tract—and a member of the family *Picornaviridae* and as such is a nonenveloped, positive-strand RNA virus. Three different poliovirus subtypes have been identified. Eradication efforts have eliminated strains 2 and 3, but the vaccine remains tripartite. Like other viruses transmitted by the fecal-oral route, poliovirus virions are very stable, especially at acidic pH, and can remain infectious for relatively long periods in food and water, its main routes of transmission. The incubation period ranges from 6 to 20 days.

Once ingested, the virus multiplies in the mucosa of the throat or small intestine. From these sites, the virus invades the tonsils and lymph nodes of the neck and terminal portion of the small intestine. Generally there are either no symptoms or a brief illness characterized by fever, headache, sore throat, vomiting, and loss of appetite. The virus sometimes enters the bloodstream, causing viremia. In most cases (more than 99%), the viremia is transient and clinical disease does not result. However, in a minority of cases, the viremia persists and the virus enters the central nervous system and causes paralytic polio. The virus has a high affinity for anterior horn motor nerve cells of the spinal cord. Once inside these cells, it multiplies and destroys the cells; this results in motor and muscle paralysis. Since the licensing of the tripartite Salk vaccine (1955) and the tripartite Sabin vaccine (1962), the incidence of polio has decreased markedly. No wild polio viruses exist in the United States. An ongoing global polio eradication effort has been very successful. Excitingly, as of 2014, 80% of the world's population now live in polio-free areas. Three polio-endemic countries remain: Afghanistan, Nigeria, and Pakistan. Substantial efforts are being

made to eradicate polio and certify these remaining countries as polio-free. However, religious views and misinformation continue to diminish vaccination efforts and civil wars interrupt public health efforts. Nonetheless, it is likely that polio will be the next human disease to be completely eradicated.

In addition to polio, there are over 100 other enteroviruses that all have the potential to invade the human central nervous system. But like poliovirus, this is very rare. In 2014 there was an outbreak of one such virus, enterovirus D68, that targeted young children with respiratory problems, such as asthma, causing life-threatening respiratory distress and in a few cases paralysis.

38.5 Zoonotic Diseases Arise from Human-Animal Interactions

After reading this section, you should be able to:

- Report the common viral diseases spread by contact with infected animals
- Identify typical signs and symptoms of zoonotic viral diseases
- Correlate zoonotic virus infection and disease severity with viral attachment factors

The diseases discussed here are caused by viruses that are normally zoonotic (animal-borne). Members of the RNA virus families *Arenaviridae, Bunyaviridae, Flaviviridae, Filoviridae,* and *Picornaviridae* are notable examples of viruses found in animal reservoirs before transmission to and between humans. Some of these viruses are exotic and rare; others are being eradicated by public health efforts. Some are found in relatively small geographic areas; others are distributed across continents. Several cause diseases with substantial morbidity and mortality.

Ebola Virus and Marburg Diseases

Ebola virus disease (**EVD**) is caused by Ebola viruses, first recognized near the Ebola River in the Democratic Republic of the Congo in Africa. They are members of the genus *Ebolavirus* in the family *Filoviridae*, a group of negative-strand RNA viruses. Five Ebola species are known: *Sudan ebolavirus*, *Tai Forst ebolavirus* (formerly *Côte d'Ivoire ebolavirus*), *Bundibugyo ebolavirus, Zaire ebolavirus,* and *Reston ebolavirus.* Members of the first four species cause disease in humans (**figure 38.22**). The fifth, *Reston ebolavirus*, was first discovered in 1989, and to date Reston viruses have caused disease only in nonhuman primates and pigs. Only Reston virus is spread by aerosol transmission. All five types of Ebola virus are transmitted by contact with body fluids. Ebola viruses cause varying degrees of hemorrhagic fever.

Viral hemorrhagic fever (**VHF**) is the term used to describe a severe, multisystem syndrome caused by several distinct viruses. Characteristically the overall host vascular system is damaged, resulting in vascular leakage (hemorrhage) and dysfunction (coagulopathy). The incubation period for EVD ranges from 2 to 21 days and is characterized by abrupt fever, headache, joint and muscle aches, sore throat, and weakness, followed by diarrhea, vomiting, and stomach pain. Signs of infection include fever, rash, red eyes, bleeding, and hiccups—symptoms alerting of internal hemorrhage. Minor hemorrhage is symptomatic in all ebolavirus infection. Severe hemorrhage is late stage and can be minimized if patients are resuscitated in time. There is no standard treatment for Ebola infection. Patients receive supportive therapy consisting of balancing patients' fluids and electrolytes, maintaining their oxygen status and blood pressure, and treating them for any complicating infections. Convelscent sera, collected from Ebola survivors, and experimental antibody cocktails have shown promising success in the 2014 treatments of ebolavirus patients. Experimental vaccines are currently being evaluated and show promise in various animal models.

Marburg disease is caused by a genetically unique RNA virus also in the *Filoviridae* family. Marburg virus (MARV) similarly causes a hemorrhagic fever. It is a rare, severe type of hemorrhagic fever that affects both humans and nonhuman primates. MARV was first recognized in 1967, when outbreaks of hemorrhagic fever occurred simultaneously in laboratories in Marburg and Frankfurt, Germany, and in Belgrade, Yugoslavia (now Serbia). The first people infected had been exposed to African green monkeys or their tissues. In Marburg, the monkeys had been imported for research and to prepare polio vaccine. MARV is indigenous to Africa, and the reservoir host of MARV is the African fruit bat, *Rousettus aegyptiacus*. The average incubation period for Marburg hemorrhagic fever is 5 to 10 days. The disease symptoms are abrupt, marked by fever, chills, headache, and myalgia. A maculopapular rash (i.e., discolored with bumps), most prominent on the chest, back, and stomach, typically appears around the fifth day after onset. Nausea, vomiting, chest pain, sore throat,

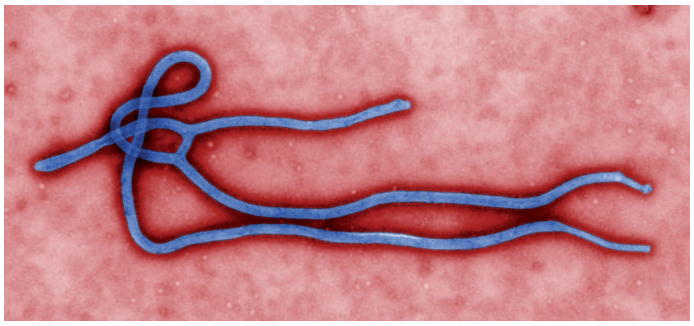

Figure 38.22 Ebola Virus Virions.

abdominal pain, and diarrhea may also occur in infected patients. Symptoms become increasingly severe and may include jaundice, delirium, liver failure, pancreatitis, severe weight loss, shock, and multiorgan dysfunction. A specific treatment for this disease is unknown. However, supportive hospital therapy should be utilized. This includes balancing the patient's fluids and electrolytes, maintaining oxygen status and blood pressure, replacing lost blood and clotting factors, and treating for other complicating infections.

Hantavirus Pulmonary Syndrome

Hantavirus pulmonary syndrome (**HPS**) is a disease caused by a negative-strand RNA virus of the family *Bunyaviridae*. HPS is typically transmitted to humans by inhalation of viral particles shed in urine, feces, or saliva of infected rodents. HPS was first recognized in 1993 and has since been identified throughout the United States. Although rare, HPS is potentially deadly. Rodent control in and around the home remains the primary strategy for preventing hantavirus infection. HPS in the United States is not transmitted from person to person, nor is it known to be transmitted by rodents purchased from pet stores.

Hantaviruses have lipid envelopes that are susceptible to most disinfectants. The length of time hantaviruses can remain infectious in the environment is variable and depends on environmental conditions. Temperature, humidity, exposure to sunlight, and even the rodent's diet, which affects the chemistry of rodent urine, strongly influence viral survival. Viability of dried virus particles has been reported at room temperature for 2 to 3 days. Hantaviruses are shed in body fluids but do not appear to cause disease in their reservoir rodent hosts. Data indicate that viral transfer may occur between rodents through biting, as field studies suggest that viral transmission in rodent populations occurs horizontally and more frequently between males. A specific treatment for HPS is unknown. Supportive therapy is used to treat symptoms, including balancing the patient's fluids and electrolytes, maintaining oxygen status and blood pressure, replacing lost blood and clotting factors, and treating for other complicating infections.

Rabies

Rabies (Latin *rabere*, rage or madness) is caused by a number of different strains of highly neurotropic viruses. Most belong to a single serotype in the genus *Lyssavirus* (Greek *lyssa*, rage or rabies), family *Rhabdoviridae*. The bullet-shaped virion contains a negative-strand RNA genome (**figure 38.23**). Rabies has been the object of human fascination, torment, and fear since the disease was first recognized. Prior to Pasteur's development of a rabies vaccine, few words were more terrifying than the cry of "mad dog!" Improvements in prevention during the past 50 years have led to almost complete elimination of indigenously acquired rabies in the United States, where rabies is primarily a disease of feral animals and domestic cats that contact feral animals. Most wild animals can become infected with rabies, but susceptibility varies according to species. Foxes, coyotes, and wolves are the most susceptible; intermediate are skunks, raccoons, insectivorous bats, and bobcats, whereas opossums are quite resistant. Worldwide, almost all cases of human rabies are attributed to dog bites. In the more than 150 developing countries and territories, where canine rabies is still endemic, rabies accounts for tens of thousands of deaths per year. In the United States, fewer than 10 cases are reported annually. Feral raccoons, skunks, and bats account for 83% of all animal cases. Occasionally other domestic animals are responsible for transmission of rabies to humans. It should be noted, however, that not all rabid animals exhibit signs of agitation and aggression (known as furious rabies). In fact, paralysis (dumb rabies) is the more common sign exhibited by rabid animals.

The virus multiplies in the salivary glands of an infected host. It is transmitted to humans or other animals by the bite of an infected animal whose saliva contains the virus; by aerosols of the virus that can be spread in caves where bats dwell; or by contamination of scratches, abrasions, open wounds, and mucous membranes with saliva from an infected animal. After inoculation, the virion's envelope spike attaches to the plasma membrane of nearby skeletal muscle cells, which the virus enters. Multiplication of the virus then occurs. When the concentration of the virus in the muscle is sufficient, the virus enters the nervous system through unmyelinated sensory and motor terminals; the binding site is the nicotinic acetylcholine receptor.

The virus spreads by retrograde axonal flow at 8 to 20 mm per day until it reaches the spinal cord, when the first specific symptoms of the disease—pain or paresthesia at the wound site—may occur. A rapidly progressive encephalitis develops as the virus quickly disseminates through the central nervous system. The

Figure 38.23 Rabies. Electron micrograph of a rabies virus virion (yellow) (×36,700). Note the bullet shape. The external surface of the virion contains spikelike glycoprotein projections that bind specifically to cellular receptors.

MICRO INQUIRY *What type of host cell does the rabies virus initially infect? To where does the virus then travel?*

virus then spreads throughout the body along the peripheral nerves, including those in the salivary glands, where it is shed in the saliva.

Within brain neurons, the virus produces characteristic Negri bodies, masses of virions or unassembled viral subunits that are visible in the light microscope. In the past, diagnosis of rabies consisted solely of examining tissue for the presence of these bodies. Today diagnosis is based on *d*irect immuno*f*luorescent *a*ntibody (DFA) of brain tissue, virus isolation, detection of Negri bodies, a rapid rabies enzyme-mediated immunodiagnosis test and by PCR testing. ▶▶| *Direct identification of infectious agents (section 36.3)*

Symptoms of rabies in humans usually begin 2 to 16 weeks after exposure and include anxiety, irritability, depression, fatigue, loss of appetite, fever, and a sensitivity to light and sound. The disease quickly progresses to paralysis. In about 50% of all cases, intense and painful spasms of the throat and chest muscles occur when the victim swallows liquids. The mere sight, thought, or smell of water can set off spasms. Consequently, rabies has been called hydrophobia (fear of water). Once symptoms of rabies develop in a human, the disease has a 100% mortality rate. Death results from destruction of the regions of the brain that regulate breathing. Safe and effective vaccines (*h*uman *d*iploid-*c*ell rabies *v*accine [HDCV] or *r*abies *v*accine *a*dsorbed [RVA]) against rabies are available; however, to be effective they must be given prior to or soon after the person has been infected. Veterinarians and laboratory personnel, who have a high risk of exposure to rabies, usually are immunized every 2 years and tested for the presence of suitable antibody titer. Prevention and control involve preexposure vaccination of dogs and cats, postexposure vaccination of humans, and preexposure vaccination of humans at special risk, including persons spending a month or more in countries where rabies is common in dogs.

Postexposure prophylaxis—rabies immune globulin for passive immunity and rabies vaccine for active immunity—is initiated to exploit the relatively long incubation period of the disease. Rabies immune globulin is typically administered directly into the wound after cleaning. The vaccine is administered as four doses given on days 3, 7, and 14 after the initial dose. This is usually recommended for anyone bitten by one of the common reservoir species (raccoons, skunks, foxes, and bats), unless it is proven that the animal was uninfected.

Some states and countries (e.g., Hawaii and Great Britain) retain their rabies-free status by imposing quarantine periods on any entering dog or cat. If an asymptomatic, unvaccinated dog or cat bites a human, the animal is typically confined and observed by a veterinarian for at least 10 days. If the animal shows no signs of rabies in that time, it is determined to be uninfected. Animals demonstrating signs of rabies are killed, and brain tissue is submitted for rabies testing.

38.6 Prion Proteins Transmit Disease

After reading this section, you should be able to:

- Describe diseases caused by prions
- Differentiate prion disease by route of infection

Prion diseases, also called **transmissible spongiform encephalopathies** (**TSEs**), are fatal neurodegenerative disorders that have attracted enormous attention not only for their unique biological features but also for their impact on public health. Prions (proteinaceous infectious particles) are thought to consist of abnormally folded proteins (PrP^{Sc}), which can induce normal forms of the protein (PrP^{C}) to fold abnormally *(see figure 6.24)*. This group of diseases includes scrapie, kuru, Creutzfeldt-Jakob disease (CJD), variant Creutzfeldt-Jakob disease (vCJD), Gerstmann-Sträussler-Scheinker disease (GSD), and fatal familial insomnia (FFI). Scrapie occurs primarily in sheep. The first of these diseases to be studied in humans was kuru, discovered in the Fore tribe of New Guinea. Carlton Gadjusek and others showed that the disease was transmitted by ritual cannibalism (especially where brains and spinal cords were eaten). The primary symptom of the human disorders is dementia, usually accompanied by manifestations of motor dysfunction such as cerebral ataxia (inability to coordinate muscle activity) and myoclonus (shocklike contractions of muscle groups). FFI is also characterized by dysautonomia (abnormal functioning of the autonomic nervous system) and sleep disturbances. These symptoms appear insidiously in middle to late adult life and last from months (CJD, FFI, and kuru) to years (GSD) prior to death. |◀◀ *Prions are composed only of proteins (section 6.7)* *Prion Diseases*

Neuropathologically these disorders produce a characteristic spongiform degeneration of the brain, as well as deposition of amyloid plaques (**figure 38.24**). Prion diseases thus share important

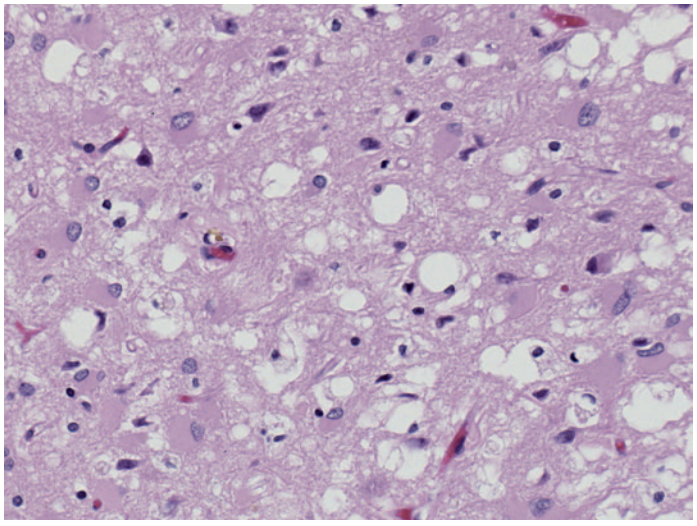

Figure 38.24 Variant Creutzfeldt-Jacob Disease (vCJD). vCJD is a prion-dependent disease that results in prominent spongiotic changes in the cortex, and loss of neurons. Note the spongiotic (holey) appearance of this brain tissue photomicrograph (magnified 100X and stained with hematoxylin and eosin).

clinical, neuropathological, and cell biological features with another, more common cerebral amyloidosis, Alzheimer's disease. Yet they cause a distinct neurological deterioration. Prion diseases are organized into three subcategories: familial (inherited) types, sporadic types, and acquired types. Familial CJD is the result of spontaneous mutation within the prion-encoding gene. Certain residues when mutated are known to give rise to CJD, but it is not clear why these amino acid substitutions confer inducible misfolding to the (PrPSc) conformation. Familial CJD is very rare, accounting for 5 to 15% of all CJD cases. It is rapidly progressive and always fatal, usually within 1 year of onset of illness.

Sporadic CJD (sCJD) has a global incidence of one case per million people per year and accounts for 75% of global CJD cases. It is most common in the 45–75 age group, with the peak age of onset being 60 to 65. There are no known gender, environmental, or lifestyle associations that would induce sCJD. This form of the disease is also rapidly progressive; symptoms move from depression and loss of coordination and walking, to loss of vision and speech, to incontinence and immobility, over an average of 4 to 5 months. Seventy percent of patients die within six months of symptom onset. CJD that is acquired is known as variant (v) CJD, so named as it is clinically and pathologically different from familial or sporadic CJD.

vCJD is acquired when a human consumes meat products from a BSE cow. Such transmission occurred during the 1980s and early 1990s in the UK, resulting in 175 cases of vCJD reported between 1996 and 2011. These data suggest a five-year incubation period. vCJD can also be acquired from a physician or surgeon, a medical treatment, or diagnostic procedures. Known as iatrogenic CJD, it has been transmitted by prion-contaminated human growth hormone, corneal grafts, and grafts of dura mater (tissue surrounding the brain). Donor screening and more thorough testing of grafts have decreased the frequency of prion transmission. Although vCJD symptoms mirror those of other CJD diseases, psychiatric symptoms are more prominent early, with dementia developing later. vCJD represents less than 5% of global CJD cases.

1. How are prions different from viruses? How are they similar?
2. In what way are spongiform encephalopathies commonly acquired?

Key Concepts

38.1 Viruses Can Be Transmitted by Airborne Routes

- More than 400 different viruses can infect humans. These viruses can be grouped and discussed according to their mode of transmission and acquisition.
- Most airborne viral diseases involve either directly or indirectly the respiratory system. Examples include chickenpox (varicella; **figure 38.1**), shingles (herpes zoster; **figure 38.2**), influenza (flu; **figure 38.3**), measles (rubeola; **figure 38.4**), rubella (German measles; **figure 38.5**), acute respiratory viruses such as SARS-CoV virus (**figure 38.6**), the eradicated smallpox (variola; **figure 38.7**), and viral pneumonia.

38.2 Arthropods Can Transmit Viral Diseases

- The arthropod-borne viral diseases are transmitted by arthropod vectors from human to human or animal to human.
- Examples of arthropod-borne diseases include eastern, western, and Venezuelan equine encephalitis, Bourbon virus disease, chikungunya disease, Heartland virus disease, and West Nile fever. All these diseases are characterized by fever, headache, nausea, vomiting, and other distinct characteristics.

38.3 Direct Contact Diseases Can Be Caused by Viruses

- Person-to-person contact is another way of acquiring or transmitting a viral disease.
- Examples of direct contact diseases include AIDS (**figures 38.8–38.12**), cold sores (**figure 38.13**), the common cold (rhinovirus; **figure 38.14**), cytomegalovirus inclusion disease (**figure 38.15**), genital herpes (**figure 38.16**), human herpesvirus 6 infections, human parvovirus B19 infection (**figure 38.17**), infectious mononucleosis, hepatitis B (serum hepatitis), hepatitis C, and hepatitis D (delta hepatitis) satellite virus (**table 38.3**).

38.4 Food and Water Are Vehicles for Viral Diseases

- Viruses that are transmitted in food and water usually grow in the intestinal system and leave the body in feces (**table 38.4**). Acquisition is generally by the oral route.
- Examples of diseases caused by food-borne viruses include acute viral gastroenteritis (rotaviruses and others), infectious hepatitis A, hepatitis E, and poliomyelitis.

38.5 Zoonotic Diseases Arise from Human-Animal Interactions

- Diseases transmitted from animals are zoonotic.
- Several animal viruses can cause disease in humans. Examples of viral zoonoses include Ebola and Marburg diseases, hantavirus pulmonary syndrome, and rabies (**figure 38.23**).

38.6 Prion Proteins Transmit Disease

- A prion disease is a pathological process caused by a transmissible agent (a prion) that remains clinically silent for a prolonged period, after which the clinical disease becomes apparent.
- Examples of prion diseases include Creutzfeldt-Jakob disease, variant Creutzfeldt-Jakob disease, kuru, Gerstmann-Sträussler-Scheinker disease, and fatal familial insomnia. These diseases are chronic infections of the central nervous system that result in progressive degenerative changes and eventual death.

Compare, Hypothesize, Invent

1. Explain why antibiotics are ineffective against viral infections. Advise a person about what can be done to relieve symptoms of a viral infection and recover most quickly. Address your advice to (a) someone who has had only a basic course in high school biology and (b) a third-grade student.
2. Several characteristics of AIDS render it particularly difficult to detect, prevent, and treat effectively. Discuss two of them. Contrast the disease with polio and smallpox.
3. From an epidemiological perspective, why are most arthropod-borne viral diseases hard to control?
4. In terms of molecular genetics, why is the common cold such a prevalent viral infection in humans?
5. Will it be possible to eradicate many viral diseases in the same way as smallpox? Why or why not?
6. Prior to the development of detection assay for HIV in the blood supply, HCV was used as a proxy. That is to say, any donated blood found to be contaminated with HBV or HCV was also assumed to be HIV positive as well. What do you think was the rationale behind the use of HCV as an indicator of HIV? Do you think this was a reasonable approach at the time?
7. In 2005 a reconstructed influenza virus containing eight genes from the 1918 Spanish influenza virus was introduced into human lung epithelial cells and mice. This virus was able to rapidly reproduce and cause sudden illness and death in mice. In 2008 these genes were replaced on an individual basis with homologues from a contemporary H1N1 influenza virus and tested for virulence. Substitution of the 1918 gene with the H1N1 hemagglutinin (HA), neuraminidase (NA), or polymerase PB1 subunit severely diminished the virulence of the 1918 virus.

   Explain why each of these genes is so critical for infection and virulence.

   Do you think there would be an additive effect in loss of virulence if more than one gene were replaced? Explain your answer and discuss what this implies with regard to the emergence of another highly virulent influenza virus capable of causing a pandemic.

   Read the original paper: Pappas, C., et al. 2008. Single gene reassortments identify a critical role for PB1, HA, and NA in the high virulence of the 1918 pandemic influenza virus. *Proc. Natl. Acad. Sci. USA* 105:3064–69.
8. Chronic wasting disease (CWD), a prion disease found in cervids (elk, deer, and moose), was first described in the 1960s and is now found in animals in at least 14 states. Despite its long history, it was unclear how the disease spread and if humans were at risk of acquiring the disease. In 2006 researchers designed and executed an experiment to determine if prions could be transmitted between cervids by contact with saliva, blood, feces, and urine. They found that CWD could be transmitted by oral contact with saliva and by blood following transfusion. This finding has raised concern among hunters and others who come in contact with cervid body fluids.

   How would you design a similar experiment to identify the transmission of scrapie between sheep and possible transmission to humans? Be sure to explain the controls you would use and how you would unequivocally document the development of disease.

   Read the original paper: Mathiason, C. K., et al. 2006. Infectious prions in the saliva and blood of deer with chronic wasting disease. *Science* 314:133.
9. In this chapter we have evaluated a number of viruses that cause human disease, suggesting that RNA viruses are the more rapidly evolving human pathogens. One common observation is that although RNA viruses replicate with much lower fidelity, they mutate (resulting in antigenic drift) and recombine (resulting in antigenic shift) with greater frequency and success than DNA viruses. Thus, RNA viruses evolve significantly faster than most DNA viruses. However, there is tremendous variation among the evolutionary rates of different RNA viruses, which is not explained by variation in mutation rates. Scientists at Rutgers University, in New Jersey, surveyed mammalian RNA virus rates of evolution and compared evolutionary rates to different properties of virus genomic architecture (e.g., RNA or DNA, ds or ss, number of segments, etc.) and host cell ecology. Interestingly, they found that the most significant predictor of long-term rates of mammalian RNA virus evolution was the host cell-generated environmental condition influencing virus tropism. In other words, host cell characteristics that entice viruses to infect them seem to drive viral evolution better than any virus-associated factor.

   What aspects of tropism (viral infection of a specific cell type) do you think would drive virus evolution? Why? How would infection of epithelial cells (respiratory or gastrointestinal) be favored over infection of neurons, for example? Can you suggest a mechanism by which RNA viruses would risk extinction in attempting to enhance infectivity?

   Read the original article: Hicks, A. L., and Duffy, S. 2014. Cell tropism predicts long-term nucleotide substitution rates of mammalian RNA viruses. *PLoS Pathog.* 10(1): e1003838. doi:10.1371/journal.ppat.1003838.

Human Diseases Caused by Bacteria

New strains of MRSA have been discovered in pigs on many U.S. and European farms.

"This Little Piggie Stayed Home"

Methicillin-resistant *Staphylococcus aureus* (MRSA) seems to be everywhere. One U.S. lab has tracked a single strain originally from European pigs to the United States. But identification of MRSA is not always easy. A novel strain of methicillin-resistant staphylococci has been identified by two independent groups. In both laboratories, several bacterial isolates were found to be methicillin resistant by culture and sensitivity techniques but negative for the primary MRSA resistance gene, *mecA*, when assayed by PCR amplification. These results suggested the bacterial isolates should not be methicillin resistant. Negative results for the *mecA* gene product, a modified penicillin-binding protein, using a slide agglutination test, also suggested that the isolated bacteria lacked methicillin resistance. To resolve the apparent paradox, scientists at a lab in England (who isolated strains from cattle) and a lab in Ireland (whose strains were from humans) independently used whole genome sequencing to probe the DNA for known drug-resistance genes. The analysis showed that these methicillin-resistant bacteria had a novel β-lactam resistance gene, similar to *mecA*, except this version of the gene was about 60% different from published sequences and the gene used for PCR testing! In a further analysis, about two-thirds of the isolates contained this novel resistance gene (now designated as *mecC*). More concerning are reports from the U.S. lab revealing that this new MRSA has infiltrated horse farms and veterinary hospitals. Only time will tell if, but more likely when, this MRSA strain will commonly be detected as the source of human infections like its *mecA* cousin.

Despite all the press MRSA and other pathogens receive, only a relatively few bacterial species are pathogenic to humans. Some human diseases have been only recently recognized; others have been known since antiquity. In this chapter, we continue our discussion of infectious disease by turning our attention to bacterial pathogens. These include bacteria that cause localized and systemic infections. We present examples of bacteria and the diseases they cause by route of transmission, as well as opportunistic bacteria. Diseases caused by bacteria categorized by the Centers for Disease Control and Prevention as select agents (potential bioterror agents) are identified within each section.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Review basic bacterial cell biology (sections 3.2–3.9)
- ✔ Explain how key pathogens cause infection (chapter 35)
- ✔ Compare and contrast the general principles of innate and adaptive immunity (sections 33.1, 34.1–34.3)

39.1 Bacteria Can Be Transmitted by Airborne Routes

After reading this section, you should be able to:

- Report the common airborne bacterial diseases
- Identify typical signs and symptoms of airborne bacterial diseases
- Correlate airborne bacterial infection and disease severity with bacterial virulence factors

Most airborne bacterial diseases infect the respiratory tract. Inhalation of infectious particles or self-inoculation can cause disease of the sinuses, throat, bronchus, or lungs. Some airborne bacteria can cause skin diseases. Some of the better known of these diseases are now discussed.

Chlamydial Pneumonia

Chlamydial pneumonia is caused by *Chlamydophila pneumoniae*. The Gram-negative chlamydiae are obligate intracellular parasites. They must grow and reproduce within host cells. Although their ability to cause human disease is widely recognized, many species grow within protists and animal cells as their natural reservoir. Infection begins when the 0.2 to 0.6 μm diameter elementary bodies (EBs) are inhaled (*see figure 21.17*). EBs are designed exclusively for transmission and infection.

Host cells phagocytose the EBs and they are held in inclusion bodies, where they reorganize to form reticulate bodies (RBs). About 8 to 10 hours after infection, the RBs undergo binary fission, and continue to divide until the host cell dies. Interestingly, a chlamydia-filled inclusion body can become large enough to be visible by light microscopy. RBs differentiate into infectious EBs after 20 to 25 hours. The host cell lyses and releases the EBs 48 to 72 hours after infection. ⏮ *Phylum* Chlamydiae *(section 21.6)*

Clinically, infections are generally mild; pharyngitis, bronchitis, and sinusitis commonly accompany some lower respiratory tract involvement. Symptoms include fever, a productive cough (respiratory secretion brought up by coughing), sore throat, hoarseness, and pain on swallowing. Infections with *C. pneumoniae* are common but sporadic. Approximately, 5 to 10% of all cases of adult pneumonia and bronchitis are caused by *C. pneumoniae,* and about 50% of adults have antibody to this bacterium. *C. pneumoniae* appears to be primarily a human pathogen directly transmitted from human to human by droplet (respiratory) secretions. Diagnosis of chlamydial pneumonia is based on symptoms and an immunofluorescence test. Macrolides are the first line of treatment, tetracycline and fluoroquinolones are also effective.

In seroepidemiological studies, *C. pneumoniae* infections have been linked with coronary artery disease, as well as vascular disease at other sites. Following a demonstration of *C. pneumoniae*–like particles in atherosclerotic plaque tissue by electron microscopy, *C. pneumoniae* genes and antigens have been detected in artery plaque. However, the microorganism is inconsistently recovered in cultures of artery plaque. As a result of these findings, a possible etiologic role of *C. pneumoniae* infection in coronary artery disease and systemic atherosclerosis is under intense scrutiny.

Diphtheria

Diphtheria (Greek *diphthera,* membrane, and *-ia,* condition) is an acute, contagious disease caused by the Gram-positive bacterium *Corynebacterium diphtheriae (see figure 24.9). C. diphtheriae* is well adapted to airborne transmission by way of nasopharyngeal secretions because it is very resistant to drying. Diphtheria mainly affects unvaccinated, poor people living in crowded conditions. Interestingly, the *tox* gene that encodes diphtheria toxin is found on a prophage, so only *C. diphtheriae* lysogens that carry this prophage cause disease. This is an example of phage conversion. Diphtheria toxin causes an inflammatory response and the formation of a grayish pseudomembrane on the pharynx and respiratory mucosa (**figure 39.1**). The pseudomembrane consists of dead host cells and cells of *C. diphtheriae.*

Diphtheria toxin is absorbed into the circulatory system and distributed throughout the body, where it may cause destruction of cardiac, kidney, and nervous tissues by inhibiting protein synthesis. The toxin is an AB toxin encoded by a single gene that gives rise to a protein with two domains, A and B (*see figure 35.6*). The B domain binds to the heparin-binding epidermal growth factor receptor on the surface of various eukaryotic cells. Once bound, the toxin enters the cytoplasm by endocytosis. The B domain contains a transmembrane region that embeds itself in the endosome membrane. Acidification of the endosome breaks a disulfide bond holding the A and B domains together and releases the A domain into the cytoplasm. The cleaved catalytic domain catalyzes the attachment of ADP-ribose (from NAD^+) to translation elongation factor-2 (EF-2). A single enzyme (i.e., catalytic domain) can exhaust the entire supply of cellular EF-2 within hours, resulting in protein synthesis inhibition and cell death. ⏮ *Order* Corynebacteriales *includes important human pathogens (section 24.1); Exotoxins (section 35.2)*

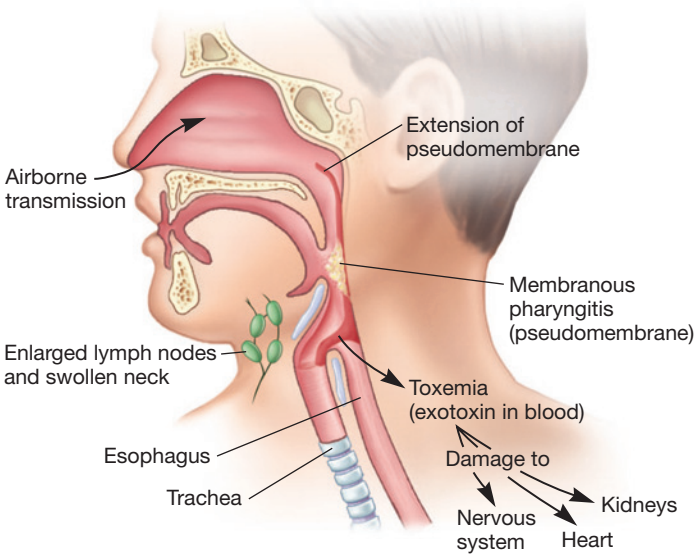
Typical signs and symptoms of diphtheria include a thick nasal discharge containing both mucus and pus, pharyngitis, fever, cough, and paralysis. Most current diphtheria cases involve people over thirty years of age who have a weakened immunity to the diphtheria toxin and live in tropical areas. Between 1980 and 2013, fewer than six diphtheria cases were reported annually in the United States, and most occurred in nonimmunized individuals. ⏮ *Vaccines immunize susceptible populations (section 37.6)*

Legionnaires' Disease

In 1976 the term **Legionnaires' disease,** or **legionellosis,** was coined to describe an outbreak of pneumonia that occurred at the Pennsylvania State American Legion Convention in Philadelphia. The bacterium responsible for the outbreak was *Legionella pneumophila*, a nutritionally fastidious, aerobic, Gram-negative rod (**figure 39.2**). This bacterium is part of the natural microbial community of soil and freshwater ecosystems, and it has been found in large numbers in air-conditioning systems and shower stalls. In fact, a variety of free-living amoebae and ciliated protozoa serve as the natural reservoir for *L. pneumophila*. These protists inhabit cooling water found in air-conditioning systems and are therefore an important part of the infection cycle. ⏮ *Class* Gammaproteobacteria *is the largest bacterial class (section 22.3)*

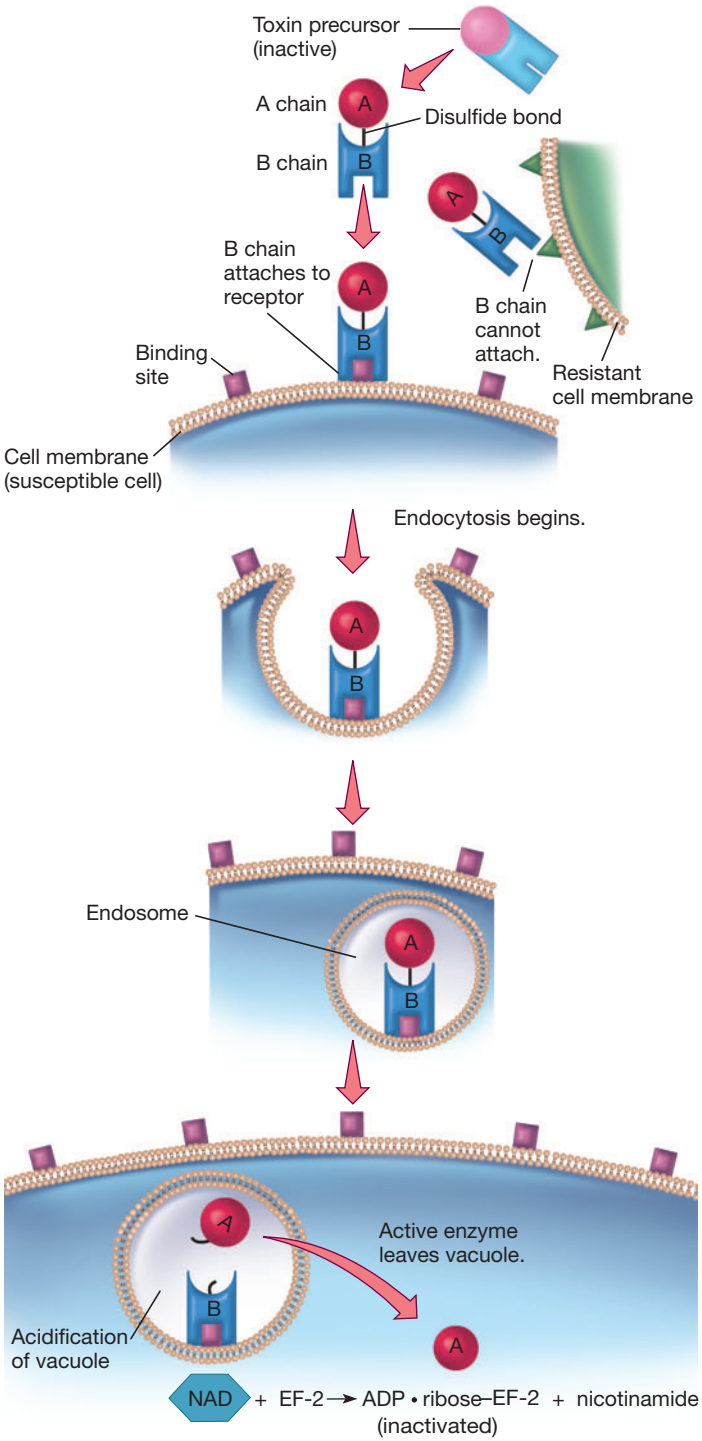
Legionella spp. multiply intracellularly within these protists, just as they do within human macrophages. This might explain why there is no human-to-human spread of legionellosis, as transmission of host cells containing intracellular bacteria is unlikely. Furthermore, most healthy people infected with *L. pneumophila* display the milder form of the disease known as Pontiac fever. Legionnaires' pneumonia is typically seen in immunocompromised individuals, including the elderly. In these cases, the bacteria reside within the phagosomes of alveolar macrophages, where they multiply and produce localized tissue destruction through export of a cytotoxic exoprotease. Symptoms start 2 to 14 days after exposure and include a high fever, nonproductive cough (respiratory secretions are not brought up during coughing), headache, neurological manifestations, and severe bronchopneumonia. Diagnosis depends on isolation of the bacterium, documentation of a rise in antibody titer over time, or the presence of *Legionella* antigens in the urine as detected by a rapid test kit. Treatment begins with supportive measures and the

Figure 39.1 Diphtheria Pathogenesis. (a) Diphtheria is a well-known, exotoxin-mediated infectious disease caused by *Corynebacterium diphtheriae*. The disease is an acute, contagious, febrile illness characterized by local oropharyngeal inflammation and pseudomembrane formation. If the exotoxin enters the blood, it is disseminated and can damage the peripheral nerves, heart, and kidneys. (b) The clinical appearance includes gross inflammation of the pharynx and tonsils marked by grayish patches (a pseudomembrane) and swelling of the entire area. (c) The B subunit of the diphtheria toxin binds to the host cell membrane facilitating entry of the A subunit, which ADP-ribosylates EF-2 to inhibit protein synthesis.



(a)

(b)



(c)

The modified EF-2 inhibits protein synthesis.

administration of erythromycin or rifampin. Death occurs in 5 to 30% of symptomatic cases.

Prevention of Legionnaires' disease depends on the identification and elimination of the environmental source of *L. pneumophila*. Chlorination, ozonation, the heating of water, and the cleaning of water-containing devices can help control the multiplication and spread of *L. pneumophila*. A variety of regulatory control measures are now in place to reduce the incidence of Legionnaires' disease in hospitals, hotels, and so on. However, use of private hot tubs, fountains, and other water systems that aerosolize water can be sources of bacteria. Since the initial outbreak of this disease in 1976, many outbreaks during summer months have been recognized in all parts of the United States. About 8,000 to 18,000 people are hospitalized each year with

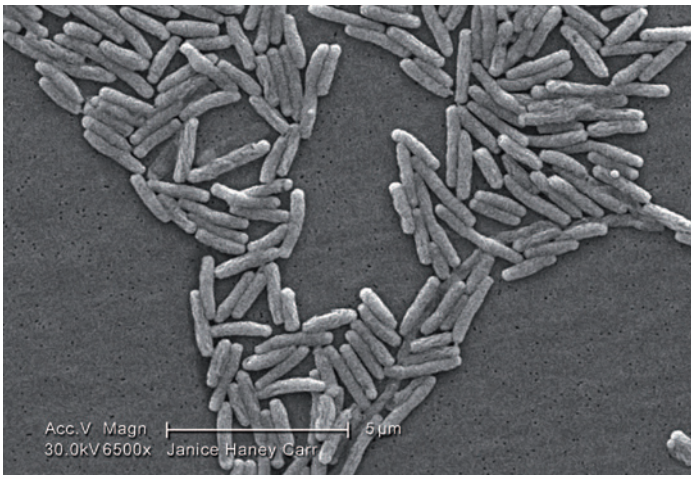


Figure 39.2 ***Legionella pneumophila.*** This peritrichously flagellated Gram-negative bacterium is the causative agent of Legionnaires' disease; SEM (×10,000).

MICRO INQUIRY *What organisms serve as the environmental reservoir for* L. pneumophila*?*

Legionnaires' disease, and about another 18,000 or more mild or subclinical cases are thought to occur.

1. Why do you think chlamydiae differentiate into specialized cell types for infection and reproduction?
2. Compare and contrast the means by which people contract chlamydial pneumonia with Legionnaires' disease.
3. What causes the typical symptoms of diphtheria? How are individuals protected against this disease?

Meningitis

Meningitis (Greek *meninx*, membrane, and *-itis*, inflammation) is an inflammation of the brain or spinal cord meninges (membranes). There are many causes of meningitis, some of which can be treated with antimicrobial agents. A variety of Gram-positive and Gram-negative bacteria cause meningitis, including *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae* serotype b, group B streptococci (*S. agalactiae*), *Listeria monocytogenes*, *E. coli, Mycobacterium tuberculosis*, *Nocardia asteroides*, *Staphylococcus aureus*, and *S. epidermidis*. However, three bacteria tend to be associated with meningitis more frequently than others: *S. pneumoniae, N. meningitidis,* and *H. influenzae* serotype b.

Accurate identification of the causative agent is essential for proper treatment of meningitis. However, this can sometimes be difficult because meningitis symptoms may be present without a microbial agent in Gram-stained specimens of cerebral spinal fluid (CSF), which also yields negative cultures. In such cases, the diagnosis often is called aseptic (meaning lack of an identifiable agent) meningitis syndrome; aseptic meningitis can be caused by a virus or protozoan. Aseptic meningitis is typically more difficult to treat as therapy targeting a specific microorganism is not possible.

The immediate sources of the bacteria responsible for meningitis are respiratory secretions from carriers. *N. meningitidis*, often referred to as meningococcus, is a normal inhabitant of the human nasopharynx (5 to 10% of humans carry the nonpathogenic serotypes). Most disease-causing *N. meningitidis* strains belong to serotypes A, B, C, Y, and W-135. In general, serotype A strains are the cause of epidemic disease in developing countries, whereas serotype B, C, Y, and W-135 strains are responsible for meningitis outbreaks in industrialized countries. Infection results from airborne transmission of the bacteria, typically through close contact with a primary carrier. The disease process is initiated by pili-mediated colonization of the nasopharynx by pathogenic bacteria (**figure 39.3**). The bacteria cross the nasopharyngeal epithelium and the blood-brain barrier (typically through endocytosis) to enter the central nervous system. Often, *N. meningitidis* also invades the bloodstream (meningococcemia), where they proliferate.

Symptoms caused by *N. meningitidis* are variable, depending on whether or not meningococcemia is established. The usual symptoms of meningitis include an initial respiratory illness or sore throat interrupted by one or more of the meningeal syndromes: vomiting, headache, lethargy, confusion, and stiff neck and back. If the bacteria have spread to the bloodstream, a characteristic rash develops along with septic shock. Once bacterial meningitis is suspected, antibiotics (penicillin or ceftriaxone) are administered immediately. In fact, antibiotics (ciprofloxicin or rifampin) are often administered prophylactically to patient contacts; if left untreated, meningococcal meningitis is fatal.

Control of *N. meningitidis* infection is with vaccination and antibiotics. Two vaccine types, meningococcal polysaccharide

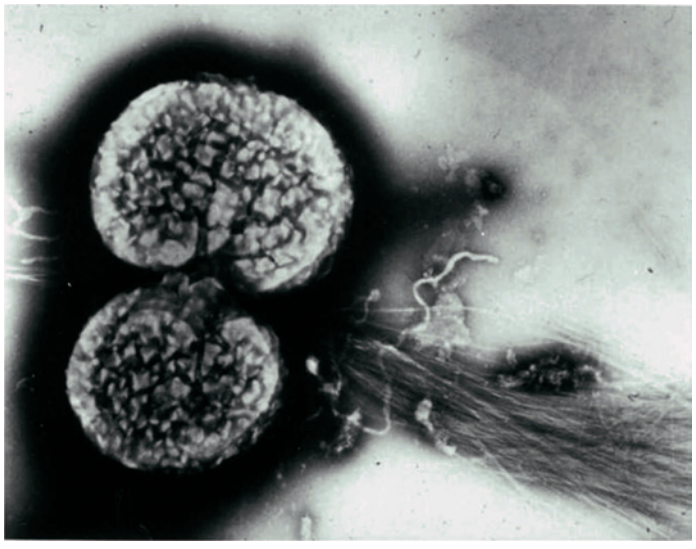

Figure 39.3 ***Neisseria meningitidis.*** Type IV pili are present on the cell surface as bundled filamentous appendages, facilitating transformation and attachment.

vaccine and meningococcal conjugate vaccine, are available. Both vaccine types are effective against serotypes A, C, Y, and W-135. Two vaccines that use recombinant proteins (antigen) are available for protection against serogroup B. Vaccination is recommended for all college students living in residence halls.

Another agent of meningitis is *H. influenzae* serotype B (Hib), a Gram-negative bacterium. Transmission is by inhalation of droplet nuclei shed by infectious individuals or carriers. Hib infects mucous membranes, resulting in sinusitis, pneumonia, and bronchitis. In addition to gaining access to the CSF, it can disseminate to the bloodstream and cause bacteremia. In the United States, *H. influenzae* disease (including pneumonia and meningitis) is primarily observed in children less than five years of age and thanks to the Hib conjugate vaccine, fewer than one case per 100,000 children occurs annually. Globally, it is estimated that *H. influenzae* serotype b causes at least 3 million cases of serious disease and almost 400,000 deaths each year.

Three to 6 percent of all *H. influenzae* infections are fatal. Furthermore, up to 20% of surviving patients have permanent hearing loss or other long-term sequelae. Therefore it is important that all children begin vaccination with the Hib conjugate vaccine at the age of two months.

Mycobacterium Infections

Mycobacteria are a large group of bacteria that are normal inhabitants of soil, water, and house dust. They cause a number of human infections that are difficult to treat. Recall that mycobacteria make cell walls that have a very high lipid content and contain mycolic acids. These complex fatty acids have 60 to 90 carbon atoms with a shorter β-hydroxy chain and a longer α-alkyl side chain (*see figure 24.11*). The presence of mycolic acids and other lipids outside the peptidoglycan layer makes mycobacteria acid-fast, which means that basic fuchsin dye cannot be removed from the cell by acid alcohol treatment. More importantly, the mycolic acids also make mycobacteria resistant to water-soluble antibiotics. ⏮ *Differential staining (section 2.3)*

M. avium Complex

Two airborne mycobacteria are noteworthy pathogens in the United States: *Mycobacterium avium* and *Mycobacterium intracellulare*. They are so closely related that they are referred to as the *M. avium* complex (MAC). Globally, *M. tuberculosis* has remained more prevalent in developing countries, whereas MAC has become the most common cause of mycobacterial infections in the United States. ⏮ *Order* Corynebacteriales *includes important human pathogens (section 24.1)*

MAC is found worldwide and infects a variety of insects, birds, and animals. Both the respiratory and the gastrointestinal tracts have been proposed as entry portals for MAC; however, person-to-person transmission is not very efficient. MAC causes a pulmonary infection in humans similar to that caused by *M. tuberculosis*. Pulmonary MAC is more common in elderly persons with preexisting pulmonary disease. The gastrointestinal tract is thought to be the most common site of colonization and dissemination in AIDS patients. It produces disabling symptoms, including fever, malaise, weight loss, night sweats, and diarrhea. Carefully controlled epidemiological studies have shown that MAC shortens survival by 5 to 7 months among persons with AIDS. ⏮ *Acquired immune deficiency syndrome (AIDS) (section 38.3)*

MAC can be isolated from sputum, blood, and aspirates of bone marrow. Acid-fast stains are of value in making a diagnosis. The most sensitive method for detection is the commercially available blood culture system. No drug is currently approved by the U.S. Food and Drug Administration (FDA) for the therapy of MAC; however, every regimen should contain either azithromycin or clarithromycin and ethambutol as a second drug. One or more of the following can be added: clofazimine, rifabutin, rifampin, ciprofloxacin, and amikacin. Regardless of the specific drugs, MAC infection is treated with two or three antimicrobials for at least 12 months.

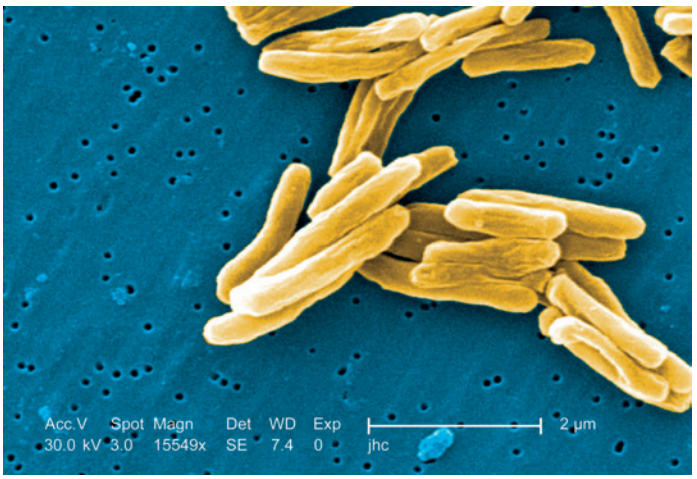
Mycobacterium tuberculosis

More than a century ago, Robert Koch identified *Mycobacterium tuberculosis* as the causative agent of **tuberculosis** (**TB**). At the time, TB was rampant, causing one-seventh of all deaths in Europe and one-third of deaths among young adults. Today TB remains a global health problem of enormous dimension. It is estimated that one-third of the world's human population is infected (with at least 2 billion people with latent infections). There were 9 million people infected with TB bacilli in 2013, and 1.5 million TB-related deaths. The 2013 incidence of TB in the United States was 9,582 cases. Worldwide, TB is caused by *M. bovis* and *M. africanum*, in addition to *M. tuberculosis* (**figure 39.4*a***). After AIDS became pandemic, the number of global TB cases increased dramatically. Because a close association exists between AIDS and TB, further spread of HIV infection among populations with a high prevalence of TB infection is resulting in dramatic increases in TB globally. Importantly, TB is the direct cause of death of over half of all AIDS patients worldwide.

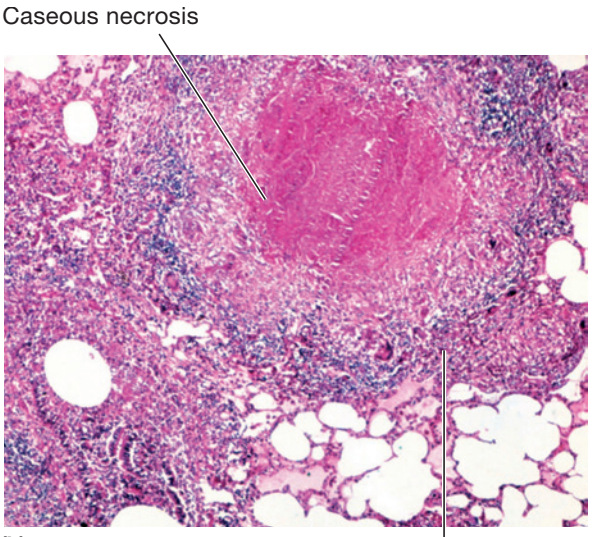
In the United States, TB occurs most commonly among the homeless, elderly, malnourished, alcoholic males, minorities, immigrants, prison populations, and Native Americans. It appears that about one-fourth to one-third of active TB cases in the United States may be due to recent transmission. Thus the majority of active cases result from the reactivation of old, dormant infections.

Infection results when the bacteria are phagocytosed by macrophages in the lungs, where they survive the normal antimicrobial processes. In fact, infected macrophages often die attempting to destroy the bacteria, thus releasing viable bacteria into respiratory spaces. The incubation period is about 4 to 12 weeks, and the disease develops slowly. The symptoms of TB are fever, fatigue, night sweats, and weight loss. A cough, which is characteristic of pulmonary involvement, may result in expectoration of bloody sputum.

M. tuberculosis (Mtb) does not produce classic virulence factors such as exotoxins, capsules, and fimbriae. Instead, Mtb has some rather unique products and properties that contribute to its



(a)



(b)

Figure 39.4 Tuberculosis. (a) Mycobacteria are rods that are a little larger than 2 µm in length (SEM). (b) In the lungs, tuberculosis is identified by the tubercle, a granuloma of white blood cells, bacteria, fibroblasts, and epithelioid cells. The center of the tubercle contains caseous (cheesy) pus and bacteria.

virulence. The unique lipids and glycolipids in the cell envelope of Mtb (*see figure 24.11*) are directly toxic to eukaryotic cells and create a hydrophobic barrier around the bacterium that facilitates impermeability and resistance to antimicrobial agents. It also protects against killing by acidic and alkaline compounds, osmotic lysis, and lysozyme. Furthermore, cell wall glycolipids associate with mannose, giving Mtb control over entry into macrophages by exploiting the macrophage mannose receptors. Once inside, Mtb inhibits phagosome-lysosome fusion by altering the phagosome membrane. Resistance to oxidative killing, inhibition of phagosome-lysosome fusion, and inhibition of diffusion of lysosomal enzymes are just some of the mechanisms that help explain the survival of Mtb inside macrophages. ◀◀ *Phagocytosis (section 33.5)*

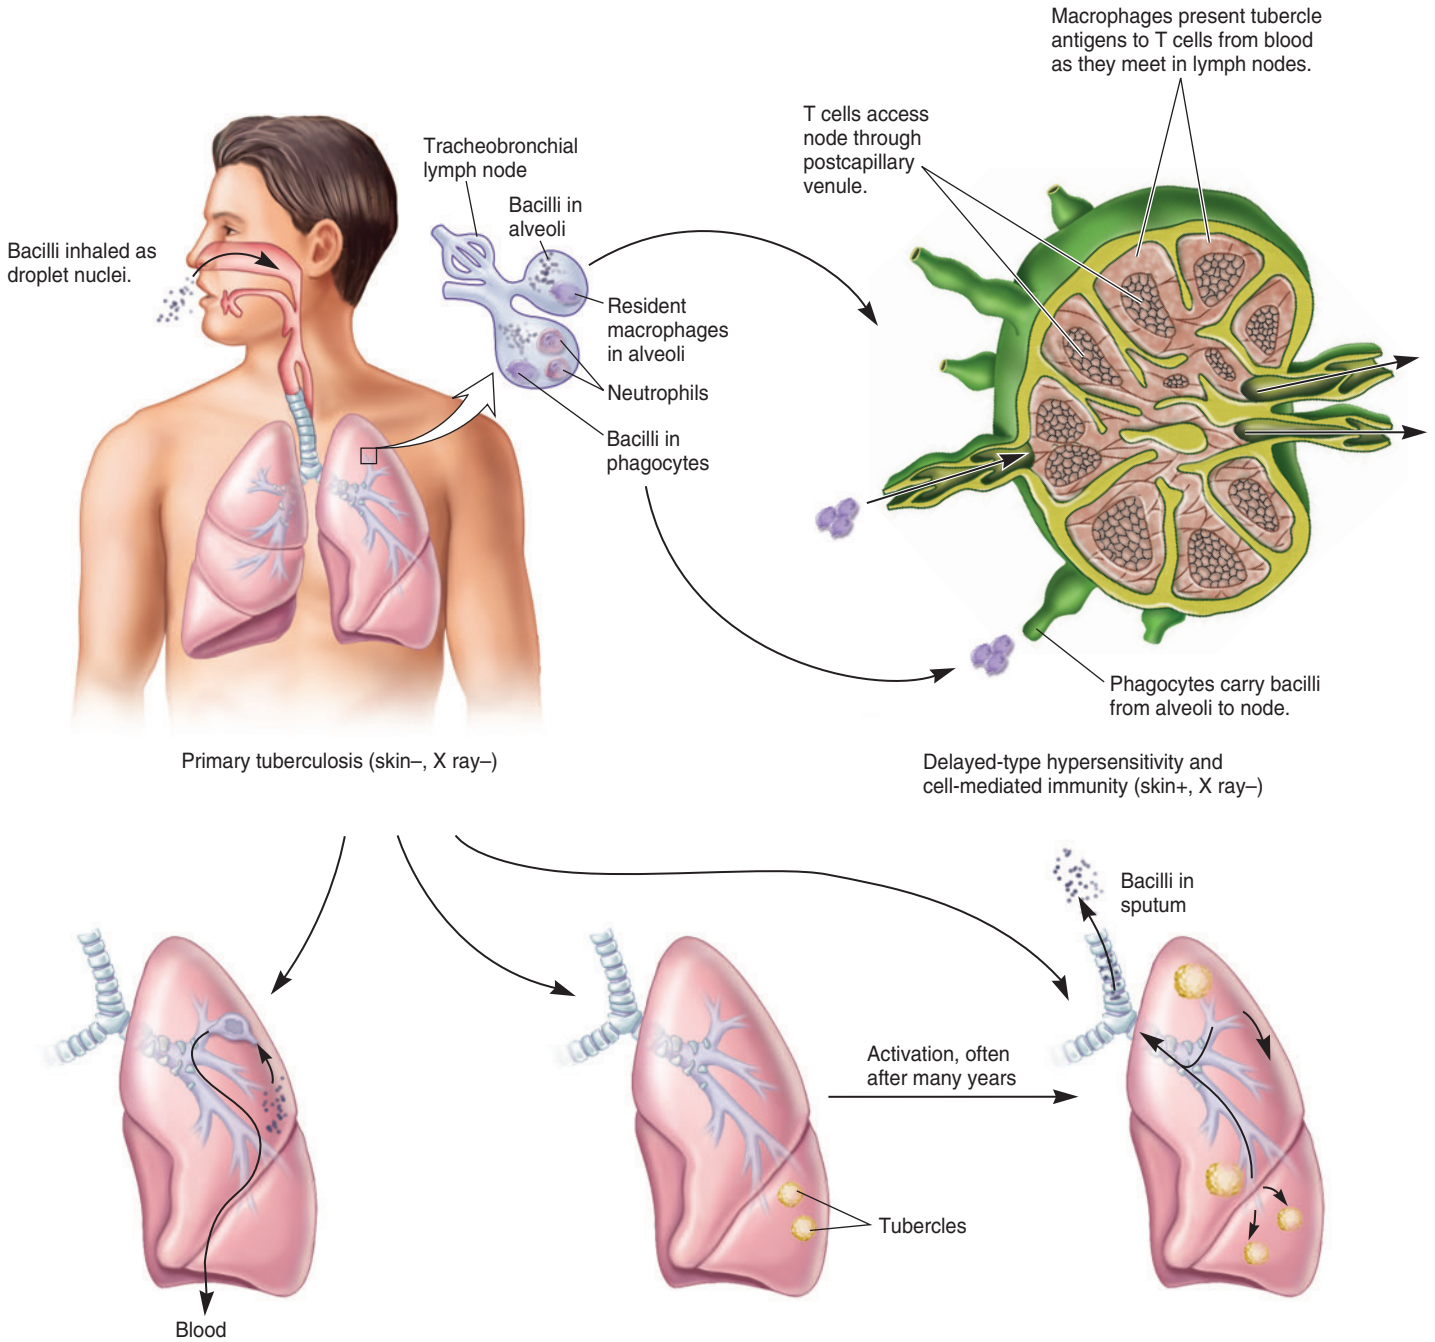
During infection, other immune cells are recruited to the site of infection by cytokines released from the responding macrophages. Together, and in response to several mycobacterial products, a hypersensitivity response results in the formation of small nodules called **tubercles** composed of bacteria, macrophages, T cells, and various human proteins (figure 39.4*b*). Tubercles are characteristic of tuberculosis and give the disease its name. The disease process usually stops at this stage, but the bacteria often remain alive within macrophage phagosomes. In some cases, the disease may become active, even after many years of latency.

In time, a tubercle may change to a cheeselike consistency and is then called a **caseous lesion** or granuloma (figure 39.4*b*). If such lesions calcify, they are called **Ghon complexes,** which show up prominently in a chest X ray. Sometimes the tubercle lesions liquefy and form air-filled **tuberculous cavities.** From these cavities, the bacteria can be disseminated to new foci throughout the body. This spreading is often called **miliary tuberculosis** due to the many tubercles the size of millet seeds that are formed in the infected tissue. It is also called **reactivation tuberculosis** because the bacteria have been reactivated in the initial site of infection. Most cases in the United States are acquired from other humans through droplet nuclei and the respiratory route (figure 39.4*c*).

TB must be treated with antimicrobial therapy. Several drugs are administered simultaneously (e.g., isoniazid [INH], plus rifampin, ethambutol, and pyrazinamide). These drugs are administered for 6 to 9 months as a way of decreasing the possibility that the bacterium develops drug resistance. However, ***m*ulti*d*rug-*r*esistant strains of *t*u*b*erculosis** (**MDR-TB**) have developed and are spreading. A multidrug-resistant strain is defined as *M. tuberculosis* that is resistant to INH and rifampin, with or without resistance to other drugs. Inadequate therapy is the most common means by which resistant bacteria are acquired, and patients who have previously undergone therapy are presumed to harbor MDR-TB until proven otherwise. Strains of Mtb considered to cause MDR-TB have emerged that are e*x*tensively *d*rug-*r*esistant (XDR); they are resistant to INH, rifampin, and the secondary antibiotics. XDR-TB is a unique challenge to public health as first-line and second-line drug resistance severely limits treatment options. For this reason, MDR-TB and XDR-TB have a higher mortality rate than drug-sensitive TB.

Drug-resistant TB arises because tubercle bacilli have spontaneous, predictable rates of chromosomal mutations that confer resistance to drugs. These mutations are unlinked; hence resistance to one drug is not associated with resistance to an unrelated drug. The observation that these mutations are not linked is the cardinal principle underlying TB chemotherapy. In the circumstances of monotherapy, erratic drug compliance, omission of one or more drugs, suboptimal dosage, poor drug absorption, or an insufficient number of active drugs in a regimen, a susceptible strain of *M. tuberculosis* may become resistant to multiple drugs within a matter of months. This is why many public health organizations worldwide practice *d*irectly *o*bserved *t*reatment *s*hort course (DOTS), in which each dose is taken in the presence of a health-care worker.

Persons infected with Mtb develop cell-mediated immunity because the bacteria stimulate a strong TH1-cell response. These



(c) *Mycobacterium tuberculosis* infection and its possible outcomes.

Figure 39.4 (*Continued*)

sensitized T cells are the basis for the tuberculin skin test. In this test, a *p*urified *p*rotein *d*erivative (PPD) of Mtb is injected intracutaneously (the Mantoux test). If the person has had TB or has been exposed to Mtb, sensitized T cells react with these proteins and a delayed hypersensitivity reaction occurs within 48 hours. This positive skin reaction appears as an induration (hardening) and reddening of the area around the injection site. In a young person, a positive skin test could indicate active tuberculosis. In older persons, it may result from previous disease, vaccination, or a false-positive test. In these cases, X rays and bacterial isolation

are completed to confirm the diagnosis. Other laboratory tests include microscopy of the acid-fast bacterium, immunoassays, and commercially available DNA probes. ⏮ *Type IV hypersensitivity (section 34.10).*

Mycoplasmal Pneumonia

Typical pneumonia has a bacterial origin (most frequently *Streptococcus pneumoniae*) with fairly consistent signs and symptoms. If the symptoms of pneumonia are different from what is usually observed, the disease is called **atypical pneumonia.** One cause of atypical pneumonia is *Mycoplasma pneumoniae*, a bacterium that lacks a cell wall and has worldwide distribution. Transmission involves close contact and airborne droplets. The disease is fairly common and mild in infants and small children; serious disease is seen principally in older children and young adults. ⏮ *Class* Mollicutes, *phylum* Tenericutes *(section 21.3)*

Because *M. pneumoniae* lacks a cell wall, cells vary in shape and stain Gram negative. Because they cannot synthesize peptidoglycan precursors, they are resistant to all β-lactam antibiotics (e.g., penicillin). Mycoplasmas typically infect the upper respiratory tract and subsequently move to the lower respiratory tract, where they attach to respiratory mucosal cells. They then produce peroxide, which may be a toxic factor, but the exact mechanism of pathogenesis is uncertain. The manifestations of this disease vary in severity from asymptomatic to a serious pneumonia. The latter is accompanied by death of the surface mucosal cells, lung infiltration, and congestion. Initial symptoms include headache, weakness, a low-grade fever, and a predominant, characteristic cough. The disease and its symptoms usually persist for weeks. The mortality rate is less than 1%.

Several rapid tests using latex-bead agglutination for *M. pneumoniae* antibodies are available for diagnosis of mycoplasmal pneumonia. When isolated from respiratory secretions, some mycoplasmas form distinct colonies with a "fried-egg" appearance on agar (*see figure 21.5*). During the acute stage of disease, diagnosis must be made by clinical observations. Tetracyclines or erythromycin are effective in treatment. There are no preventive measures.

Pertussis

Pertussis (Latin *per*, intensive, and *tussis*, cough), also called "whooping cough," is caused by the Gram-negative bacterium *Bordetella pertussis*. *B. parapertussis* is a closely related species that causes a milder form of the disease. Pertussis bacteria colonize the respiratory epithelium to produce a disease characterized by fever, malaise, uncontrollable cough, and cyanosis (bluish skin color resulting from inadequate tissue oxygenation). Whooping cough gets its name from the characteristically prolonged and paroxysmal coughing that ends in an inspiratory gasp, or whoop. Pertussis is a highly contagious, vaccine-preventable disease that primarily affects children. In 2013 the World Health Organization (WHO) indicated that there are approximately 16 million global cases of pertussis per year, of which 195,000 children, mostly infants less than six months old, die. The overall number of pertussis cases had been increasing in the United States since the 1980s, reaching 48,277 cases (and 20 deaths) in 2012. The number of cases in 2013 decreased to 28,639 (with 13 deaths), but 2014 saw a 30% increase in cases, most likely due to the emergence of new strains of *B. pertussis* not covered by the vaccine. ⏮ *Order* Burkholderiales *includes recently evolved pathogens (section 22.2)*

Disease transmission occurs by inhalation of the bacterium in droplets released from an infectious person. The incubation period is 7 to 14 days. Once inside the upper respiratory tract, the bacteria colonize the cilia of the mammalian respiratory epithelium through fimbria-like structures called filamentous hem-agglutinins that bind to complement receptors on phagocytes. Additionally, some of the components of the *B. pertussis* toxin assist in adherence to cilia by bridging bacterial and host cells; subunit S2 binds to cilial glycolipids (lactosylceramide), and subunit S3 binds to phagocyte glycoproteins. Thus attachment is an important virulence factor in the initiation of the disease.

B. pertussis produces several toxins, of which the pertussis toxin (PTx) is most important. PTx is an AB exotoxin (*see figure 35.6*). The B portion of the toxin is composed of five polypeptides (S2–S5; there are two S4 subunits) that bind to specific carbohydrates on cell surfaces and then transport the A subunit to the plasma membrane, where it is inserted and released into the cytoplasm. The A subunit (S1) is an ADP-ribosyl transferase, similar to the diphtheria toxin. However, PTx adds ADP-ribose moieties to the regulator of the host cell's adenyl cyclase, locking it in the active state so that ATP is continuously converted to cyclic AMP (cAMP). This results in an increase in intracellular levels of cAMP, which accelerates mucin secretion and alters water transport, affecting electrolyte balance. *B. pertussis* also produces its own adenyl cyclase, which further increases intracellular cAMP, tracheal cytotoxin, and dermonecrotic toxin, which destroy epithelial tissue. Working together, the adenyl cyclase, tracheal cytotoxin, and pertussis toxin provoke secretory cells in the respiratory tract to produce nitric oxide, which kills nearby ciliated cells, inhibiting removal of bacteria and mucus. The secretion of a thick mucus also impedes ciliary action. These actions make breathing difficult and lead to the whooping sound on inhalation.

Pertussis is divided into three stages. (1) The catarrhal stage, so named because of the mucous membrane inflammation, resembles the common cold. (2) The paroxysmal stage is characterized by prolonged coughing sieges. During this stage, the infected person

tries to cough up the mucous secretions by making five to 15 rapidly consecutive coughs followed by the characteristic whoop—a hurried, deep inspiration. The catarrhal and paroxysmal stages last about 6 weeks. (3) The convalescent stage, when final recovery occurs, may take several months.

Laboratory diagnosis of pertussis is by culture of the bacterium, fluorescent antibody staining of smears from nasopharyngeal swabs, other antibody-based detection tests, and PCR. The development of a strong, lasting immunity takes place after an initial infection. Treatment is with a macrolide. Trimethoprim-sulfamethoxasole can also be used. Treatment ameliorates clinical illness when begun during the catarrhal phase and may also reduce the severity of the disease when begun within 2 weeks of the onset of the paroxysmal cough. Prevention is with the DTaP vaccine, starting as early as two to three months of age. It is now recommended that all previously vaccinated adults get a booster vaccine.

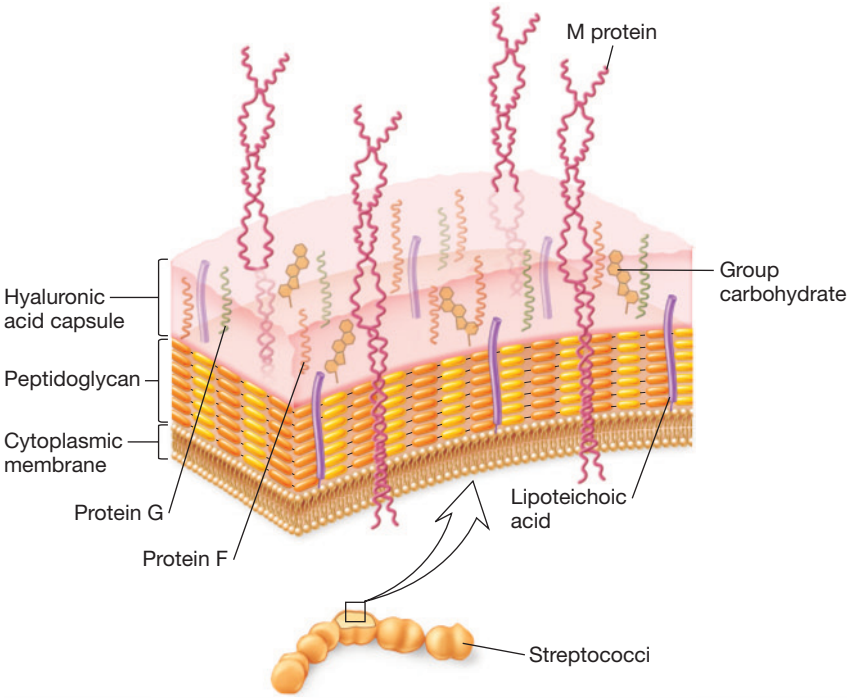

Figure 39.5 Streptococcal Cell Envelope. The M protein is a major virulence factor for group A streptococci. It facilitates bacterial attachment to host cells and has antiphagocytic activity. Protein G prevents attack by antibodies because it binds to the Fc portion of antibody molecules, preventing the antigen-binding site from interacting with the bacterium. Protein F is an epithelial cell attachment factor.

MICRO INQUIRY *How is the M protein also thought to be involved in poststreptococcal diseases?*

Streptococcal Diseases (Group A)

Pathogenic streptococci, commonly called strep, are a heterogeneous group of Gram-positive bacteria. In this group, *Streptococcus pyogenes* (group A, β-hemolytic streptococci) is one of the most important bacterial pathogens. The different serotypes of **group A streptococci** (**GAS**) produce (1) extracellular enzymes that break down host molecules; (2) streptokinases, enzymes that activate a host-blood factor that dissolves blood clots; (3) the cytolysins streptolysin O and streptolysin S, which kill host leukocytes; and (4) capsules and M protein, which help to retard phagocytosis (**figure 39.5**). M protein, a filamentous protein anchored in the streptococcal cell membrane, facilitates attachment to host cells and prevents opsonization by complement protein C3b. It is the major virulence factor of GAS. Although over 50 different *S. pyogenes* M proteins have been identified, types 1, 3, 12, and 28 are commonly found in patients with streptococcal toxic shock and multiorgan failure. ◀◀ *Complement is a cascading enzyme system (section 33.3)*

S. pyogenes is widely distributed among humans; some people become asymptomatic carriers. Individuals with acute infections may spread the pathogen, and transmission can occur through respiratory droplets, as direct or indirect contact. ◀◀ *Order* Lactobacillales *(section 23.3)*

Diagnosis of a streptococcal infection is based on both clinical and laboratory findings. Several rapid tests are available. Treatment is with penicillin or macrolide antibiotics. There is no vaccine for *S. pyogenes*. The best control measure is prevention of transmission. Individuals with a known infection should be isolated and treated. Personnel working with infected patients should follow standard aseptic procedures.

Streptococcal Pharyngitis

Streptococcal pharyngitis is one of the most frequent bacterial infections of humans and is commonly called strep throat (**figure 39.6**). The GAS are spread by droplets of saliva or nasal secretions. The incubation period in humans is 2 to 4 days.

The action of the strep bacteria in the throat (**pharyngitis**) or on the tonsils (**tonsillitis**) stimulates an inflammatory response and the lysis of white and red blood cells. An inflammatory exudate consisting of cells and fluid is released from the blood vessels and deposited in the surrounding tissue in about 50% of patients with strep pharyngitis. This is accompanied by a general feeling of discomfort or malaise, fever, and headache. Prominent physical manifestations include redness, edema, and lymph node enlargement in the throat. Signs and symptoms alone are not diagnostic because they are manifested by several viral infections as well. Several common rapid test kits are available for diagnosing strep throat. In the absence of complications,

Figure 39.6 Streptococcal Pharyngitis (Strep Throat).

MICRO INQUIRY *What causes the exudate seen in strep throat? Is it seen in all cases?*

the disease can be self-limiting and may disappear within a week. However, antibiotic treatment (penicillin, cephalosporins, or a macrolide antibiotic for penicillin-allergic people) can shorten the infection and clinical syndromes, and is especially important in children for the prevention of complications such as rheumatic fever and glomerulonephritis, as discussed next. Infections in older children and adults tend to be milder and less frequent due in part to the immunity developed against the many serotypes encountered in early childhood.

Poststreptococcal Diseases

The poststreptococcal diseases caused by GAS are glomerulonephritis and rheumatic fever. They occur 1 to 4 weeks after an acute streptococcal infection. These two diseases are the most serious problems associated with streptococcal infections in the United States.

Glomerulonephritis, also called **Bright's disease,** is an inflammatory disease (type II hypersensitivity reaction) of the renal glomeruli—membranous structures within the kidney where blood is filtered. Damage results from the deposition of antigen-antibody complexes, possibly involving the streptococcal M protein, in the glomeruli. The complexes cause destruction of the glomerular membrane, allowing proteins and blood to leak into the urine. Clinically, the affected person exhibits edema, fever, hypertension, and hematuria (blood in the urine). The disease occurs primarily among school-age children. Diagnosis is based on clinical history, physical findings, and confirmatory evidence of prior streptococcal infection. The incidence of glomerulonephritis in the United States is less than 0.5% of streptococcal infections. Penicillin G or erythromycin can be given for any residual streptococci. However, there is no specific therapy once kidney damage has occurred. About 80 to 90% of all cases undergo slow, spontaneous healing of the damaged glomeruli, whereas others develop a chronic form of the disease. The latter may require a kidney transplant or lifelong renal dialysis. ⏮ *Type II hypersensitivity (section 34.10)*

Rheumatic fever is an autoimmune disease characterized by inflammatory lesions involving the heart valves, joints, subcutaneous tissues, and central nervous system. The exact mechanism of rheumatic fever development remains unknown. However, it has been associated with prior streptococcal pharyngitis of specific M protein strains. The disease occurs most frequently among children six to fifteen years of age and manifests itself through a variety of signs and symptoms, making diagnosis difficult. In the United States, rheumatic fever has become very rare (less than 0.05% of streptococcal infections). It occurs 100 times more frequently in tropical countries. Therapy is directed at decreasing inflammation and fever, and controlling cardiac failure. Salicylates and corticosteroids are the mainstays of treatment. Although rheumatic fever is rare, it is still the most common cause of permanent heart valve damage in children.

39.2 Arthropods Can Transmit Bacterial Diseases

After reading this section, you should be able to:

- Report the common arthropod-borne bacterial diseases
- Identify typical signs and symptoms of arthropod-borne bacterial diseases
- Correlate arthropod-borne bacterial infection and disease severity with bacterial virulence factors

Bacteria cause fewer arthropod-borne diseases than do viruses and protozoa. However, they are of interest either historically (plague, typhus) or because they have emerged into human populations (ehrlichiosis, Lyme disease).

Lyme Disease

Lyme disease (**LD, Lyme borreliosis**) was first observed among people of Old Lyme, Connecticut, in 1975. It has become the most common tick-borne zoonosis in the United States. Annually, an average of approximately 30,000 confirmed cases of Lyme disease are reported to the CDC, with 94% of these located in only 12 states. The disease is also present in Europe and forested areas of Asia.

At least three spirochete species are responsible for this disease. *Borrelia burgdorferi* is the primary cause of Lyme disease in the United States, whereas *B. garinii* and *B. afzelii* appear to cause the disease in Europe (**figure 39.7*a***). Rodents and other

(a) (b) (c)

Figure 39.7 Lyme Disease. (a) The spirochete *Borrelia burgdorferi*. (b) An unengorged adult tick (*Ixodes scapularis*; bottom) is about the size of pinhead, and an engorged adult (top) can reach the size of a jelly bean. (c) The typical rash (erythema migrans) showing concentric rings around the initial site of the tick bite.

MICRO INQUIRY *What are the three stages of Lyme disease? What other spirochete disease does this resemble?*

wild animals are the natural hosts; although adult deer ticks feed on deer, deer do not become infected. In the northeastern United States, the reservoir of *B. burgdorferi* is the white-footed mouse. Spirochetes are transmitted to humans by the bite of infected black-legged (or deer) ticks (*Ixodes scapularis*; figure 39.7*b*). On the Pacific Coast, especially in California, the reservoir is a dusky-footed woodrat and the tick *I. pacificus*. ◀◀ *Phylum Spirochaetes (section 21.8)*

Clinically, Lyme disease is a complex illness with three major stages. The initial, localized stage occurs a week to 10 days after an infectious tick bite. The illness sometimes begins with erythema migrans, an expanding, ring-shaped skin lesion with a red outer border and partial central clearing (figure 39.7*c*). This is accompanied by flulike symptoms (malaise and fatigue, headache, fever, and chills). However, often the tick bite is unnoticed, or the skin lesion is missed due to skin coloration or its obscure location, such as on the scalp. Thus treatment, which is effective at this stage, may not be started because the illness is assumed to be "just the flu."

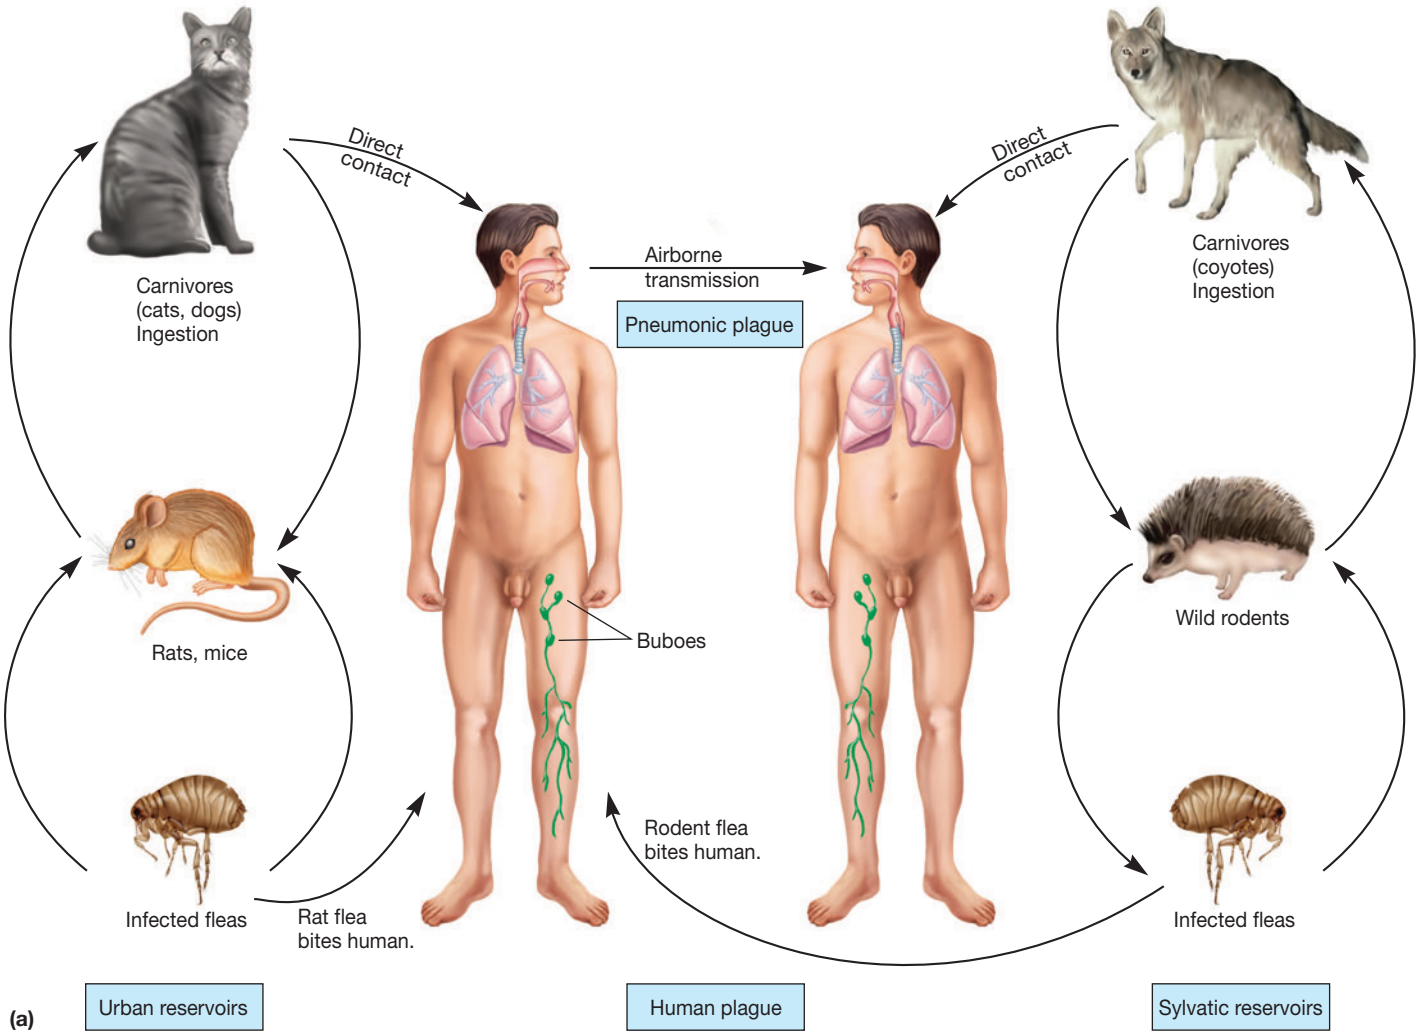
The second, disseminated stage may appear weeks or months after the initial infection. It consists of several symptoms such as neurological abnormalities, heart inflammation, and bouts of arthritis, usually in major joints such as the elbows or knees. Current research indicates that Lyme arthritis might be an autoimmune response to major histocompatibility (MHC) molecules on cells in the synovium (joint) that are similar to the bacterial antigens. Inflammation that produces organ damage is initiated and possibly perpetuated by the immune response to one or more spirochetal proteins. Finally, like the progression of syphilis—another disease caused by a spirochete—the late stage may appear years later. Infected individuals may develop neuron demyelination with symptoms resembling Alzheimer's disease and multiple sclerosis. Behavioral changes can also occur. ◀◀ *Major histocompatibility complex (section 34.4)*

Laboratory diagnosis of LD is based on (1) serological testing (Lyme ELISA) for IgM or IgG antibodies to the pathogen and Western blot for specific bacterial proteins, (2) detection of *Borrelia* DNA in patient specimens (especially synovial fluid) after amplification by PCR, and (3) recovery of the spirochete from patient specimens, although cultures are laborious with modest success. Treatment with doxycycline early in the illness results in prompt recovery and prevents arthritis and other complications. If nervous or cardiac system involvement is suspected, intravenous penicillin or ceftriaxone is used because it can cross the blood-brain barrier. ◀◀ *Polymerase chain reaction amplifies targeted DNA (section 17.2)*

Prevention and control of LD involve environmental modifications such as clearing and burning tick habitat and the application of acaricidal compounds, which destroy mites and ticks. An individual's risk of acquiring LD may be greatly reduced by education and personal protection.

Plague

Plague (Latin *plaga*, pest) is caused by the Gram-negative bacterium *Yersinia pestis*. It is transmitted from rodent to human by the bite of an infected flea, direct contact with infected animals or their products, or inhalation of contaminated airborne droplets (**figure 39.8*a***). Between 1,000 and 2,000 cases of plague are reported to the WHO each year; U.S. cases average seven annually. Initially spread by contact with flea-infested animals, *Y. pestis* can then spread among people by airborne transmission. Once in the human body, the bacteria multiply in the blood and lymph. Symptoms include subcutaneous hemorrhages, fever, chills, headache, extreme exhaustion, and the appearance of enlarged lymph nodes called **buboes** (hence the old name, **bubonic plague**) (figure 39.8*b*). In 50 to 70% of the untreated cases, death



(b)

Figure 39.8 Plague. (a) Plague is spread to humans through (1) the urban cycle and rat fleas, (2) the sylvatic cycle, centering on wild rodents and their fleas, or (3) by airborne transmission from an infected person, leading to pneumonic plague. Dogs, cats, and coyotes can also acquire the bacterium by ingestion of infected animals. (b) Enlarged lymph nodes called buboes are characteristic of *Yersinia* infection.

follows in 3 to 5 days from toxic conditions caused by the large number of bacilli in the blood.

An important factor in the virulence of *Y. pestis* is its ability to survive and proliferate inside phagocytic cells, rather than being killed by them. Like many other Gram-negative pathogens, *Y. pestis* uses a type III secretion system (a kind of molecular syringe) to deliver effector proteins. *Y. pestis* secretes plasmid-encoded yersinial outer membrane proteins (YOPS) into phagocytic cells to counteract natural defense mechanisms and help the bacteria multiply and disseminate in the host (**figure 39.9**). ⏮ *Order* Enterobacteriales *includes pathogens and mutualists (section 22.3); Pathogenicity islands (section 35.2)*

In the southwestern part of the United States, plague occurs primarily in wild ground squirrels, chipmunks, mice, and prairie dogs. However, massive human epidemics occurred in Europe during the Middle Ages, where the disease was known as the Black Death due to black-colored, subcutaneous hemorrhages. Infections now occur in humans only sporadically or in limited outbreaks.

Pneumonic plague arises (1) from primary exposure to infectious respiratory droplets from a person or animal with

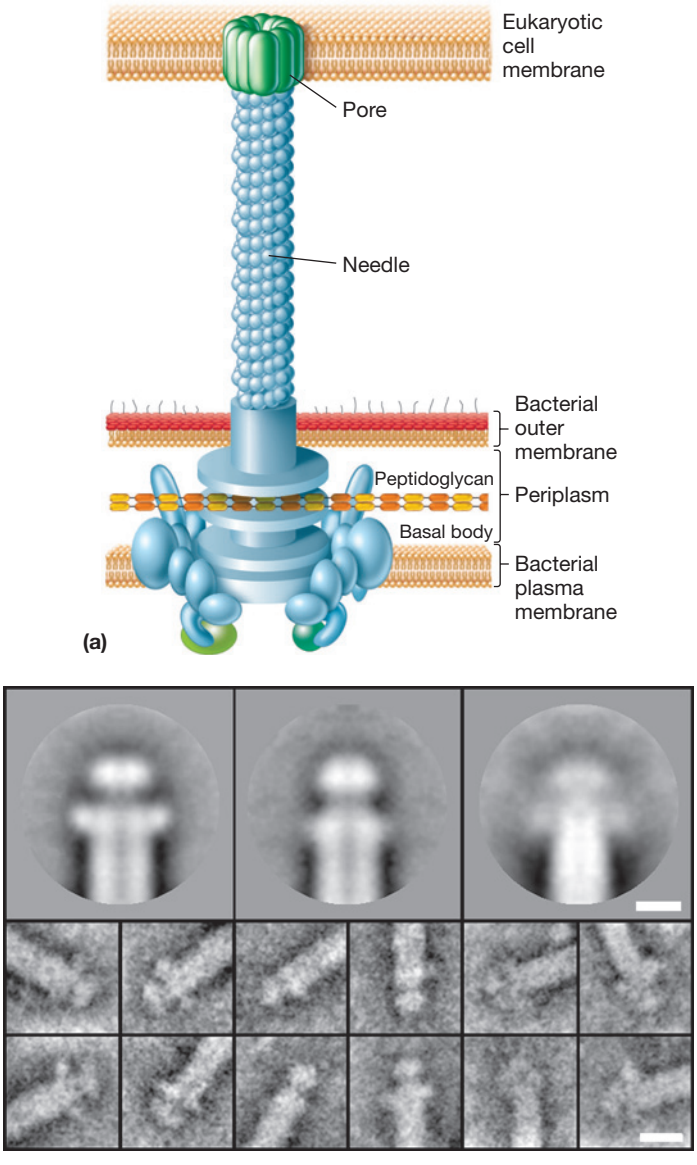


Figure 39.9 Type III Secretion System. (a) X-ray fiber diffraction studies resolve the injectisome as a helical structure. (b) Scanning tunneling electron microscopy reveals the injectisome tip, indicating how it may lock into the translocator pore on the target cell.

respiratory plague or (2) secondary to blood-borne spread in a patient with bubonic or septicemic plague. Pneumonic plague can also arise from accidental inhalation of *Y. pestis* in the laboratory. The mortality rate for this kind of plague is almost 100% if it is not recognized within 12 to 24 hours. Obviously great care must be taken to prevent the spread of airborne infections to personnel who care for pneumonic plague patients.

Because the plague bacillus is listed as a potential bioterrorism agent, sentinel laboratory identification of *Y. pestis* is restricted to initial staining and culture tests. Confirmation of the identity of *Y. pestis* by PCR, advanced serological studies, and other approved practices is restricted to national reference laboratories. Treatment is with streptomycin and gentamycin, although fluoroquinolones, chloramphenicol, or tetracycline can also be used, and recovery from the disease provides immunity. Prevention and control involve flea and rodent control, isolation of human patients, prophylaxis or abortive therapy of exposed persons, and vaccination (USP Plague vaccine) of persons at high risk. (e.g., park rangers, veterinarians).

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever is caused by the rickettsia, *Rickettsia rickettsii*. Although this disease was originally detected in the Rocky Mountain area, most cases occur east of the Mississippi River. The disease is transmitted by ticks and usually occurs in people who are or have been in tick-infested areas. There are two principal vectors: *Dermacentor andersoni*, the wood tick, which is active during the spring and early summer in the Rocky Mountain states; and *D. variabilis*, the dog tick, which has assumed greater importance and is almost exclusively confined to the eastern half of the United States. Unlike other rickettsias, *R. rickettsii* can pass from generation to generation of ticks through their eggs in a process known as transovarian passage. Therefore, no animals are needed as reservoirs for the continued propagation of this rickettsia in the environment.

The rickettsial bacteria are harbored in the tick intestinal tract and are deposited on humans when the tick defecates after feeding. Humans are typically infected by rubbing or scratching the site where the tick is feeding. Once inside the skin, the rickettsias enter the endothelial cells of small blood vessels, where they multiply and produce a characteristic rash that is caused by inflamed blood vessels. Therefore this rash is considered a vasculitis. The bacteria induce phagocytosis by macrophages responding to the infection, but then escape the phagosome and reproduce in the cytosol (*see figure 22.6*). They continue to reproduce until the host cell bursts, releasing bacteria to infect other host cells. Rickettsias are very different from most other bacteria in physiology and metabolism. Described as an energy parasite, rickettsias have a membrane carrier protein that exchanges internal ADP for external ATP. Thus bacterial growth and reproduction continue at the expense of the host cell. ⏮ *Rickettsias are obligate intracellular bacteria (section 22.1); Phagocytosis (section 33.5)*

Rocky Mountain spotted fever (RMSF) is characterized by the sudden onset of a headache, high fever, chills, and a skin rash (**figure 39.10**) that initially appears on the ankles and wrists, and then spreads to the trunk of the body. The symptoms reflect the accumulation of lysed host cells and toxic effects of rickettsial cell walls. If the disease is not treated, the rickettsias destroy blood vessels in the heart, lungs, or kidneys and cause death within 8 days after infection. Usually, however, severe pathological changes are avoided by antibiotic therapy (doxycycline), development of immune resistance, and supportive therapy. Diagnosis is made through observation of symptoms and signs such as the characteristic rash and by serological tests. The best means of prevention remains avoidance of tick-infested habitats and animals. RMSF cases are reported year-round, with the greatest incidence between May and August. The CDC reports approximately 2,000 cases per year.

Figure 39.10 Rocky Mountain Spotted Fever. Typical rash occurring on the arms consists of generally distributed, sharply defined macules.

39.3 Direct Contact Diseases Can Be Caused by Bacteria

After reading this section, you should be able to:

- Report the common bacterial diseases spread by direct contact
- Identify typical signs and symptoms of bacterial diseases spread by direct contact
- Correlate direct contact bacterial infection and disease severity with bacterial virulence factors

Most of the direct contact bacterial diseases involve the skin or underlying tissues. Others result from bacterial infection of mucous membranes. Occasionally, bacteria penetrate beyond the skin to cause disseminated disease. We now discuss some of the better-known bacterial contact diseases.

Gas Gangrene (Clostridial Myonecrosis)

Clostridium perfringens, C. novyi, and *C. septicum* are Gram-positive, endospore-forming rods termed the histotoxic clostridia. All can produce a necrotizing infection of skeletal muscle called **gas gangrene** (Greek *gangraina*, an eating sore) or **clostridial myonecrosis** (Greek *myo*, muscles, and *necrosis*, death); however, *C. perfringens* is the most common cause. Analysis of the *C. perfringens* genome sequence reveals that the microbe possesses the genes for fermentation with gas production but lacks genes encoding enzymes for the TCA cycle or a respiratory chain. Nonetheless,

Figure 39.11 Gas Gangrene (Clostridial Myonecrosis). Necrosis of muscle and other tissues results from the numerous toxins produced by *Clostridium perfringens*.

C. perfringens has an extraordinary doubling time of only 8 to 10 minutes when in the human host, making diagnosis and treatment of gangrene critical. ⏮ *Class* Clostridia *(section 23.1)*

Histotoxic (tissue damaging) clostridia occur in the soil worldwide and also are part of the normal endogenous microflora of the human large intestine. Contamination of injured tissue with spores from soil containing histotoxic clostridia or bowel flora is the usual means of transmission. Infections are commonly associated with wounds resulting from abortions, automobile accidents, military combat, or frostbite. If the spores germinate in anoxic tissue, the bacteria grow and secrete α-toxin (a lecithinase), which breaks down muscle tissue by disrupting cell membranes and causing cell lysis. Growth often results in accumulation of gas (mainly hydrogen as a result of carbohydrate fermentation) and toxic breakdown products of skeletal muscle tissue (**figure 39.11**). ⏮ *Exotoxins (section 35.2)*

Clinical manifestations of gas gangrene include severe pain, edema, drainage, and muscle necrosis. The pathology arises from progressive skeletal muscle necrosis due to the effects of the toxin. Other enzymes produced by the bacteria degrade collagen and tissue, facilitating spread of the disease.

Gas gangrene is a medical emergency! Laboratory diagnosis is through recovery of the appropriate species of clostridia accompanied by the characteristic disease symptoms. Treatment is extensive surgical removal of all dead tissue, the administration of antitoxin, and antimicrobial therapy with penicillin and tetracycline. Hyperbaric oxygen therapy (the use of high concentrations of oxygen at elevated pressures) is also effective. The oxygen saturates the infected tissue and thereby prevents the growth of the obligately anaerobic clostridia. Prevention and control include debridement of contaminated traumatic wounds plus antimicrobial prophylaxis and prompt treatment of all wound infections. Interestingly, laboratory-raised, sterile maggots are also used to remove dead and infected tissue. Amputation of limbs often is necessary to prevent further spread of the disease.

Group B Streptococcal Disease

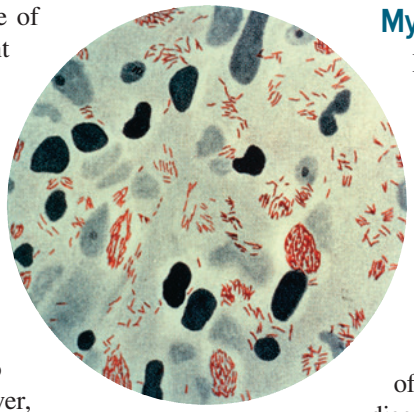
Streptococcus agalactiae, or **group B streptococcus** (**GBS**), is a Gram-positive bacterium that causes illness in newborn babies, pregnant women, the elderly, and adults compromised by other

severe illness. In fact, GBS is the leading cause of sepsis and meningitis in newborns, a frequent cause of newborn pneumonia, and a common cause of life-threatening neonatal infections. GBS in neonates is more common than rubella and congenital syphilis. Nearly 75% of infected newborns present symptoms in the first week of life; premature babies are more susceptible. Most GBS cases are apparent within hours to less than seven days after birth. This is called "early-onset disease." GBS can also develop in infants who are one week to three months old ("late-onset disease"); however, this is very rare. Meningitis is more common with late-onset disease. Interestingly, about half of the infants with late-onset GBS disease are associated with a mother who is a GBS carrier; the source of infection for the other newborns with late-onset GBS disease is unknown. Infant mortality due to GBS disease is about 5%. Babies who survive GBS disease, particularly those with meningitis, may have permanent disabilities, such as hearing or vision loss or developmental disabilities. The CDC reports approximately 20,000 total cases of invasive GBS annually.

GBS disease is diagnosed when the Gram-positive, β-hemolytic streptococcus is grown from cultures of otherwise sterile body fluids, such as blood or spinal fluid. GBS cultures may take 24 to 72 hours for robust growth to appear. Confirmation of GBS is by latex agglutination immunoassay. An FDA-approved DNA test for GBS is also available if rapid diagnosis of disease is necessary or culture results are equivocal.

GBS is transmitted directly from person to person. Many people are asymptomatic GBS carriers—they are colonized by GBS but do not become ill from it. Adults can carry GBS in the bowel, vagina, bladder, or throat. Twenty-five percent of pregnant women carry GBS in the rectum or vagina. Thus a fetus may be exposed to GBS before or during birth if the mother is a carrier. GBS carriage is temporary; that is, carriers do not harbor the bacteria for life. GBS carriage can be detected during pregnancy by the presence of the bacterium in culture specimens of either the vagina or the rectum. The CDC recommends that pregnant women have vaginal and rectal specimens cultured for GBS in late pregnancy (35 to 37 weeks' gestation). A positive culture result means that the mother carries GBS—not that she or her baby will definitely become ill. Women who carry GBS are not given oral antibiotics before labor because antibiotic treatment at this time does not prevent GBS disease in newborns. An exception to this is when GBS is identified in urine during pregnancy, which indicates an active infection and is treated promptly. Carriage of GBS, in either the vagina or rectum, becomes important at the time of labor and delivery or any time the placental membrane ruptures. At this time, antibiotics are effective in preventing the spread of GBS from mother to baby.

GBS infections in both newborns and adults are usually treated with intravenous penicillin or ampicillin, unless resistance or hypersensitivity is indicated. A GBS vaccine based on genomic analysis has been under development. However, GBS vaccine development is problematic due to antigen-shifting serotypes. ▶▶| *Vaccines (section 42.1)*



Mycobacterial Skin Infections

Many pathogenic species of nontuberculous mycobacteria cause skin or soft-tissue infections. These diseases often are hard to diagnose as they may cause diverse and misleading signs and symptoms. Two skin-associated diseases caused by nontuberculous mycobacteria are presented here. Leprosy has a reputation from history that caused people with the disease to be shunned, rather than helped. We discuss leprosy because it is a complicated disease that still often stigmatizes its victims. In contrast, we also discuss an emerging mycobacterial infection associated with the recent trend of tattoo art.

Leprosy

Leprosy (Greek *lepros*, scaly, scabby, rough), a skin disease caused by *Mycobacterium leprae,* can be severely disfiguring. The only reservoirs of proven significance are humans and armadillos. The disease most often occurs in tropical countries, and the global leprosy incidence is approximately 220,000 cases. The United States reported 82 confirmed cases in 2012 (last available data), with cases in 33 states; 69.5% of the cases were reported by California, Florida, Hawaii, and Texas. Transmission of leprosy is most likely to occur when individuals are exposed for prolonged periods to infected individuals who shed large numbers of *M. leprae*. Nasal secretions probably are the infectious material for family contacts. |◀◀ *Order* Corynebacteriales *includes important human pathogens (section 24.1)*

The incubation period for leprosy is about 3 to 5 years but may be much longer, and the disease progresses slowly. The bacterium invades peripheral nerve and skin cells, and reproduces as an obligately intracellular parasite. It is most frequently found in Schwann cells that surround peripheral nerve axons and in mononuclear phagocytes. The earliest symptom is usually a slightly pigmented skin eruption several centimeters in diameter. Approximately 75% of all individuals with this early, solitary lesion heal spontaneously because they mount an effective cell-mediated immune response. However, in some individuals, this immune response may be so weak that one of two distinct forms of the disease occurs: tuberculoid or lepromatous leprosy.

Tuberculoid (neural) leprosy is a mild, nonprogressive form of leprosy associated with a delayed-type hypersensitivity reaction to antigens on the surface of *M. leprae*. It is characterized by damaged nerves and regions of the skin that have lost sensation and are surrounded by a border of nodules (**figure 39.12**). Afflicted individuals who do not develop hypersensitivity have a relentlessly progressive form of the disease, called **lepromatous (progressive) leprosy,** in which large numbers of *M. leprae* develop in the skin cells. The bacteria kill skin tissue, leading to a progressive loss of facial features, fingers, toes, and other structures. Moreover, disfiguring nodules form all over the body. Nerves are also infected but usually are less damaged than in tuberculoid leprosy. |◀◀ *Type IV hypersensitivity (section 34.10)*

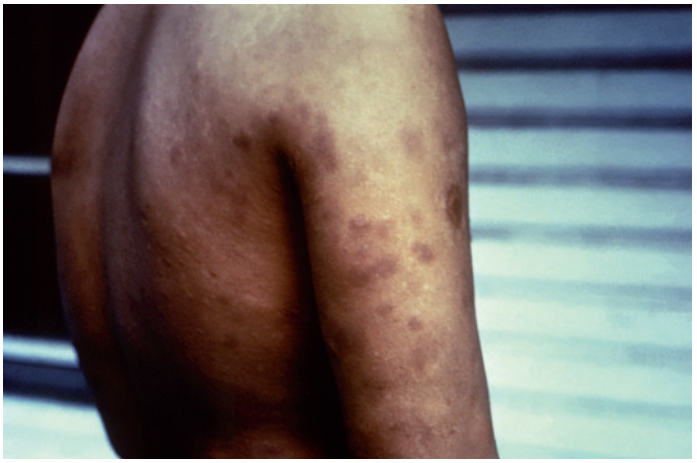


Figure 39.12 Leprosy. In tuberculoid leprosy, the skin manifests shallow, painless lesions.

MICRO INQUIRY *What are the chief differences between tuberculoid and lepromatous leprosy?*

Because the leprosy bacillus cannot be cultured in vitro, laboratory diagnosis is supported by the demonstration of the bacterium in biopsy specimens using direct fluorescent antibody staining. Serodiagnostic methods, such as the fluorescent leprosy antibody absorption test and ELISA, have been developed.

Treatment is accomplished with rifampicin combined with dapsone to treat tuberculous leprosy. Rifampicin with clofazimine is combined with dapsone to treat lepromatous leprosy. Dapsone (diacetyl dapsone) acts by inhibiting the synthesis of dihydrofolic acid through competition with para-aminobenzoic acid (*see figure 9.11*). Identification and treatment of patients with leprosy is the key to control. Children of presumably contagious parents should be given chemoprophylactic drugs until treatment of their parents has made them noninfectious.

Tattoo-Associated Mycobacterial Infections

Sporadic cases and outbreaks of tattoo-associated mycobacterial infections remind us that emerging diseases do not have to be exotic. Rapidly growing mycobacteria (RGM) are a nontuberculous group of mycobacteria commonly found in water, soil, and dust. RGM were found to be the cause of 142 cases, from 11 countries, of tattoo-associated skin infections. *Mycobacterium chelonae* was identified as the elusive agent responsible for these cases. The index case was a 49-year-old man who had over 100 small pimplelike pustules and reddened skin blotches within two-week-old tattoos. Examination of biopsy specimens were negative for bacteria, including acid-fast bacilli. However, culture of the specimen revealed *M. chelonae*. Five additional cases were also reported that had a range of skin lesions, including pink, red, and purple papules; scaly papules; granulomatous papules; lichenoid papules; pustules; and plaques. The common link to all six cases was the inking of tattoos by the same artist; all of the lesions were found to be concentrated in "gray wash" (areas of shading using gray tones) within the tattoos. Other tattoo-associated infections, caused by *M. haemophilum*, were identified in two otherwise healthy males, who developed painless rashes about three days after receiving tattoos. Their tattoo sites then filled with numerous nodular pustules that failed to resolve with initial antibiotic therapy. In fact, it took nine months of multicourse antibiotic regimens to eradicate the infection in one of the patients. The only common link in these two cases was the use of tap water to dilute the tattoo ink.

Laboratory diagnosis for rapidly growing mycobacterial organisms is by culture and routine bacterial staining. Antibiotic sensitivity testing is also important when weighing treatment options. As with other mycobacterial infections, multiple antibiotics may be used concurrently to control the infection. Treatment of rapidly growing mycobacterial skin infections is successful with macrolide antibiotics (e.g., clarithromycin or azithromycin), orally and topically, but may take many months. Topical steroids may also be indicated to control the lesions.

2. Why do you think the slow growth rate of *M. leprae* makes leprosy treatment more difficult?

Peptic Ulcer Disease and Gastritis

Peptic ulcer disease is caused by the Gram-negative, spiral bacillus *Helicobacter pylori*. Found in gastric biopsy specimens from patients with gastritis, *H. pylori* is responsible for most cases of chronic **gastritis** not associated with another known primary cause (e.g., autoimmune gastritis or eosinophilic gastritis). Importantly, untreated *H. pylori* infection can lead to gastric cancer and it has been classified as a Class I carcinogen by the World Health Organization (WHO). ⏮ *Class* Epsilonproteobacteria *ranges from pathogens to deep-sea bacteria (section 22.5)*

H. pylori colonizes only gastric mucus-secreting cells, beneath the gastric mucous layers, and surface fimbriae are believed to be one of the adhesins associated with this process (**figure 39.13**). *H. pylori* binds to Lewis B antigens, which are part of the blood group antigens that determine blood group O. *H. pylori* also binds to the monosaccharide sialic acid, which is found in the glycoproteins on the surface of gastric epithelial cells. The bacterium moves into the mucous layer to attach to mucus-secreting cells. Movement into the mucous layer may be aided by the fact that *H. pylori* is a strong producer of urease. Urease activity creates a localized alkaline environment when hydrolysis of urea produces ammonia. The increased pH may protect the bacterium from gastric acid until it is able to grow under the layer of mucus in the stomach. The potential virulence factors responsible for epithelial cell damage and inflammation probably include proteases, phospholipases, cytokines, and cytotoxins.

Laboratory identification of *H. pylori* is by culture of gastric biopsy specimens, examination of stained biopsies for the presence of bacteria, detection of serum IgG, the urea breath test,

Figure 39.13 ***Helicobacter pylori*, the Causative Agent of Peptic Ulcer Disease.** Scanning electron micrograph (×3,441) of *H. pylori* adhering to gastric cells.

MICRO INQUIRY *How does* H. pylori *increase the local pH in its gastric microenvironment?*

urinary excretion of (^{15}N) ammonia, stool antigen assays, or detection of urease activity in biopsies. The goal of *H. pylori* treatment is the complete elimination of the organism. Treatment is two-pronged: use of drugs to decrease stomach acid (proton pump inhibitors) and antibiotics (metronidazole and tetracycline, amoxicillin, or clarithromycin) to kill the bacteria.

Approximately 50% of the world's population is estimated to be infected with *H. pylori*. It is most likely transmitted from person to person (usually acquired in childhood), although infection from a common exogenous source cannot be completely ruled out, and some think that it is spread by food or water. Support for person-to-person transmission comes from evidence of clustering within families and from reports of higher than expected prevalences in residents of custodial institutions such as nursing homes.

Sexually Transmitted Diseases

Sexually transmitted diseases (STDs) represent a worldwide public health problem. There are over 30 different bacteria, viruses, and parasites that are transmitted between humans through sexual contact. The various viruses that cause STDs are presented in chapter 38, and the yeasts and protozoa in chapter 40. The most common bacterial conditions include chlamydial infections, gonorrhea, and syphilis. These and other sexually transmitted bacteria, and the diseases they cause, are presented in **table 39.1**.

The spread of most STDs is currently out of control. The WHO estimates that the annual global number of new STD cases is 499 million, with most infections occurring in fifteen- to thirty-year-old individuals. Importantly, STDs represent the single most frequent cause of preventable infertility, especially among women. In the United States, STDs remain a major public health challenge. The 2013 sexually transmitted disease *Surveillance Report* published by the Centers for Disease Control and Prevention (CDC) indicated that while substantial progress has been made in preventing, diagnosing, and treating certain STDs, 20 million new infections occur each year, nearly half of them among people aged fifteen to twenty-four. STDs also exact a tremendous economic toll, with direct medical costs estimated at $15.6 billion annually in the United States alone. Many cases of STDs go undiagnosed; others are not reported at all. This is particularly problematic as women with untreated chlamydia or gonorrhea infections risk infertility, and both men and women with papillomavirus infection have a greater risk of cancer.

STDs were formerly called venereal diseases (from Venus, the Roman goddess of love) and may sometimes be referred to as sexually transmitted infections (STIs). Although they occur most frequently in the most sexually active age group, anyone who has sexual contact with an infected individual is at increased risk. In general, the more sexual partners a person has, the more likely the person will acquire an STD.

As noted in previous chapters, some of the microorganisms that cause STDs can also be transmitted by nonsexual means. Examples include transmission by contaminated hypodermic needles and syringes shared among intravenous drug users and transmission from infected mothers to their infants. Some STDs can be cured quite easily, but others are presently difficult or impossible to cure. Because treatments are often inadequate, prevention is essential. Preventive measures are based mainly on better education, barrier protection, and treatment of infected individuals with chemotherapeutic agents.

Chlamydial Diseases

Chlamydia is the most frequently reported sexually transmitted bacterial disease. Over 1.4 million cases of chlamydia were reported to the CDC in 2013. However, this number is thought to be grossly underestimated as most people with chlamydial infections have no symptoms and thus go undiagnosed. The most frequently isolated species causing an STD is *C. trachomatis*. Chlamydia is transmitted through anal, oral, and vaginal sex, and it can be transmitted from mother to child during vaginal childbirth. Symptoms of chlamydial disease vary widely. Males may have few or no manifestations (including a urethral discharge, burning during urination, and itching); however, complications such as inflammation of reproductive structures can occur. Females may be asymptomatic or have a severe infection of the cervix and urethra. Symptoms in women include abnormal vaginal discharge and burning on urination. Bacteria can spread from the vaginal areas to the rectum. The infection may also spread from the cervix to the fallopian tubes, leading to **pelvic inflammatory disease** (**PID**), with symptoms of abdominal

Table 39.1 Summary of the Major Sexually Transmitted Diseases (STDs) Caused by Bacteria

Microorganism	Disease	Comments	Treatment
Chlamydia trachomatis	Nongonococcal urethritis (NGU); cervicitis, pelvic inflammatory disease (PID), lymphogranuloma venereum	Serovars D-K cause most of the STDs in the U.S.; lymphogranuloma venereum rare in the U.S.	Doxycycline and azithromycin
Haemophilus ducreyi	Chancroid ("soft chancre")	Open sores on the genitals can lead to scarring without treatment; on the rise in the U.S.	Azithromycin and ceftriaxone
Helicobacter cinaedi, H. fennelliae	Diarrhea and rectal inflammation in men who have sex with other men	Common in immunocompromised individuals	Metronidazole, macrolides
Mycoplasma genitalium	Implicated in some cases of NGU	Only recently described as an STD	Azithromycin
Mycoplasma hominis	Implicated in some cases of PID	Widespread, often asymptomatic but can cause PID in women	Azithromycin
Neisseria gonorrhoeae	Gonorrhea, PID	Most commonly reported STD in the U.S.; usually symptomatic in men and asymptomatic in women; antibiotic-resistant strains	Doxycycline and azithromycin
Treponema pallidum subsp. *pallidum*	Syphilis, congenital syphilis	Manifests many clinical syndromes	Benzathine penicillin G or doxycycline
Ureaplasma urealyticum	Urethritis	Widespread, often asymptomatic but can cause PID in women and NGU in men; premature birth	Azithromycin or doxycycline

pain, back pain, fever, nausea, and unusual vaginal bleeding (**figure 39.14**). Furthermore, chlamydial infections of the throat can occur in men or women who have oral sex with infected partners. In pregnant females, chlamydial infections are especially serious because they are directly related to miscarriage, stillbirth, inclusion conjunctivitis, and infant pneumonia. Chlamydia is effectively treated with a macrolide or doxycycline; because it is very often co-transmitted with *N. gonorrheae*, patients treated for gonorrhea are also treated for chlamydia.

Gonorrhea

Gonorrhea (Greek *gono*, seed, and *rhein*, to flow) is an acute, infectious, sexually transmitted disease of the mucous membranes of the genitourinary tract, eye, rectum, and throat (table 39.1). It is caused by the Gram-negative, diplococcus *Neisseria gonorrhoeae*. These bacteria are also referred to as **gonococci** and have a worldwide distribution. It is estimated that there are over 700,000 cases of gonorrhea in the United States each year, but fewer than half are reported. For example, in 2013 approximately 301,000 cases were reported to the CDC. ⏮ *Order* Neisseriales *includes important pathogens (section 22.2)*

Once inside the body, gonococci attach to the microvilli of mucosal cells by means of type IV pili and protein II, which function as adhesins. This attachment prevents the bacteria from being washed away by normal cervical and vaginal discharges or by the flow of urine. They are often endocytosed by mucosal cells and may even be transported through the cells to the intercellular spaces and subepithelial tissue, a process known as

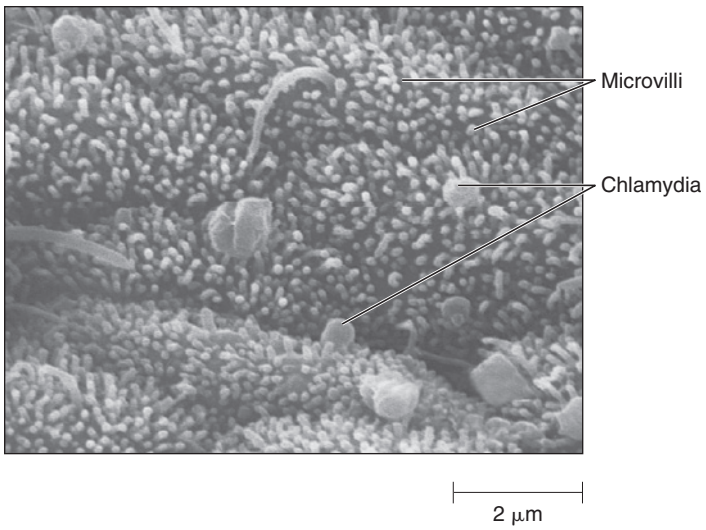

Figure 39.14 ***Chlamydia trachomatis*** **Attached to the Mucosa of a Fallopian Tube.**

transcytosis. The host tissue becomes infiltrated by immune cells, which phagocytose the bacterium. Neutrophils can be observed that contain gonococci inside phagosomes, where the gonococci can survive because they can withstand the harsh phagosomal environment (**figure 39.15*a***). Because gonococci are intracellular at this time, the host's defenses have little effect on the bacteria. Additionally, gonococci alter their adhesin proteins in response to host recognition (a process known as antigenic or phase variation), forcing immune cells to repeatedly re-identify and re-respond to the bacteria. Neutrophils are later replaced by fibrous tissue that may lead to urethral closing, or stricture, in males. ⏮ *Cells of the immune system (section 33.4); Phagocytosis (section 33.5)*

In males, the incubation period is 2 to 8 days. The onset consists of a urethral discharge of yellow, creamy pus and frequent, painful urination accompanied by a burning sensation. In females, the cervix is the principal site infected. The disease is more insidious in females, and few women experience any symptoms. However, some symptoms may begin 7 to 21 days after infection. These are generally mild; some vaginal discharge may occur. The gonococci also can infect the Fallopian tubes and surrounding tissues, leading to PID. This occurs in 10 to 20% of infected females. Gonococcal PID is a major cause of sterility and ectopic pregnancies because of scar formation in the Fallopian tubes. Gonococci disseminate most often during menstruation, a time in which there is an increased concentration of free iron available to the bacteria. In both genders, disseminated gonococcal infection with bacteremia may occur. This can lead to involvement of the joints (gonorrheal arthritis), heart (gonorrheal endocarditis), or pharynx (gonorrheal pharyngitis).

Gonorrheal eye infections can occur in newborns as they pass through an infected birth canal. The resulting disease is called **ophthalmia neonatorum,** or **conjunctivitis of the newborn** (figure 39.15*b*). This was once a leading cause of blindness in many parts of the world. To prevent this disease, as well as chlamydial conjunctivitis, erythromycin or silver nitrate in dilute solution is placed in the eyes of newborns. This treatment is required by law in the United States and many other nations.

Laboratory diagnosis of gonorrhea relies on the successful growth of *N. gonorrhoeae* in culture to determine oxidase reaction, Gram-stain reaction, and colony and cell morphology. Because gonococci are very sensitive to adverse environmental conditions and survive poorly outside the body, specimens should be plated directly; when this is not possible, special transport media are necessary. A DNA probe for *N. gonorrhoeae* has been developed and is used to supplement other diagnostic techniques.

Gonorrhea is currently treated with a single injection of cephtriaxone because penicillin- and fluoroquionolone-resistant strains are prevalent worldwide. Alarmingly, some strains are also gaining resistance to cephalosporins. Because *N. gonorrheae* and *C. trachomatis* are often co-transmitted, treatment for gonorrhea also includes a macrolide or tetracycline to treat chlamydia. Later stages of gonorrhea are more difficult to treat and may require much larger drug doses over a longer period of time.

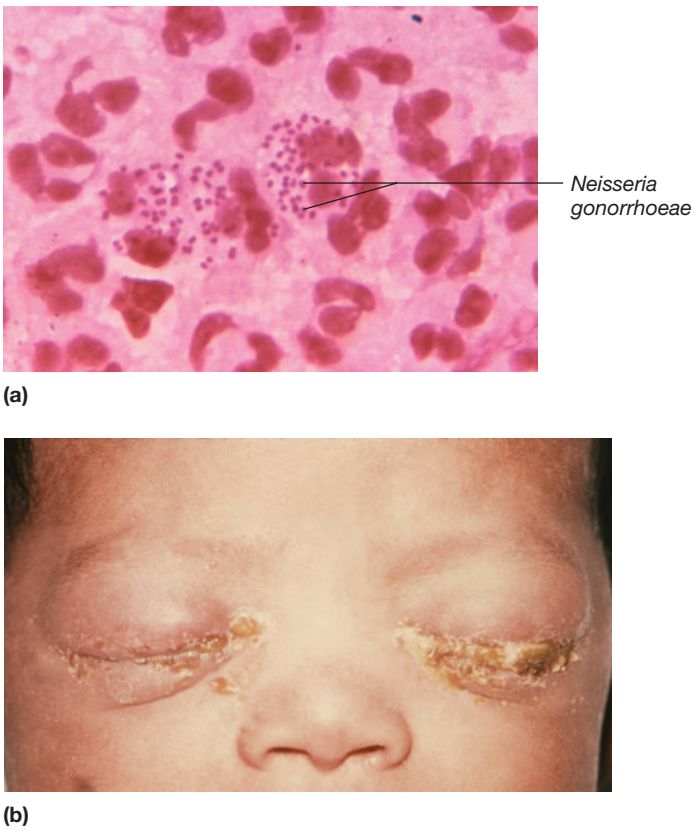

Figure 39.15 Gonorrhea. (a) Gram stain of male urethral exudate showing *Neisseria gonorrhoeae* (diplococci) inside a neutrophil; light micrograph (×500). Although the presence of Gram-negative diplococci in exudates is a probable indication of gonorrhea, the bacterium should be isolated and identified. (b) Gonococcal ophthalmia neonatorum in a one-week-old infant.

Syphilis

Syphilis (Greek *syn*, together, and *philein*, to love) is a contagious, ulcerative disease (table 39.1) caused by the spirochete *Treponema pallidum* subsp. *pallidum* (*T. pallidum*; *see figure 21.18*). Infection occurs through intimate contact with the infected lesion of a sexual partner. Syphilis has been called by a number of slang words, but it has also been known as the "great imitator" as its many signs and symptoms mimic those of other diseases. The signs and symptoms of syphilis vary depending on the stage of infection (primary, secondary, latent, and tertiary), and initial signs of infection may be obscured, depending on the site of bacterial entry. **Congenital syphilis** is the disease transmitted in utero from mother to child. ⏮ *Phylum* Spirochaetes *(section 21.8)*

As a spirochete, *T. pallidum* has a corkscrew morphology allowing it to easily enter the body through mucous membranes and minor breaks or abrasions of the skin. It replicates locally, inducing an ulceration, before it migrates to the regional lymph nodes, where it rapidly spreads throughout the body. Three recognizable stages of syphilis occur in untreated individuals. In the primary stage, after an incubation period of about 10 days to

(a)

(c)

Figure 39.16 Syphilis. (a) Primary syphilitic chancre of the penis. (b) Whole body rash of secondary syphilis. (c) Late-stage tertiary syphilis marked by masses of swollen and dead, fiberlike tissue.

MICRO INQUIRY *Which of these clinical manifestations are associated with syphilis transmission? Explain.*

3 weeks or more, the initial symptom is a small, painless, reddened ulcer, or **chancre** (French, meaning a destructive sore) with a hard ridge that appears at the infection site and contains spirochetes (**figure 39.16*a***). Contact with the chancre during sexual contact may result in disease transmission. In about one-third of the cases, the disease does not progress further and the chancre disappears. Serological tests are positive in about 80% of the infected individuals during this stage (**figure 39.17**).

Within 2 to 10 weeks after the primary lesion appears, the disease may enter the secondary stage, which is characterized by a highly variable skin rash (figure 39.16*b*). By this time, 100% of the individuals are serologically positive. Other symptoms during this stage include the loss of hair in patches, malaise, and fever. Both the chancre and the rash lesions are infectious.

After several weeks, the disease becomes latent. During the latent period, the disease is not normally infectious, except for possible transmission from mother to fetus. After many years, tertiary stage disease develops in about 40% of untreated individuals. During this stage, masses of dead, fibrous tissue called **gummas** (figure 39.16*c*) form in the skin, bone, and nervous system as the result of hypersensitivity reactions. This stage also is characterized by a great reduction in the number of spirochetes in the body. Involvement of the central nervous system may result in tissue loss that can lead to cognitive deficits, blindness, a "shuffle" walk (tabes), or insanity. Many of these symptoms have been associated with such well-known people as Al Capone, Francisco Goya, Henry VIII, Adolf Hitler, Scott Joplin, Friedrich Nietzsche, Franz Schubert, Oscar Wilde, and Kaiser Wilhelm (**Disease 39.1**). ⏮ *Hypersensitivities (section 34.10)*

Diagnosis of syphilis is through clinical history, physical examination, and immunoassay. Because humans respond to *T. pallidum* with the formation of antitreponemal antibody and a complement-fixing reagin, serological tests are very informative. Examples include tests for nontreponemal antigens (VDRL) and treponemal antibodies. PCR testing is also available to amplify and identify specific treponemal genes. ⏮ *Immune complex formation (section 34.8)*

Treatment in the early stages of the disease is easily accomplished with a single dose of long-acting benzathine penicillin G or a two-week course of doxycycline, for penicillin-allergic individuals. Later stages of syphilis are more difficult to treat and require much larger doses over a longer period. For example,

in neurosyphilis cases, treponemes occasionally survive drug treatment. Immunity to syphilis is not complete, and subsequent infections can occur.

Prevention and control of syphilis depend on (1) public education, (2) prompt and adequate treatment of all new cases, (3) follow-up on sources of infection and contact so they can be treated, and (4) prophylaxis (barrier protection) to prevent exposure. At present, the incidence of syphilis, as well as other sexually transmitted diseases, is rising in most parts of the world. An estimated 12 million new cases continue to occur each year. The latest available U.S. data report that there were 56,471 total cases of syphilis in 2013, a 10% increase over the previous year. Most of these cases were in men who have sex with other men, who were also co-infected with HIV.

Staphylococcal Diseases

Staphylococci are among the most important bacteria that cause disease in humans. They are normal inhabitants of the upper respiratory tract, skin, intestine, and vagina. Staphylococci are members of a group of invasive Gram-positive bacteria known as the **pyogenic** (pus-producing) cocci. These bacteria cause various suppurative (pus-forming) diseases in humans (e.g., boils, carbuncles, abscesses, impetigo contagiosa). The genus *Staphylococcus* consists of Gram-positive cocci, 0.5 to 1.5 μm in diameter (*see figure 23.11*). The cell wall peptidoglycan and teichoic acid contribute to the pathogenicity of staphylococci. ⏮ *Family* Staphylococcaceae *(section 23.3)*

Staphylococci can be divided into pathogenic and relatively nonpathogenic strains based on synthesis of the enzyme coagulase. The coagulase-positive species *S. aureus* is the most important human pathogen in this genus. Coagulase-negative staphylococci

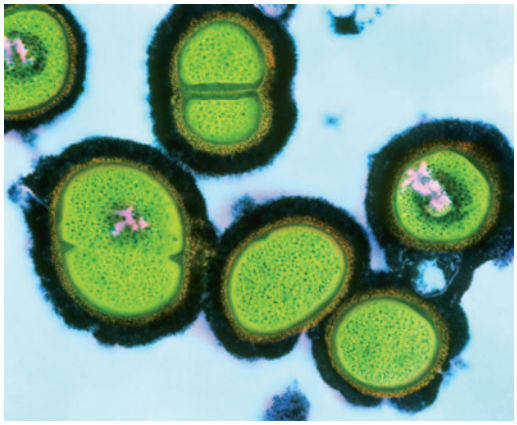
DISEASE

39.1 A Brief History of Syphilis

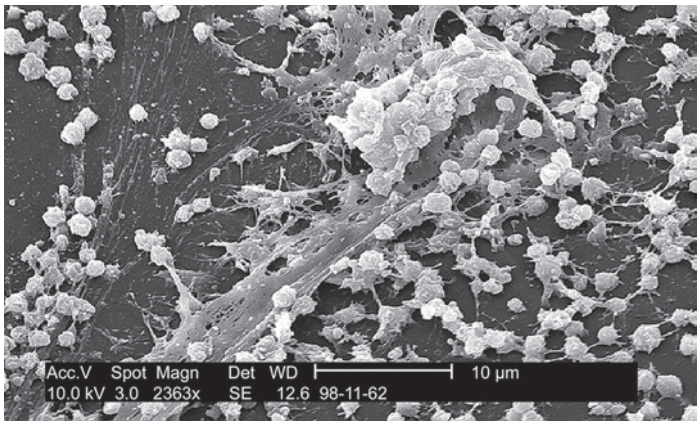
Syphilis was first recognized in Europe near the end of the fifteenth century. During this time, the disease reached epidemic proportions in the Mediterranean areas. According to one hypothesis, syphilis is of New World origin and Christopher Columbus (1451–1506) and his crew acquired it in the West Indies and introduced it into Spain after returning from their historic voyage. Another hypothesis is that syphilis had been endemic for centuries in Africa and may have been transported to Europe at the same time that vast migrations of the civilian population were occurring (1500). Others believe that the Vikings, who reached the New World well before Columbus, were the original carriers.

Syphilis was initially called the Italian disease, the French disease, and the great pox as distinguished from smallpox. In 1530 the Italian physician and poet Girolamo Fracastoro wrote the poem "Syphilis sive Morbus Gallicus" ("Syphilis or the French Disease"). In this poem, a Spanish shepherd named Syphilis is punished for being disrespectful to the gods by being cursed with the disease. Several years later, Fracastoro published a series of papers in which he described the possible mode of transmission of the "seeds" of syphilis through sexual contact.

Its venereal transmission was not definitely shown until the eighteenth century. Recognition of the different stages of syphilis was demonstrated in 1838 by Philippe Ricord, who reported his observations on more than 2,500 human inoculations. In 1905 Fritz Schaudinn and Erich Hoffmann discovered the causative bacterium, and in 1906 August von Wassermann introduced the diagnostic test that bears his name. In 1909 Paul Ehrlich introduced an arsenic derivative, arsphenamine or salvarsan, as therapy.



(a)



(b)

Figure 39.18 Slime and Biofilm. (a) Cells of *S. aureus* producing slime (transmission electron microscopy, ×10,000). (b) A biofilm on the inner surface of an intravenous catheter. Extracellular polymeric substances, mostly polysaccharides, surround and encase the staphylococci (scanning electron micrograph, ×2,363).

(CoNS) such as *S. epidermidis* are nonpigmented, and are generally less invasive. However, they have increasingly been associated, as opportunistic pathogens, with serious nosocomial infections.

Staphylococci are further classified into slime producers (SP) and nonslime producers (NSP). The ability to produce slime has been proposed as a marker for pathogenic strains of staphylococci (**figure 39.18*a***). Slime is a viscous, extracellular glycoconjugate that allows these bacteria to adhere to smooth surfaces such as prosthetic medical devices and catheters. Scanning electron microscopy has clearly demonstrated that biofilms (figure 39.18*b*) consisting of staphylococci encased in a slimy matrix are formed in association with biomaterial-related infections (**Disease 39.2**). Slime also appears to inhibit neutrophil chemotaxis, phagocytosis, and antimicrobial

DISEASE

39.2 Biofilms

Biofilms consist of microorganisms immobilized at a substratum surface and typically embedded in an organic polymer matrix of microbial origin. They develop on virtually all surfaces immersed in natural aqueous environments, including both biological (aquatic plants and animals) and abiological (concrete, metal, plastics, stones). Biofilms form particularly rapidly in flowing aqueous systems where a regular nutrient supply is provided to the microorganisms. Extensive microbial growth, accompanied by excretion of copious amounts of extracellular organic polymers, leads to the formation of visible slimy layers (biofilms) on solid surfaces. ⏮ *Biofilms are common in nature (section 7.5)*

Insertion of a prosthetic device into the human body often leads to the formation of biofilms on the surface of the device. The microorganisms primarily involved are *Staphylococcus epidermidis,* other coagulase-negative staphylococci, and Gram-negative bacteria. These normal skin inhabitants possess the ability to tenaciously adhere to the surfaces of inanimate prosthetic devices. Within the biofilms, they are protected from the body's normal defense mechanisms and also from antibiotics; thus the biofilm also provides a source of infection for other parts of the body as bacteria detach during biofilm sloughing.

Some examples of biofilms of medical importance include:

1. The deaths following massive infections of patients receiving Jarvik 7 artificial hearts
2. Cystic fibrosis patients harboring great numbers of *Pseudomonas aeruginosa* that produce large amounts of alginate polymers, which inhibit the diffusion of antibiotics
3. Teeth, where biofilm forms plaque that leads to tooth decay (figure 39.34)
4. Contact lenses, where bacteria may produce severe eye irritation, inflammation, and infection
5. Air-conditioning and other water retention systems where potentially pathogenic bacteria, such as *Legionella* species, may be protected by biofilms from the effects of chlorination.

Table 39.2 Various Enzymes and Toxins Produced by Staphylococci

Product	Physiological Action
β-lactamase	Breaks down β-lactam antibiotics
Catalase	Converts hydrogen peroxide into water and oxygen and reduces killing by phagocytosis
Coagulase	Reacts with prothrombin to form a complex that can cleave fibrinogen and cause the formation of a fibrin clot; fibrin may also be deposited on the surface of staphylococci, which may protect them from destruction by phagocytic cells; coagulase production is synonymous with invasive pathogenic potential
DNase	Destroys DNA
Enterotoxins	Are divided into heat-stable toxins of six known types (A, B, C1, C2, D, E); responsible for the gastrointestinal upset typical of food poisoning
Exfoliative toxins A and B (superantigens)	Cause loss of the surface layers of the skin in scalded-skin syndrome
Hemolysins	Alpha hemolysin destroys erythrocytes and causes skin destruction. Beta hemolysin destroys erythrocytes and sphingomyelin around nerves.
Hyaluronidase	Also known as spreading factor; breaks down hyaluronic acid located between cells, allowing for penetration and spread of bacteria
Panton-Valentine leukocidin	Inhibits phagocytosis by granulocytes and can destroy these cells by forming pores in their phagosomal membranes
Lipases	Break down lipids
Nuclease	Breaks down nucleic acids

Proteases	Break down proteins
Toxic shock syndrome toxin-1 (a superantigen)	Is associated with the fever, shock, and multisystem involvement of toxic shock syndrome

agents (*see figure 35.9*). ◀◀ *Biofilms are common in nature (section 7.5)*

Staphylococci are common in nature and harbored by either an asymptomatic carrier or a person with the disease (i.e., an active carrier). They can be spread by the hands, expelled from the respiratory tract, or transported in or on animate and inanimate objects. Staphylococci can produce disease in almost every organ and tissue of the body. For the most part, however, staphylococcal disease occurs in people whose defensive mechanisms have been compromised, such as patients in hospitals.

Staphylococci produce disease through their ability to multiply and spread widely in tissues and through their production of many virulence factors (**table 39.2**). Some of these factors are exotoxins, and others are enzymes thought to be involved in staphylococcal invasiveness *(see figure 23.11b)*. Many toxin genes are carried on plasmids; in some cases, genes responsible for pathogenicity reside on both a plasmid and the bacterial chromosome. The pathogenic capacity of a particular *S. aureus* strain is due to the combined effect of extracellular factors and toxins, together with the invasive properties of the strain. At one end of the disease spectrum is staphylococcal food poisoning, caused solely by the ingestion of preformed enterotoxin (table 39.2). At the other end of the spectrum are staphylococcal bacteremia and disseminated abscesses in most organs of the body.

The classic example of a staphylococcal lesion is the localized abscess of a domed pustule (**figure 39.19**). When *S. aureus* becomes established in a hair follicle, tissue necrosis results. Coagulase is produced and forms a fibrin wall around the lesion that limits the spread. Within the center of the lesion, liquefaction of necrotic tissue occurs, and the abscess spreads in the direction of least resistance. The abscess may be either a furuncle (boil) or a carbuncle. The central necrotic tissue drains, and healing eventually occurs. However, the bacteria may spread from any focus through lymph or blood to other parts of the body.

Newborn infants and children can develop a superficial skin infection characterized by the presence of encrusted pustules. This disease, called impetigo contagiosa, can be caused by

Figure 39.19 Staphylococcal Skin Infections. Draining abscess on the hip.

S. aureus or group A streptococci. It is contagious and can spread rapidly through a nursery, day care, or school. It usually occurs in areas where sanitation and personal hygiene are poor.

Staphylococcal scalded skin syndrome (**SSSS**) is another common staphylococcal disease. SSSS is caused by strains of *S. aureus* that produce **exfoliative toxin** (**exfoliatin**). This protein is usually plasmid encoded, although in some strains, the toxin gene is on the bacterial chromosome. This toxin clips proteins that keep epidermal cells attached to the underlying skin layer, so the epidermis peels off to reveal a red area underneath—thus the name of the disease. SSSS is seen most commonly in infants and children, and neonatal nurseries occasionally suffer large outbreaks of the disease.

Toxic shock syndrome (**TSS**) is a staphylococcal disease with potentially serious consequences. Most cases of this syndrome have occurred in females who used superabsorbent tampons. These tampons can trigger a change in the normal vaginal flora, thereby enabling the growth of toxin-producing *S. aureus*. Toxic shock syndrome is characterized by low blood pressure, fever, diarrhea, an extensive skin rash, and shedding of the skin (**figure 39.20**). TSS results from the massive overproduction of cytokines by T cells induced by the TSST-1 protein (or to staphylococcal enterotoxins B and C1). TSST-1 is a **superantigen** that binds both class II MHC receptors and T-cell receptors, stimulating T-cell responses in the absence of specific antigen. Superantigens activate 5 to 30% of the total T-cell population, whereas specific antigens activate only 0.01 to 0.1% of the T-cell population. The net effect of cytokine overproduction is circulatory collapse leading to shock and multiorgan failure. Tumor necrosis factor α (TNF-α) and interleukins (IL) 1 and 6 are strongly associated with superantigen-induced shock. Mortality rates for TSS are 30 to 70%, and morbidity following surgical debridement and amputation is very high. For these reasons, staphylococcal and streptococcal superantigens are categorized as select agents; their production and use are restricted, as they may be used as bioterror agents.

|◀◀ *Superantigens (section 34.5)*

The definitive diagnosis of staphylococcal disease can be made only by isolation and identification of the staphylococcus involved. This requires culture, catalase, coagulase, and other biochemical tests. Commercial rapid test kits also are available. There is no specific prevention for staphylococcal disease. The mainstay of treatment is the administration of specific antibiotics: vancomycin, cefotaxime, ceftriaxone, or rifampin and others. Because of the prevalence of drug-resistant strains (e.g., methicillin-resistant staphylococci), all staphylococcal isolates should be tested for antimicrobial susceptibility. Cleanliness, good hygiene, and aseptic management of lesions are the best means of control.

Methicillin-Resistant *Staphylococcus aureus* (MRSA)

Isolates of *Staphylococcus aureus* resistant to several specific antibiotics are known as ***m*ethicillin-*r*esistant *S*taphylococcus *a*ureus** (**MRSA**). MRSA is resistant to currently available β-lactam antibiotics, including penicillins (e.g., penicillin, amoxicillin), "antistaphylococcal" penicillins (e.g., methicillin, oxacillin), and cephalosporins (e.g., cephalexin). Antibiotic resistance is driven by the *mecA* (and *mecC*) gene encoding an altered penicillin-binding protein (see chapter-opening story). Otherwise healthy people can acquire MRSA infections, usually on or in the skin, such as abscesses, boils, and other pus-filled lesions. Around 94,000 infections and 18,000 deaths directly due to MRSA occur annually in the United States. When the infection is acquired by people who have not been hospitalized (i.e., in the past year) or had a medical procedure (e.g., dialysis, surgery, catheters) recently, the infection is referred to as a *c*ommunity-*a*ssociated (CA)-MRSA infection. However, MRSA seems to be predominantly a nosocomial infection, with growing evidence that it is widely distributed in livestock populations (cows, pigs, horses). Importantly, CA-MRSA strains are now being reported inside health-care settings. Nearly 300,000 strains of *S. aureus* are known, with a growing number of them resistant to one or more

Figure 39.20 Effects of Toxic Shock Toxin. Toxic shock toxin produces a rash, resembling measles, 3 to 5 days into the toxemia.

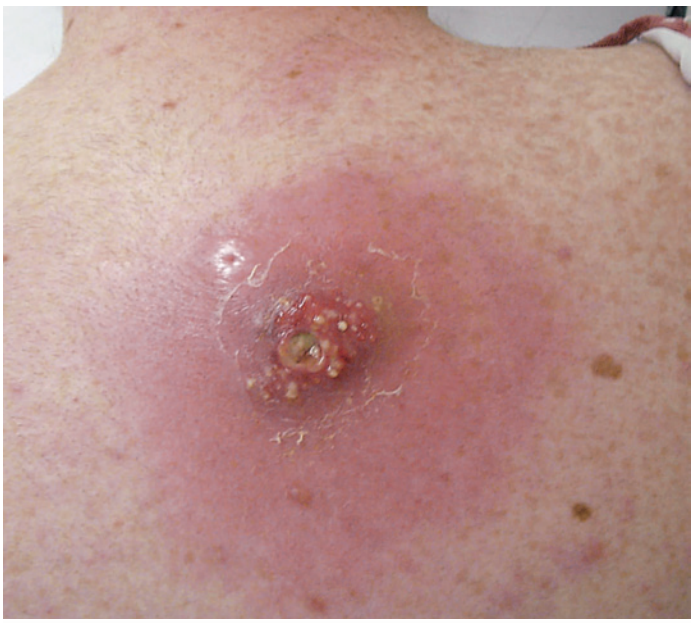

Figure 39.21 Methicillin-Resistant *Staphylococcus aureus* Wound.

MICRO INQUIRY *To what drugs, besides methicillin, are MRSA strains resistant?*

antibiotics. Their movement from farm to grocery, home, and hospital has serious consequences for human health.

MRSA can be diagnosed by culture and sensitivity or molecular testing. However, the CDC suggests that all skin diseases compatible with *S. aureus* infections be treated as MRSA until proven otherwise. Similar to other infections caused by staphylococci, MRSA infections begin as a bump or reddened area on the skin that looks like a large pimple. In other words, MRSA infection would appear as fluid-filled pustules, with a yellow or white center, central point, or "head," that may be draining pus (**figure 39.21**).

Treatment is by incision and drainage, as for other purulent (pus-filled) skin infections. Antimicrobial therapy is prescribed in addition to incision and drainage, while awaiting laboratory results. Doxycycline, minocycline, trimethoprim, and sulfamethoxazole, and rifampin are treatment options. Importantly, vancomycin (an antibiotic thought to be the drug of last resort) is no longer a sure treatment for MRSA as vancomycin-resistant strains occur worldwide. Good aseptic technique is paramount in preventing the transmission of MRSA from patients to healthcare workers.

Streptococcal Diseases

Streptococci that are transmitted through the air are discussed in section 39.1. Superficial cutaneous disease caused by streptococci include cellulitis, impetigo, and erysipelas. Streptococcal disease can also invasively infect the skin, spreading deeper into the tissue, often reaching the underlying muscle. This tissue is a very rich "growth medium" for streptococci, providing the nutrients for rapid replication. We discuss both the superficial and invasive streptococcal diseases next.

Cellulitis, Impetigo, and Erysipelas

Cellulitis is a diffuse, spreading infection of subcutaneous skin tissue. The resulting inflammation is characterized by a defined area of redness (erythema) and the accumulation of fluid (edema). In addition to streptococci, a number of other bacteria can cause cellulitis.

The most frequently diagnosed skin infection caused by *S. pyogenes* is **impetigo** (impetigo also can be caused by *Staphylococcus aureus*; figure 39.19*b*). Impetigo is a superficial cutaneous infection, most commonly seen in children, usually located on the face, and characterized by crusty lesions and vesicles surrounded by a red border. Impetigo is most common in late summer and early fall. Treatment of impetigo is with topical mupirocin. In severe cases, penicillin or a cephalosporin is the drug of choice; erythromycin is prescribed for those individuals who are allergic to β-lactams.

Erysipelas (Greek *erythros*, red, and *pella*, skin) is an acute infection and inflammation of the dermal layer of the skin. It occurs primarily in infants and people over thirty years of age with a history of streptococcal sore throat. The skin often develops painful, reddish patches that enlarge and thicken with a sharply defined edge. Recovery usually takes a week or longer if no treatment is given. The drugs of choice for the treatment of erysipelas are erythromycin and penicillin. Erysipelas may recur periodically at the same body site for years.

Invasive Streptococcal Infections

The development of disease initiated by *Streptococcus pyogenes* (invasive group A strep [GAS, *p. 867*]) appears to depend on the presence of specific virulent strains (e.g., M-1 and M-3 serotypes) and predisposing host factors (surgical or nonsurgical wounds, diabetes, and other underlying medical problems). A life-threatening infection begins when GAS strains penetrate a mucous membrane or take up residence in a wound such as a bruise. This infection can quickly lead either to **necrotizing fasciitis** (Greek *nekrosis*, deadness, Latin *fascis*, band or bandage, and *itis*, inflammation), which destroys the sheath covering skeletal muscles, or to **myositis** (Greek *myos*, muscle, and *-itis*), the inflammation and destruction of skeletal muscle and fat tissue (**figure 39.22**). Because necrotizing fasciitis and myositis arise and spread so quickly, they have been colloquially called "galloping gangrene."

Globally, there are over 10 million cases of strep throat and impetigo annually. It is estimated that approximately 9,000 to 11,500 cases of invasive GAS infections occur annually in the United States (1,000 to 1,800 deaths), and 6 to 7% of these are associated with necrotizing conditions. Rapid treatment is necessary to reduce the risk of death due to necrotizing fasciitis, and penicillin G remains the treatment of choice. In addition,

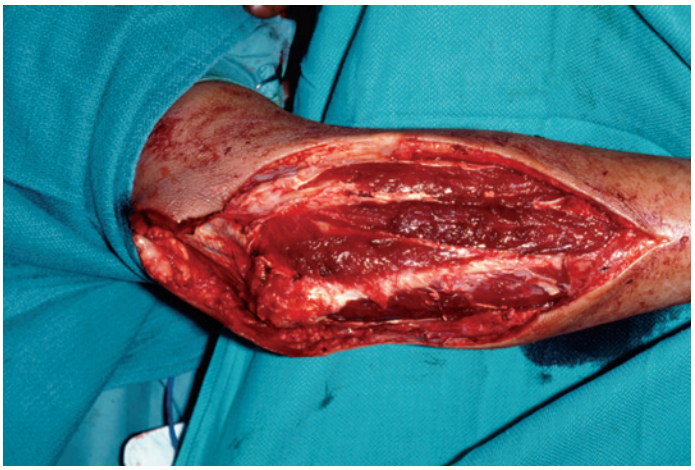

Figure 39.22 Necrotizing Fasciitis. Rapidly advancing streptococcal disease can lead to large necrotic sites, sometimes with blisters that rupture and expose the dying tissue. This is often called flesh-eating disease or necrotizing fasciitis.

MICRO INQUIRY *What virulence factors enable the rapid invasion of certain strep A strains?*

surgical removal of dead and dying tissue usually is needed in more advanced cases.

One reason invasive GAS strains are so deadly is that about 85% of them carry the genes for the production of streptococcal pyrogenic exotoxins A and B (Spe exotoxins). Exotoxin A acts as a superantigen, a nonspecific T-cell activator. Like all superantigens, it quickly stimulates T cells to begin producing abnormally large quantities of cytokines. The cytokines damage the endothelial cells that line blood vessels, causing fluid loss and rapid tissue death from a lack of oxygen. Another pathogenic mechanism involves secretion of exotoxin B, a protease that rapidly destroys tissue by breaking down proteins. ⏮ *Superantigens (section 34.5)*

Since 1986 it has been recognized that GAS infections can also trigger streptococcal toxic shock syndrome (STSS), characterized by a precipitous drop in blood pressure, failure of multiple organs, and a very high fever. STSS is caused by GAS that produce one or more streptococcal pyrogenic exotoxins. STSS has a mortality rate of 40%.

Tetanus

Tetanus (Greek *tetanos*, to stretch) is caused by *Clostridium tetani*, an anaerobic, Gram-positive, endospore-forming rod (*see figure 23.3*). The spores of *C. tetani* are commonly found in hospital environments, in soil and dust, and in the feces of many farm animals and humans. Transmission to humans is associated with skin wounds. Any break in the skin can allow *C. tetani* spores to enter. If the oxygen tension is low enough, the spores germinate and release the neurotoxin tetanospasmin.

Figure 39.23 The Toll of Tetanus. Sir Charles Bell's portrait (c. 1821) of a soldier wounded in the Peninsular War in Spain shows opisthotonus resulting from tetanus.

Tetanospasmin is an endopeptidase that selectively cleaves the synaptic vesicle membrane protein synaptobrevin. This prevents release of inhibitory neurotransmitters (γ-aminobutyric acid and glycine) at synapses within the spinal cord motor nerves. The result is uncontrolled stimulation of skeletal muscles (spastic paralysis). A second toxin, **tetanolysin,** is a hemolysin that aids in tissue destruction. ⏮ *Class Clostridia (section 23.1)*

Early in the course of the disease, tetanospasmin causes tension or cramping and twisting in skeletal muscles surrounding the wound and tightness of the jaw muscles. With more advanced disease, there is trismus ("lockjaw"), an inability to open the mouth because of the spasm of the masseter muscles. Facial muscles may go into spasms, producing the characteristic expression known as risus sardonicus. Spasms or contractions of the trunk and extremity muscles may be so severe that there is boardlike rigidity, painful convulsions, and backward bowing of the back so that the heels and back approach each other (opisthotonus; **figure 39.23**). Death results from respiratory failure caused by spasms of the diaphragm and intercostal respiratory muscles.

Prevention of tetanus involves the use of the tetanus toxoid. The toxoid is given routinely with diphtheria toxoid and acellular *B. pertussis* vaccine. Infants receive four doses by 18 months of age and every 10 years afterward. Adults receive boosters every 10 years.

Control measures for tetanus are not possible because of the wide dissemination of the bacterium in the soil and the long survival of its spores. The case fatality rate in generalized tetanus ranges from 30 to 90% because tetanus treatment is not very effective. Therefore prevention is all important and depends on (1) active immunization with toxoid, (2) proper care of wounds contaminated with soil, (3) prophylactic use of antitoxin, and (4) administration of penicillin. Tetanus is rare; fewer than 20 cases of tetanus are now reported annually in the

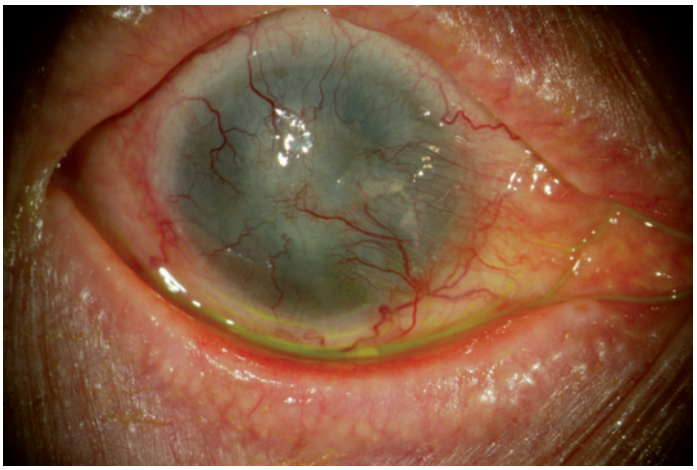

Figure 39.24 Trachoma. An active infection showing marked follicular hypertrophy of the eyelid. The inflammatory nodules cover the thickened conjunctiva of the eye.

United States—the majority of which are in IV drug users and diabetics.

Trachoma

Trachoma (Greek *trachoma*, roughness) is a contagious disease caused by *Chlamydia trachomatis* serotypes A–C. It is one of the oldest known infectious diseases of humans and is the greatest single cause of blindness throughout the world: annually, 2.2. million are infected worldwide, and about half of these develop irreversible blindness. In hyperendemic areas, most children are chronically infected within a few years of birth. Active disease in adults over age 20 is three times as frequent in females as in males because of mother-child contact. Although trachoma is uncommon in the United States, except among Native Americans in the Southwest, it is widespread in Asia, Africa, and South America. *C. trachomatis* can also cause "pink eye," a milder form of eye infection, but also highly contagious.

Trachoma is transmitted by contact with inanimate objects such as soap and towels, by hand-to-hand contact that carries *C. trachomatis* from an infected eye to an uninfected eye, or by flies. The disease begins abruptly with an inflamed conjunctiva. This leads to an inflammatory cell exudate and necrotic eyelash follicles (**figure 39.24**). The disease usually heals spontaneously. However, with reinfection, secondary infections, vascularization of the cornea, pannus (tissue flap) formation, and scarring of the conjunctiva can occur. If scar tissue accumulates over the cornea, blindness results.

Diagnosis of trachoma is by serologic methods. Treatment is surgery to treat the blinding stage and antibiotics (doxycycline, macrolides, or tetracycline) to treat infection. However, prevention and control of trachoma depend more on health education and personal hygiene—such as access to clean water for washing—than on treatment.

6. How does *C. trachomatis* serotypes A–C cause trachoma? Describe how it is transmitted, and the way in which blindness may result.

39.4 Food and Water Are Vehicles for Bacterial Diseases

After reading this section, you should be able to:

- Report the common food-borne and waterborne bacterial diseases
- Identify typical signs and symptoms of food-borne and waterborne bacterial diseases
- Correlate food-borne and waterborne bacterial infection and disease severity with bacterial virulence factors

Many microorganisms that contaminate food and water can cause acute gastroenteritis—inflammation of the stomach and intestinal lining. When food is the source of the pathogen, the condition is often called **food poisoning.** Gastroenteritis can arise in two ways. Some bacteria cause a food infection. Alternatively, the pathogen may secrete an exotoxin that contaminates the food and is then ingested by the host. This is referred to as a **food intoxication** because the toxin is ingested and the presence of living microorganisms is not required. Because these toxins disrupt the functioning of the intestinal mucosa, they are called **enterotoxins.** Common symptoms of enterotoxin poisoning are nausea, vomiting, and diarrhea.

Worldwide, there are nearly 1.7 billion cases of diarrheal disease annually. In fact, diarrheal diseases are second only to respiratory diseases as a cause of adult death; they are the leading cause of childhood death, and in some parts of the world, they are responsible for more years of potential life lost than all other causes combined. For example, each year around 800,000 children (about 2,200 a day) die from diarrheal diseases. In the United States, estimates exceed 10,000 deaths per year from diarrhea, and an average of 500 childhood deaths are reported.

This section describes several of the more common bacterial gastrointestinal infections, food intoxications, and waterborne diseases. **Table 39.3** summarizes many of the bacterial pathogens responsible for food poisoning, and **table 39.4** lists many important waterborne bacterial pathogens. The protozoa responsible for food-borne and waterborne diseases are covered in chapter 40. ▶▶| *Food-borne disease outbreaks (section 41.3)*

Table 39.3 Bacteria That Cause Acute Bacterial Diarrhea and Food Poisoning

Organism	Incubation Period (Hours)	Vomiting	Diarrhea	Fever	Common Source
Staphylococcus aureus	1–8 (rarely, up to 18)	+++	+	–	Staphylococci grow in meats, dairy and bakery products and produce enterotoxins.
Bacillus cereus	2–16	+++	++	–	Reheated fried rice causes vomiting or diarrhea.
Clostridium perfringens	8–16	±	+++	–	Clostridia grow in rewarmed meat dishes.
Clostridium botulinum	18–24	±	Rare	–	Clostridia grow in anoxic foods (e.g., canned goods) and produce toxin.
Escherichia coli (enterohemorrhagic)	3–5 days	±	++	±	Generally associated with ingestion of undercooked ground beef and unpasteurized fruit juices and cider.
Escherichia coli (enterotoxigenic strain)	24–72	±	++	–	Raw fruits and vegetables, contaminated water; common cause of traveler's diarrhea.
Vibrio parahaemolyticus	6–96	+	++	±	Organisms grow in seafood and in gut and produce toxin or invade.
Vibrio cholerae	24–72	+	+++	–	Found in fecally contaminated water; grows on exoskeleton of marine invertebrates (e.g., copepods).
Shigella spp. (mild cases)	24–72	±	++	+	Raw fruits and vegetables, contaminated water; causes toxin-mediated disease.
Salmonella spp. (gastroenteritis)	8–48	±	++	+	Poultry is most common source.
Salmonella enterica serovar Typhi (typhoid fever)	10–14 days	±	±	++	Humans are the only source of this serovar; it resides in the gallbladder in carriers.
Clostridium difficile	Days to weeks after antibiotic therapy	–	+++	+	Two reservoirs include humans and environments contaminated with spores.
Campylobacter jejuni	2–10 days	–	+++	++	Infection by oral route from foods, (commonly poultry), pets. Organism grows in small intestine.
Yersinia enterocolitica	4–7 days	±	++	+	Food-borne (most commonly pork).

Adapted from Geo. F. Brooks, et al., Medical Microbiology, *21st ed. Copyright 1998 Appleton & Lange, Norwalk, CT.*

Pathogenesis	Clinical Features and Treatment
Enterotoxins act on gut receptors that transmit impulses to medullary centers.	Abrupt onset (2–6 hours after consumption), intense vomiting for up to 24 hours, recovery in 24–48 hours. Occurs in persons eating the same food. No treatment usually necessary except to restore fluids and electrolytes.
Enterotoxins formed in food or in gut from growth of *B. cereus*.	Incubation period of 8–16 hours, mainly vomiting and diarrhea.
Enterotoxins produced during sporulation in gut; causes hypersecretion.	Abrupt onset of profuse diarrhea; vomiting occasionally. Recovery usual without treatment in 1–4 days.
Toxin absorbed from gut and blocks acetylcholine release at neuromuscular junction.	Difficulty speaking or breathing. Treatment requires clearing the airway, ventilation, and intravenous polyvalent antitoxin. Exotoxin present in food and serum. Mortality rate high.
Toxins cause epithelial necrosis in colon; mild to severe complications.	Symptoms vary from mild to severe bloody diarrhea. The toxin can be absorbed, becoming systemic and producing hemolytic uremic syndrome, most frequently in children.
Heat-labile (LT) and heat-stable (ST) enterotoxins cause hypersecretion in small intestine.	Usually abrupt onset of diarrhea; vomiting rare. A serious infection in newborns. In adults, “traveler’s diarrhea” is usually self-limited in 1–3 days.
Toxin causes hypersecretion; vibrios invade epithelium; stools may be bloody.	Abrupt onset of diarrhea in groups consuming the same food, especially crabs and other seafood. Recovery is usually complete in 1–3 days. Food and stool cultures are positive.
Toxin causes hypersecretion in small intestine; infective dose $>10^5$ vibrios; cholera stool classically described as “rice-water” consistency.	Abrupt onset of liquid diarrhea in endemic area. Needs prompt replacement of fluids and electrolytes IV or orally. Tetracyclines shorten excretion of vibrios. Stool cultures positive.
Organisms invade epithelial cells; blood, mucus, and neutrophils in stools; infective dose $<10^3$ organisms.	Abrupt onset of diarrhea, often with blood and pus in stools, cramps, and lethargy. Stool cultures are positive. Trimethoprim-sulfamethoxazole, ampicillin, or chloramphenicol given in severe cases. Do not give opiates. Often self-limited. Restore fluids.
Superficial infection of gut, little invasion; infective dose $>10^5$ organisms.	Gradual or abrupt onset of diarrhea and low-grade fever. Nausea, headache, and muscle aches common. Administer no antimicrobials unless systemic dissemination is suspected. Stool cultures are positive. Prolonged carriage is frequent.
Symptoms due to exotoxin; infective dose $\geq 10^7$ organisms.	Initially fever, headache, malaise, anorexia, and muscle pains. Fever may reach 104°F (40°C) by the end of the first week of illness and lasts for 2 or more weeks. Diarrhea often occurs, and abdominal pain, cough, and sore throat may be prominent. Antibiotic therapy shortens duration of the illness.
Toxins causes epithelial necrosis in colon; pseudomembranous colitis.	Especially after abdominal surgery, abrupt bloody diarrhea and fever. Toxins in stool. Oral vancomycin useful in therapy.
Invasion of mucous membrane; toxin production uncertain.	Fever, diarrhea; PMNs and fresh blood in stool, especially in children. Usually self-limited. Special media needed for culture at 43°C. Erythromycin given in severe cases with invasion. Usual recovery in 5–8 days.
Gastroenteritis; occasional bacteremia; toxin produced occasionally.	Severe abdominal pain, diarrhea, fever; PMNs and blood in stool; polyarthritis, erythema nodosum, especially in children. Gentamicin used in severe cases.

Table 39.4 Waterborne Bacterial Pathogens

Organism	Reservoir	Comments
Aeromonas hydrophila	Free-living	Sometimes associated with gastroenteritis, cellulitis, and other diseases
Campylobacter jejuni	Bird and animal reservoirs	Major cause of diarrhea; common in processed poultry; a microaerophile
Helicobacter pylori	Free-living	Can cause gastritis, peptic ulcers, gastric adenocarcinomas
Legionella pneumophila	Free-living and associated with protozoa	Found in cooling towers, evaporators, condensers, showers, and other water sources
Leptospira spp.	Infected animals	Hemorrhagic effects, jaundice
Mycobacterium spp.	Infected animals and free-living	Complex recovery procedure required
Pseudomonas aeruginosa	Free-living	Swimmer's ear and related infections
Salmonella enteriditis	Animal intestinal tracts	Common in many waters
Vibrio cholerae	Free-living	Found in many waters, including estuaries
Vibrio parahaemolyticus	Free-living in coastal waters	Causes diarrhea in shellfish consumers
Yersinia enterocolitica	Frequent in animals and in the environment	Waterborne gastroenteritis

Botulism

Food-borne **botulism** (Latin *botulus*, sausage) is a form of food poisoning where the disease results from ingesting the preformed botulinum toxin, not the bacteria. The most common source of disease is home-canned food that has not been heated sufficiently to kill contaminating *Clostridium botulinum* spores. The spores then germinate, and a toxin is produced during anaerobic vegetative growth. If the food is later eaten without adequate cooking, the active toxin causes disease.

Botulinum toxin is an AB neurotoxin that binds to the same target as tetanus toxin, the synaptobrevin of motor neurons, but with opposite effects (**figure 39.25**). It selectively cleaves the synaptic vesicle membrane protein synaptobrevin, thereby preventing release of the neurotransmitter

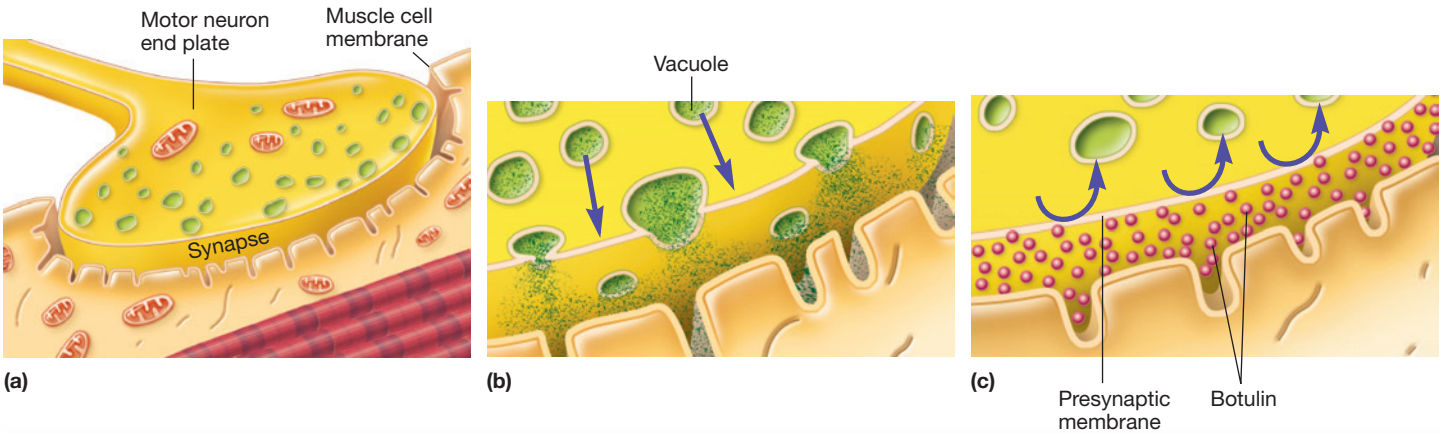

Figure 39.25 The Physiological Effects of *Botulinum* Toxin. (a) The relationship between the motor neuron and the muscle at the neuromuscular junction. (b) In the normal state, acetylcholine released at the synapse crosses to the muscle and creates an impulse that stimulates muscle contraction. (c) In botulism, the toxin enters the motor end plate and attaches to the presynaptic membrane, where it blocks release of the acetylcholine. This prevents impulse transmission and keeps the muscle from contracting.

MICRO INQUIRY *How do the neurological effects of botulinum toxin differ from those of tetanus toxin?*

TECHNIQUES & APPLICATIONS

39.3 Clostridial Toxins as Therapeutic Agents: Benefits of Nature's Most Toxic Proteins

Some toxins are currently used for the treatment of human disease. Specifically, botulinum toxin, the most poisonous biological substance known, is used for the treatment of specific neuromuscular disorders characterized by involuntary muscle contractions. Since approval of type-A botulinum toxin (Botox) by the FDA in 1989 for three disorders (strabismus [crossing of the eyes], blepharospasm [spasmotic contractions of the eye muscles], and hemifacial spasm [contractions of one side of the face]), the number of neuromuscular problems treated has increased to include other tremors, migraine and tension headaches, and other maladies. In 2000 dermatologists and plastic surgeons began using Botox to temporarily eradicate wrinkles caused by repeated muscle contractions as we laugh, smile, or frown. The remarkable therapeutic utility of botulinum toxin lies in its ability to specifically and potently inhibit involuntary muscle activity for an extended duration. Overall, clostridia (currently one of the largest and most diverse groups of bacteria and includes about 130 species) produce more protein toxins than any other known bacterial genus and are a rich reservoir of toxins for research and medicinal uses. For example, research is underway to use clostridial toxins or toxin domains for drug delivery, prevention of food poisoning, and the treatment of cancer and other diseases. The remarkable success of botulinum toxin as a therapeutic agent has thus created a new field of investigation in microbiology.

acetylcholine. As a consequence, muscles do not contract in response to motor neuron activity, and flaccid paralysis results (**Techniques & Applications 39.3**). Symptoms of botulism occur within 12 to 72 hours of toxin ingestion and include blurred vision, difficulty swallowing and speaking, bilateral muscle weakness, nausea, and vomiting. Treatment relies on supportive care and polyvalent antitoxin. If untreated, up to 5% of patients die of either respiratory or cardiac failure within a few days. Approximately 150 cases of botulism occur in the United States annually.

Infant botulism is the most common form of botulism in the United States with about 100 cases reported each year. It appears that ingested spores, which may be naturally present in honey or house dust, germinate in the infant's intestine. *C. botulinum* then multiplies and produces the toxin. The infant becomes constipated, listless, generally weak, and eats poorly. Death may result from respiratory failure. It is therefore recommended that infants not be fed honey.

Campylobacter jejuni Gastroenteritis

Campylobacter jejuni causes an estimated 1.3 million cases of ***Campylobacter*** **gastroenteritis** (**campylobacteriosis**) and subsequent diarrhea in the United States each year. Studies with chickens, turkeys, and cattle have shown that as much as 50 to 100% of a flock or herd of these birds or animals excrete *C. jejuni*. It also can be isolated in high numbers from surface waters. It is transmitted to humans by contaminated food and water, contact with infected animals, or anal-oral sexual activity. ⏮ *Class* Epsilonproteobacteria *ranges from pathogens to deep-sea bacteria (section 22.5)*

The incubation period for campylobacteriosis is 2 to 10 days. *C. jejuni* invades the epithelium of the small intestine, causing inflammation, and also secretes an exotoxin that is antigenically similar to the cholera toxin. Symptoms include diarrhea, high fever, severe inflammation and ulceration of the intestine, and bloody stools. *C. jejuni* infection has also been linked to Guillain-Barré syndrome, a disorder in which the body's immune system attacks peripheral nerves, resulting in life-threatening paralysis. ⏮ *Exotoxins (section 35.2)*

Laboratory diagnosis is presumptive using culture-independent tests and microscopy; definitive diagnosis is by culture in a CO_2-enriched atmosphere. The disease is usually self-limited, and treatment is supportive; fluids, electrolyte replacement, and erythromycin may be used in severe cases. Recovery usually takes from 5 to 8 days. Prevention and control involve good personal hygiene and food-handling precautions, including pasteurization of milk and thorough cooking of poultry.

Cholera

Cholera is an acute diarrheal disease caused by infection of the intestine with the Gram-negative, comma-shaped bacterium *Vibrio cholerae* (**figure 39.26**). Infection is usually mild or without symptoms in most healthy adults but can be severe. The disease is characterized by profuse watery diarrhea, vomiting, and leg cramps. These symptoms result from rapid loss of body fluids leading to dehydration and shock. Death can occur within hours if left untreated. Throughout recorded history, cholera (Greek *chole*, bile) has caused seven pandemics in various areas of the world, especially in Asia, the Middle East, and Africa. The disease has been rare in the United States since the 1800s; only a few cases are reported each year (17 cases in 2012), with over 90% of U.S. cases being travel-associated. Unfortunately, 2010 will be remembered for the resurgence of cholera in Haiti. After Haiti

Figure 39.26 ***Vibrio cholerae*, the Causative Agent of Cholera.**
V. cholerae adhering to intestinal epithelium; scanning electron micrograph (×12,000). Notice that the bacteria are slightly curved with a single polar flagellum.

had gone almost 100 years without cholera, well-intentioned relief workers responding to a devastating earthquake imported cholera bacteria to Haiti, where they caused 717,203 cholera cases and about 9,000 deaths. Cholera epidemics are a testament to how quickly bacteria can invade and infect.

Although there are many *V. cholerae* serogroups, only the toxigenic O1 and O139 (encapsulated) organisms have caused epidemics. *V. cholerae* O1 is divided into two biotypes, Classical and El Tor. Each biotype is divided into two serotypes, Inaba and Ogawa. Interestingly, the cholera toxin gene (ctxAB) is carried by the temperate CTX filamentous bacteriophage, which exists as a prophage within toxin-producing strains of *V. cholerae*. The receptor for the phage is the toxin coregulated pilus—the same structure used to colonize the host's gut. Thus *V. cholerae* is an excellent example of how horizontal transfer of genes can confer pathogenicity.

Cholera is transmitted by ingesting food or water contaminated by fecal material from infected individuals. The incubation period is 3 to 72 hours and infection with serotypes O1 or O139 results in mild to severe diarrhea. Approximately 20% of those with severe diarrhea have watery diarrhea; 10-20% of those with watery diarrhea produce "rice-water-stool," so named because of the flecks of mucus floating in it. The bacteria adhere to the intestinal mucosa of the small intestine, where they are not invasive but secrete cholera toxin, an AB toxin (*see figure 35.6*). The A subunit enters the intestinal epithelial cells and activates the enzyme adenyl cyclase by the addition of an ADP-ribosyl group in a way similar to that employed by pertussis toxin. This results in hypersecretion of water and chloride ions while inhibiting absorption of sodium ions. The infected person loses massive quantities of fluid and electrolytes, causing abdominal muscle cramps, vomiting, fever, and diarrhea. The diarrhea can be so profuse that a person can lose 10 to 15 liters of fluid during the infection. Death may result from the elevated concentrations of blood proteins, caused by reduced fluid levels, which leads to circulatory shock and collapse.

Evidence indicates that passage through the human host enhances infectivity, although the exact mechanism is unclear. Before *V. cholerae* exits the body in watery stools, some unknown aspect of the intestinal environment stimulates the activity of certain bacterial genes. These genes, in turn, seem to prepare the bacteria for ever more effective colonization of their next victims, possibly fueling epidemics. *V. cholerae* can also be free-living in warm, alkaline, and saline environments.

Treatment is by oral rehydration therapy with NaCl plus glucose to stimulate water uptake by the intestine; doxycycline or tetracycline antibiotics may also be given. The most reliable control methods are based on proper sanitation, especially of water supplies. The mortality rate without treatment is often over 50%, but with treatment and supportive care, it is less than 1%.

Escherichia coli Gastroenteritis

Every year, millions of people travel internationally. Unfortunately, a large percentage of these travelers acquire a rapidly acting, dehydrating condition called traveler's diarrhea. This diarrhea results from an encounter with certain viruses, bacteria, or protozoa usually absent from the traveler's normal environment. This is the basis for the popular warnings to international travelers: "Don't drink the local water" and "Boil it, peel it, cook it, or forget it."

One of the major causative agents is *Escherichia coli*. Normal, residential *E. coli* is harmless and provides assistance in the metabolism of the food we eat. *E. coli* strains have become pathogenic by acquiring new genetic information through horizontal gene transfer. Expression of virulence genes often alters the bacterial surface proteins (antigens). Thus, strains of *E. coli* are readily tracked by serotyping. Two of the most commonly used serotyping antigens are the H (flagellar) and the O (LPS) antigens.

Although the vast majority of *E. coli* strains are nonpathogenic members of the normal intestinal microbiota, pathogenic strains cause diarrheal disease by several mechanisms. Six categories (pathotypes) of diarrheagenic *E. coli* are recognized (**figure 39.27**): enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enteropathogenic *E. coli* (EPEC), enteroaggregative *E. coli* (EAEC), enterohemorrhagic *E. coli* (EHEC), and diffusely adhering *E. coli* (DAEC). ETEC, EIEC, EPEC, and EAEC are all found in human feces; transmission is from poor hand hygiene. ⏮ *Order* Enterobacteriales *includes pathogens and mutualists (section 22.3)*

The **enterotoxic *E. coli*** (**ETEC**) strains produce one or both of two distinct enterotoxins responsible for diarrhea. The toxins are distinguished by their heat stability: heat-stable enterotoxin (ST) and heat-labile enterotoxin (LT) (figure 39.27*a*). The genes for ST

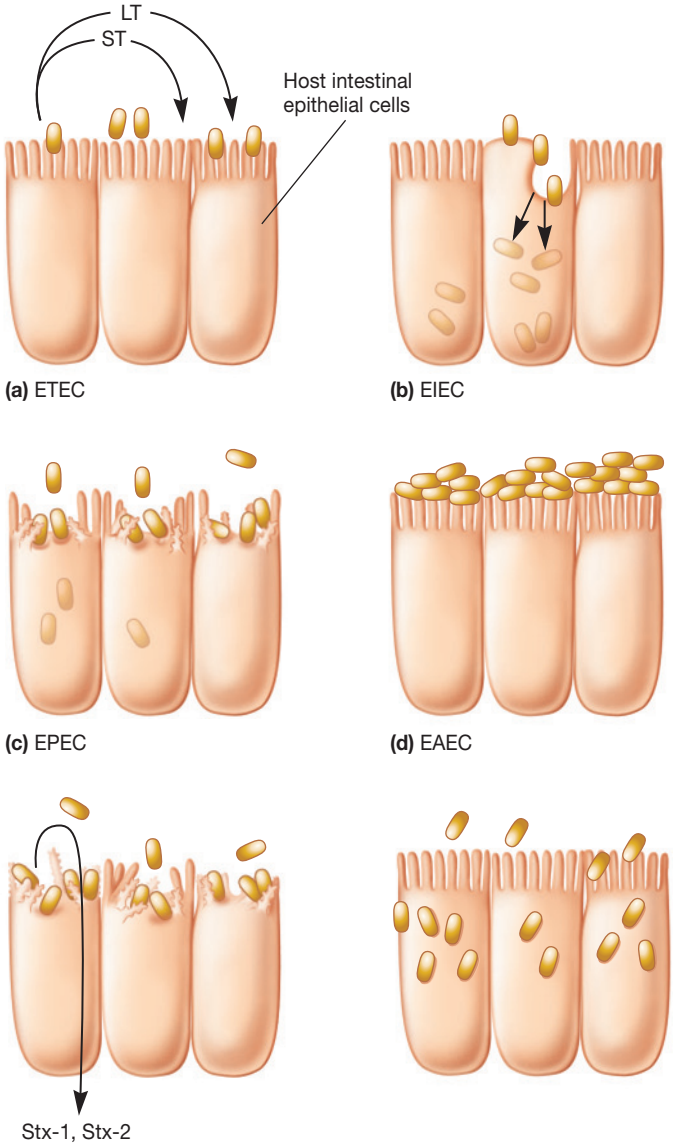

Figure 39.27 Six Strains of Diarrheagenic *E. coli*. Each strain of diarrhea-causing *E. coli* can be classified by the nature of its interaction with host intestinal epithelial cells.

MICRO INQUIRY *To which* E. coli *class does the strain O157:H7 belong?*

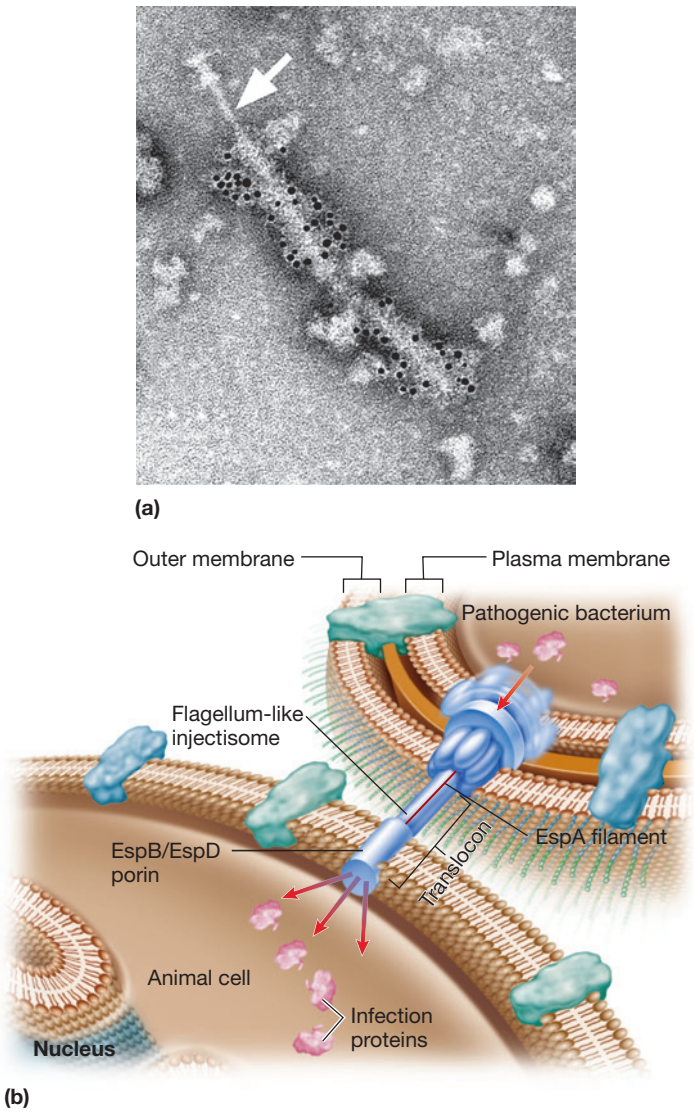

Figure 39.28 Type Three Secretion (TTS) System of Enteropathogenic *E. coli* (EPEC). (a) Transmission electron micrographs of TTS structures from EPEC cells. TTS sheathlike structures are labeled with 6 nm immunogold particles; the needle complexes, neck, and stem components (white arrows) remain unlabeled. (b) The TTS proteins function like a syringe to inject virulence proteins into a host cell.

and LT production and for colonization factors are usually plasmid-borne and acquired by horizontal gene transfer. ST and LT induce hypersecretion of electrolytes and water into the intestinal lumen, triggering the watery diarrhea characteristic of an ETEC infection.

The **enteroinvasive *E. coli*** (**EIEC**) strains cause diarrhea by penetrating and multiplying within the intestinal epithelial cells (figure 39.27*b*). The ability to invade epithelial cells is similar to that of *Shigella* spp.; it is associated with the presence of a large virulence plasmid. EIEC strains also produce an enterotoxin that stimulates diarrhea and dysentery symptoms.

The **enteropathogenic *E. coli*** (**EPEC**) strains attach to the brush border of intestinal epithelial cells using an adhesin known as intimin and cause a specific type of cell damage called effacing lesions (figure 39.27*c*). Proteins encoded by a LEE (*l*ocus of *e*nterocyte *e*ffacement) region of a pathogenicity island cause effacing lesions or attaching-effacing (AE) lesions. This ultimately results in destruction of brush border microvilli (hemorrhagic colitis) adjacent to adhering bacteria. AE lesions result from the delivery of specific virulence proteins through a LEE-encoded type III secretion (TTS) system, into host cell membranes (**figure 39.28**). The EPEC virulence proteins are homologous to *Yersinia* TTS Yop proteins that lyse red blood

cells. Cell destruction leads to the subsequent bloody diarrhea. EPEC is an important cause of infantile diarrhea in underdeveloped countries.

The **enteroaggregative *E. coli*** (**EAEC**) strains adhere to epithelial cells in localized regions, forming clumps of bacteria with a "stacked brick" appearance (figure 39.27*d*). EAEC can also acquire the shiga toxin gene(s) to produce toxin that causes prolonged diarrhea in children.

The **enterohemorrhagic *E. coli*** (**EHEC**) or **Shiga toxin–producing *E. coli*** (**STEC**) are zoonotic pathogens transferred to humans by water or food. There are 200 to 400 serotypes that carry the bacteriophage-encoded genetic determinants for Shiga toxin (Stx-1 and/or Stx-2 proteins; figure 39.27*e*). Some EHEC strains also carry the LEE gene sequence to produce AE lesions, causing hemorrhagic colitis (HC) with severe abdominal pain and cramps followed by bloody diarrhea. Stx-1 and Stx-2 have also been implicated in the extraintestinal disease hemolytic uremic syndrome (HUS), a severe hemolytic anemia that leads to kidney failure. It is believed these toxins kill vascular endothelial cells. A major form of STEC (EHEC) in North America is *E. coli* O157:H7 (STEC O157), which has caused many outbreaks of HC and HUS in the United States since it was first recognized in 1982. A variety of other STEC serotypes cause similar disease. Currently there are an estimated 265,000 STEC (36% STEC O157) cases in the United States each year, resulting in an average of 60 deaths. Despite the variety of STEC serotypes, most laboratories do not test for non-O157 strains, so the actual incidence of EHEC is underreported. Importantly, STECs are the only strains passed in nonhuman (animal) feces. Thus animal manure and farm contamination of foods are major sources of these bacteria. ▶▶| *Food-borne disease outbreaks (section 41.3)*

The **diffusely adhering *E. coli*** (**DAEC**) strains are not typical human pathogens. They are mentioned here because they have occasionally been associated with watery diarrhea. They have been observed to adhere over the entire surface of epithelial cells and usually cause disease in immunologically naïve or malnourished children (figure 39.27*f*). It has been suggested that DAEC may have an as-yet undefined virulence factor.

Diagnosis of traveler's diarrhea caused by *E. coli* is based on travel history and symptoms. Laboratory diagnosis is by isolation of the specific type of *E. coli* from feces and identification using DNA probes, the determination of virulence factors, and the polymerase chain reaction. Treatment is with fluid and electrolytes plus doxycycline and trimethoprim-sulfamethoxazole. Recovery can be without complications except in EHEC damage to kidneys. Prevention and control involve avoiding contaminated food and water.

Sepsis and Septic Shock

Sepsis is clinically defined as the systemic response to a microbial infection. This response is manifested by two or more of the following conditions: temperature above 102.2°F (39°C) or below 96.8°F (36°C); heart rate above 90 beats per minute; respiratory rate above 20 breaths per minute; and leukocyte count above 12,000 cells per cubic milliliter or below 4,000 cells per cubic milliliter. These lead to **septic shock,** which is sepsis associated with severe hypotension (low blood pressure) despite adequate fluid replacement. Sepsis is a response to an infection that is complicated by the release of cytokines causing body-wide inflammation. Cytokines activate the clotting and complement cascades; they cause blood to clot indiscriminately and to leak from blood vessels.

Gram-negative sepsis is most commonly caused by *E. coli, Salmonella* spp., *Klebsiella* spp., *Enterobacter* spp., or *Pseudomonas aeruginosa*. Endotoxin, or more specifically, the lipid A moiety of lipopolysaccharide (LPS), an integral component of the outer membrane of Gram-negative bacteria, is the primary initiator of septic shock, although Gram-positive bacteria and fungi are also known to do this. We discuss sepsis and septic shock here because (1) some microbial diseases and their effects cannot be categorized under a specific mode of transmission, and (2) we discuss many of the Gram-negative pathogens in this section. |◀◀ *Typical Gram-negative cell walls include additional layers besides peptidoglycan (section 3.4)*

Sepsis is a medical emergency. Septic shock is the most common cause of death in intensive care units and the thirteenth most common cause of death in the United States. Unfortunately, the incidence of sepsis and septic shock continues to rise: more than one million cases per year with an estimated 28–50% of these ending in death.

The pathogenesis of sepsis and septic shock begins with the proliferation of the microorganism at the infection site (*see figure 35.8*). The microorganism may invade the bloodstream directly or may proliferate locally and release various products into the bloodstream. These products include both structural components of the microorganisms (e.g., endotoxin, teichoic acid) along with superantigens (staphylococcal entertoxins) and exotoxins synthesized by the microorganism. All of these products can stimulate the release of the endogenous mediators (e.g., cytokines like TNF-α, IL-1, IL-6, and IL-18) of sepsis from endothelial cells, monocytes, macrophages, neutrophils, and plasma cell precursors. The ensuing "cytokine storm" has profound physiological effects on the heart, vasculature, and other body organs. Other than antimicrobial agents to control infection, there is no drug therapy (despite vigorous research efforts) to stem the septic cascade. Thus, the consequences of septic shock are either recovery or death. Death usually ensues if one or more organ systems fail completely. |◀◀ *Virulence defines a pathogen's success (section 35.2)*

Salmonellosis

Salmonellosis (*Salmonella* gastroenteritis) is caused by over 2,000 *Salmonella* serovars. Based on DNA homology studies, all

known *Salmonella* serovars are thought to belong to a single species, *Salmonella enterica*. The most frequently isolated serovars from humans are Typhimurium and Enteritidis. (Serovar names are not italicized and the first letter is capitalized.) An estimated 1.2 million cases of salmonellosis occur annually in the United States; of these, approximately 19,000 result in hospitalization, and 380 result in death.

The initial source of the bacterium is the intestinal tracts of birds and other animals. Humans acquire the bacteria from contaminated water or foods such as beef products, poultry, eggs, or egg products. Once the bacteria are in the body, the incubation time is only about 12 to 72 hours. Disease results when the bacteria multiply and invade the intestinal mucosa. Abdominal pain, cramps, diarrhea, nausea, vomiting, and fever are the most prominent symptoms, which usually persist for 4 to 7 days but can last for several weeks. During the acute phase of the disease, as many as 1 billion *Salmonella* cells can be found per gram of feces. Most adult patients recover, but the loss of fluids can cause problems for children and elderly people. Persons with severe diarrhea may require rehydration therapy with intravenous fluids. Antibiotics are not usually given unless the infection spreads from the intestines.

Other serovars of *Salmonella* are infrequently isolated from humans. We mention a few of these because of their ability to cause occasional epidemics. **Typhoid** (Greek *typhodes*, smoke) fever is caused by *Salmonella enterica* serovar Typhi and is acquired by ingestion of food or water contaminated by feces of infected humans or person-to-person contact. In earlier centuries, the disease occurred in great epidemics. The incubation period for typhoid fever is about 10 to 14 days. The bacteria colonize the small intestine, penetrate the epithelium, and spread to lymphoid tissue, blood, liver, and gallbladder. After approximately 3 months, most individuals stop shedding bacteria in their feces. However, a few individuals continue to shed the pathogen for extended periods but show no symptoms. In these carriers, the bacteria continue to grow in the gallbladder and reach the intestine through the bile duct. This was almost certainly the case for "Typhoid Mary" (*see Historical Highlights 37.4*).

S. Agona, *S.* Heidelberg, *S.* Montevideo, and *S.* Mbandaka, and *S.* Tennessee have also been reported as contaminants of cereal products, chicken, tahini sesame paste, and peanut butter. The ongoing concern over food safety has prompted greater diligence for the detection and reporting of food contamination, so it is not so unusual to learn of foods contaminated with *Salmonella* spp. The CDC and FDA respond quickly with efforts to identify the strain and remove contaminated foods from the supply chain. Food contamination by *Salmonella* spp. demonstrates (1) the continued potential for farmed-food contamination and (2) the speed with which a public health response can occur. Of note, however, is the increasing concern regarding infection resulting from antibiotic-resistant *Salmonella* spp. *S.* Typhimurium is now resistant to at least five antimicrobial agents. Another serovar, *S.* Newport, is resistant to at least seven agents.

Shigellosis

Shigellosis, or bacillary dysentery, is a diarrheal illness resulting from an acute inflammatory reaction of the intestinal tract caused by the four species of the genus *Shigella*. Globally, *Shigella* spp. are estimated to cause up to 165 million cases of disease, with 600,000 deaths, per year. About 14,000 cases a year are reported in the United States. However, real numbers may be 20 times greater because mild cases of disease typically are not reported. The predominant disease-causing species in the United States and other industrialized countries is *S. sonnei*. *S. flexneri* predominates in the developing world. *S. boydii* infections are uncommon, along with *S. dysenteriae*.

The organism is transmitted by the fecal-oral route and is most prevalent among children, especially one- to four-year-olds. The infectious dose is only around 10 to 200 bacteria. In the United States, shigellosis is a particular problem in day-care centers and crowded custodial institutions.

Shigellae are intracellular parasites that multiply within the villus cells of the colonic epithelium. The bacteria induce Peyer's patch cells to phagocytose them. After being ingested by macrophages, the bacteria disrupt the phagosome membrane and are released into the cytosol, where they reproduce. They then invade adjacent mucosal cells. Both endotoxins and exotoxins may participate in disease progression, but the bacteria do not usually spread beyond the colonic epithelium. Watery stools often contain blood, mucus, and pus. In severe cases, the colon can become ulcerated. Virulent shigellae produce a heat-labile AB exotoxin known as Shiga toxin (Stx). The A subunit protein is subsequently released from the B protein units and cleaves host cell 28S rRNA, inhibiting protein synthesis. One target of the B protein seems to be the glomerular endothelium; toxin action on these cells leads to kidney failure. Additionally, like *Y. pestis* and the EPEC and EHEC pathotypes of *E. coli*, shigellae also use a type III secretion system to deliver virulence factors to target epithelial cells. ⏮ *Phagocytosis (section 33.5); Exotoxins (section 35.2)*

The incubation period for shigellosis usually ranges from 1 to 3 days, and the organisms are shed over a period of 1 to 2 weeks. The disease normally is self-limiting in adults and lasts an average of 4 to 7 days; in infants and young children, it may be fatal. Fluid and electrolyte replacement are usually sufficient to treat disease; antibiotics may not be required in mild cases, although they can shorten the duration of symptoms and limit transmission to family members. Sometimes, particularly in malnourished infants and children, neurological complications and kidney failure occur. Antibiotic-resistant strains are becoming a problem. Prevention is a matter of good personal hygiene and maintenance of a clean water supply.

Staphylococcal Food Poisoning

Staphylococcal food poisoning is the major type of food intoxication in the United States. It is caused by ingestion of improperly stored or cooked food (particularly foods such as ham, processed meats, chicken salad, pastries, ice cream,

and hollandaise sauce) in which *S. aureus* has been allowed to reproduce and release enterotoxins. Because these enterotoxins are heat stable, the food can be properly cooked, killing the bacteria without destroying the toxin. Staphylococcal enterotoxins (SE) are primarily produced by *S. aureus,* although other staphylococci produce them. SE are structurally related, single-chain proteins with molecular weights between 26,000 and 29,000; they are antigenically distinct. Thirteen different SE have been identified; SE A, B, C1, C2, C3, D, and E are the most common. Typical symptoms include severe abdominal pain, cramps, diarrhea, explosive vomiting, and nausea. The onset of symptoms is rapid (usually 1 to 8 hours) and of short duration (usually less than 24 hours). The mortality rate of staphylococcal food poisoning is negligible among healthy individuals.

Treatment of staph food poisoning primarily involves keeping hydrated while letting the toxin flush from the body. The toxemia usually resolves without medication. Death due to staph food poisoning is very rare, but it has occurred in infants, the elderly, and individuals who are immunocompromised. Prevention is through thorough hand washing during food preparation and the use of safe cooking and dining practices.

39.5 Zoonotic Diseases Arise from Human-Animal Interactions

After reading this section, you should be able to:

- Report the common bacterial diseases spread by contact with infected animals
- Identify typical signs and symptoms of zoonotic bacterial diseases
- Correlate zoonotic bacterial infection and disease severity with bacterial virulence factors

Diseases transmitted from animals to humans are called zoonotic diseases, or zoonoses. A number of important human pathogens begin as normal flora or parasites of animals and can often adapt to cause disease in humans. Here we highlight a few of the more notable diseases and the agents that cause them.

Anthrax

Anthrax (Greek *anthrax*, coal) is a highly infectious animal disease caused by the Gram-positive, endospore-forming *Bacillus anthracis*. *B. anthracis* is found worldwide and can be transmitted to humans by direct contact with infected animals (cattle, goats, sheep) or their products, especially hides. *B. anthracis* spores remain viable in soil and animal products for decades (*see figure 23.8a*). Although strains of *B. anthracis* have very little genetic variation, it is now possible to separate all known strains into five categories (providing some clues to their geographic sites of origin) based on the number of tandem repeats in various genes.

There are three forms of anthrax disease. When the bacterium enters through a cut or abrasion of the skin, **cutaneous anthrax** results. Inhaling spores may result in **pulmonary anthrax,** also known as woolsorter's disease. If spores reach the gastrointestinal tract, **gastrointestinal anthrax** may result. *B. anthracis* bacteremia can develop from any form of anthrax. Discounting the 2001 bioterrorism events in the United States, more than 95% of anthrax is the cutaneous form. Spores and vegetative bacteria are detected by skin macrophages and dendritic cells. In pulmonary anthrax, the spores (1 to 2 μm in diameter) are inhaled and lodge in the alveolar spaces, where they are engulfed by alveolar macrophages. Symptoms of gastrointestinal anthrax typically occur after the ingestion of undercooked meat containing spores and include nausea, vomiting, fever, and abdominal pain.

B. anthracis carries two plasmids that encode virulence factors. One plasmid has genes involved in the synthesis of a polyglutamyl capsule that inhibits phagocytosis, and the other bears genes for the synthesis of an exotoxin. *B. anthracis* exotoxin is composed of three proteins: protective antigen (PA), edema factor (EF), and lethal factor (LF). Macrophages have many receptors on their plasma membranes to which PA attaches. Attachment continues until seven PA-receptor complexes gather in a doughnut-shaped ring (**figure 39.29**). The ring acts like a syringe, boring through the plasma membrane

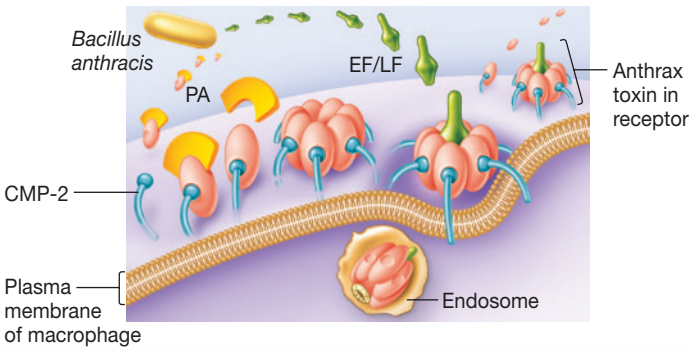

Figure 39.29 Anthrax. A protein called protective antigen (PA) delivers two other proteins, edema factor (EF) and lethal factor (LF), to the capillary morphogenesis protein-2 (CMP-2) receptor on the cell membrane of a target macrophage, where PA, EF, and LF are transported to an endosome. PA then delivers EF and LF from the endosome into the cytoplasm of the macrophage, where they exert their toxic effects.

MICRO INQUIRY *By what mechanisms do EF and LF kill macrophages?*

of the macrophage. Toxin moieties EF and LF are then engulfed by the macrophage and shuttled to an endosome (*see figure 33.19*). Once there, PA molecules form a pore that pierces the endosomal membrane, and EF and LF enter the cytosol. Toxin activity results in fluid release, with the formation of edema. Additionally, LF prevents the transcription factor nuclear factor kappa B ($NF_{\kappa}B$) from regulating numerous cytokine and other genes needed for an effective immune response. As thousands of macrophages die, they release their lysosomal contents, leading to fever, internal bleeding, septic shock, and rapid death. Without antibiotic treatment and supportive therapy, mortality rates approach 100% for inhalational and gastrointestinal anthrax, and between 20 and 50% for cutaneous anthrax.

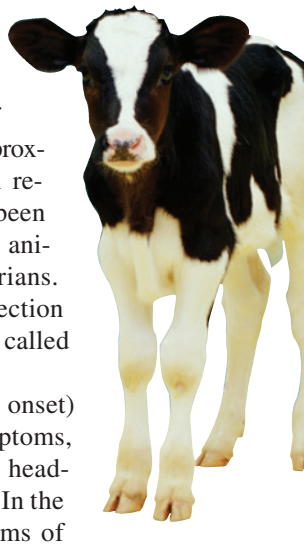
Between 2,000 and 20,000 cases of anthrax are estimated to occur worldwide annually, primarily in developing countries; in the United States, the annual incidence was less than one case per year—a rate maintained for 20 years until 2001. The 2001 occurrence of 22 cases of anthrax has spotlighted concern about anthrax as a weapon of bioterrorism.

Treatment of each form of anthrax is the same: ciprofloxacin, penicillin, or doxycycline are successful only if begun before a critical concentration of toxin has accumulated. Although antibiotics may kill the bacterium or suppress its growth, the exotoxin can still eventually kill the patient. Thus, supportive care is essential in preventing death. Vaccination of animals, primarily cattle, is an important control measure. However, people with a high occupational risk, such as those who handle infected animals or their products, including hides and wool, should be immunized. U.S. military personnel also receive the vaccine. ⏮ *Bioterrorism readiness is an integral component of public health microbiology (section 37.7)*

Brucellosis (Undulant Fever)

The genus *Brucella* contains important human and animal pathogens. **Brucellosis,** also called undulant fever, is caused by faintly staining coccobacilli of the species *B. abortus, B. melitensis, B. suis,* or *B. canis*. These bacteria are commonly transmitted through consumption of contaminated animal products or through abrasions of the skin while handling infected mammals (cattle, sheep, goats, pigs, and, rarely, dogs). The most common route is ingestion of contaminated milk products. Direct person-to-person spread of brucellosis is extremely rare. However, infants may be infected through their mother's breast milk; sexual transmission of brucellosis has also been reported. Although uncommon, transmission of brucellosis may also occur through transplantation of contaminated blood or tissue. A controversy in the northwestern United States over the transmission of brucellosis, endemic in the wild bison and elk populations, to otherwise *Brucella*-free cattle has continued for many years. ⏮ *Class* Alphaproteobacteria *includes many oligotrophs (section 22.1)*

In the United States, human *Brucella* infections (primarily *B. melitensis*) occur more frequently when individuals ingest unpasteurized milk or dairy products. Brucellosis also has occurred in laboratory workers—culturing the organisms concentrates them and increases the risk of their aerosolization. For the past 10 years, approximately 110 cases of brucellosis have been reported annually. Most of these cases have been in slaughterhouse workers, meat inspectors, animal handlers, veterinarians, and laboratorians. Important for tourists is the potential infection through unpasteurized cheeses, sometimes called "village cheeses."



Brucellosis, in the acute (8 weeks from onset) form, presents as nonspecific, flulike symptoms, including fever, sweats, malaise, anorexia, headache, myalgia (muscle pain), and back pain. In the undulant (rising and falling) form, symptoms of brucellosis include cyclic fevers, arthritis, and testicular inflammation. Neurologic symptoms may occur acutely in up to 5% of the cases. In the chronic form (1 year from onset), brucellosis symptoms may include chronic fatigue, depression, and arthritis. Mortality is low, less than 2%. Treatment is usually with doxycycline and rifampin in combination for 6 weeks to prevent recurring infection. The insidious disease, potential for food supply disruption, and significant morbidity associated with *Brucella* infection have prompted its restriction as a select agent; the public health impact, should it be used as a bioweapon, would be substantial. ⏮ *Bioterrorism readiness is an integral component of public health microbiology (section 37.7)*

Psittacosis (Ornithosis)

Psittacosis (ornithosis) is a worldwide infectious disease of birds that is transmissible to humans. Since 1996 fewer than 50 confirmed cases have been reported in the United States each year; typically 1 or 2. Psittacosis was first described in association with parrots and parakeets, both of which are psittacine birds. The disease is now recognized in many other birds—among them, pigeons, chickens, ducks, and turkeys—and the general term ornithosis (Latin *ornis*, bird) is used.

Ornithosis is caused by *Chlamydophila psittaci*. Humans contract this disease either by handling infected birds or by inhaling dried bird excreta that contains viable *C. psittaci*. Ornithosis is recognized as an occupational hazard within the poultry industry, particularly to workers in turkey-processing plants. Incubation is typically 5 to 19 days. After entering the respiratory tract, the bacteria are transported to the cells of the liver and spleen. The bacteria multiply within these cells and then invade the lungs, where they cause inflammation, hemorrhaging, and pneumonia. Endocarditis (inflammation of the heart muscle), hepatitis, and neurologic complications may occasionally occur. With doxycycline or tetracycline therapy, the mortality rate is about 2%.

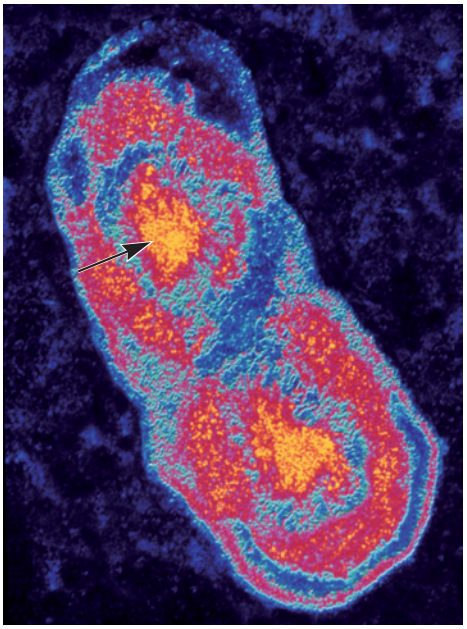


Figure 39.30 ***Coxiella burnetii.*** Note the unique endospore-like structure (at arrowhead) within the vegetative cell.

Q Fever

The Q in **Q fever** stands for query because the cause of the fever was long unknown. The disease is now known to be caused by the γ-proteobacterium *Coxiella burnetii*. *C. burnetii* can survive outside host cells by forming resistant, endospore-like bodies (**figure 39.30**). This bacterium infects both wild animals and livestock. Cattle, sheep, and goats are the primary reservoirs. It does not need an arthropod vector for transmission, but in animals, ticks (many species) transmit *C. burnetii*. By contrast, human transmission is primarily by inhalation of dust contaminated with bacteria from dried animal feces or urine, or consumption of unpasteurized milk. Importantly, organisms are shed in high numbers within amniotic fluids and the placenta during birthing. The organisms are resistant to heat, drying, and many common disinfectants. These features enable the bacteria to survive for long periods in the environment. The disease can occur in epidemic form among slaughterhouse workers and sporadically among farmers and veterinarians. Each year, fewer than 30 cases of Q fever are reported in the United States. However, approximately 3% of U.S. adults and an additional 10-20% of high-risk populations (farmers, veterinarians, etc.) have antibodies suggesting prior exposure to *C. burnetii*. ⏮ *Class* Gammaproteobacteria *is the largest bacterial class (section 22.3)*

In humans, Q fever is an acute illness characterized by the sudden onset of severe headache, malaise, confusion, sore throat, chills, sweats, nausea, chest pain, myalgia, and high fever. It is rarely fatal, but endocarditis occurs in about 10% of the cases. Five to 10 years may elapse between the initial infection and the appearance of endocarditis. During this interval, the bacteria reside in the liver and often cause hepatitis. The fatality rate is approximately 4%.

Diagnosis of Q fever is made by national reference laboratories using PCR or culture of the bacterium and fluorescent antibody and agglutination tests. Treatment is with doxycycline and is most effective when initiated within the first 3 days of illness. Prevention and control involve public education, protective clothing, and vector control. An attenuated live vaccine is available from the U.S. Army for high-risk laboratory workers. Importantly, *C. burnetii* is a microorganism of concern as a biological threat agent. ⏮ *Bioterrorism readiness is an integral component of public health microbiology (section 37.7)*

Tularemia

The Gram-negative bacterium *Francisella tularensis* is widely found in animal reservoirs in the United States and causes the disease **tularemia** (from Tulare, a county in California where the disease was first described). It may be transmitted to humans by biting arthropods (ticks and deer flies), direct contact with infected tissue (rabbits), inhalation of aerosolized bacteria, or ingestion of contaminated food or water. However, tularemia is most often transmitted through contact with infected animals; it is called rabbit fever in the central United States because it is often a disease of hunters who skin their catch. After an incubation period of 2 to 10 days, a primary ulcerative lesion appears at the infection site, lymph nodes enlarge, and a high fever develops.

Diagnosis is made by national reference laboratories using PCR or culture of the bacterium and fluorescent antibody and agglutination tests. Treatment is with streptomycin, tetracycline, or aminoglycoside antibiotics for 10 to 21 days. Prevention and control involve public education, protective clothing, and vector control. An attenuated live vaccine is available from the U.S. Army for high-risk laboratory workers. Typically 150 to 200 cases of tularemia are reported annually in the United States. *F. tularensis* is also a microorganism of concern as a biological threat agent. Because public health preparedness efforts in the United States have shifted toward a stronger defense against biological terrorism, public health and medical management protocols following a potential release of tularemia are now in place. ⏮ *Bioterrorism readiness is an integral component of public health microbiology (section 37.7)*

3. How is ornithosis transmitted?
4. Describe the disease of tularemia. Why is *F. tularensis* considered a potential agent of bioterrorism?

39.6 Opportunistic Diseases Can Be Caused by Bacteria

After reading this section, you should be able to:

- Explain how disease can result from human microbiota that is normal to another body site
- Cite specific environmental conditions that result from overgrowth of one bacterial species
- Design a model of bacterial biofilm formation to explain its role in human disease

Recall that the normal microbiota of a human can also become pathogenic, especially if they gain access to a tissue site that is not their regular environment or they overgrow other normal flora. Microbes that are otherwise members of the normal microbiota but become pathogens are referred to as opportunists; they cause opportunistic disease. We discuss a few examples of opportunistic disease next.

Antibiotic-Associated Colitis (Pseudomembranous Colitis)

Antibiotic-associated colitis is a spectrum of disease caused by the overgrowth of *Clostridium difficile*. *C. difficile* can be part of the human intestinal microbiota but is kept at low numbers by other bacteria. However, when the other bacteria are inhibited or killed during antibiotic chemotherapy, *C. difficile* grows unchecked. The disease spectrum (*C. difficile* infection, or CDI) includes uncomplicated diarrhea, pseudomembranous colitis (a viscous collection of inflammatory cells, dead cells, necrotic tissue, and fibrin that obstructs the intestine), and toxic megacolon (inflammation that results in intestinal tissue necrosis), which can, in some instances, lead to sepsis and death (**figure 39.31**). *C. difficile* is an anaerobic, spore-forming bacillus that can be found in the intestines of healthy people and often in health-care facilities. The most common antibiotics associated with the development of CDI are amoxicillin, ampicillin, cephalosporins, and clindamycin. When antibiotics reduce the other bacteria, *C. difficile* bacteria multiply, produce toxins, and sporulate. Importantly, even short stays in health-care facilities predispose people to *C. difficile* infection. Three toxins can be expressed by *C. difficile*: enterotoxin (toxin A) and a cytotoxin (toxin B), both of which are responsible for the inflammation and diarrhea, and binary toxin, which alters the host cell cytoskeleton. Toxin genes are located within the pathogenicity locus. The most common symptom of CDI is watery diarrhea, consisting of three or more bowel movements per day for 2 or more days. Other common symptoms include fever, loss of appetite, nausea, and abdominal cramping or tenderness.

C. difficile is the most commonly recognized cause of diarrhea in hospitalized patients, as spores from one patient can be transmitted to others. Antibiotic use is the main modifiable risk factor for CDI. In addition to suppressing other bacteria and thereby promoting *C. difficile* overgrowth, antibiotics increase the risk of selecting for antimicrobial-resistant strains. It is likely that alteration of the complex colonic ecology provides an environment for *C. difficile* to thrive and produce disease. Ironically, treatment of CDI is by oral metronidazole or oral vancomycin. Newer therapies showing success include (1) the use of a probiotic milk shake containing *Lactobacillus casei, L. bulgaricus,* and *Streptococcus thermophilus* to prevent antibiotic-associated diarrhea caused by *C. difficile*; and (2) the transplantation of fecal material to replenish a healthy colonic microbiota (*see p. 685*).

Bacterial Vaginosis

Bacterial vaginosis is caused by *Gardnerella vaginalis* (a Gram-positive to Gram-variable, pleomorphic, nonmotile rod), *Mobiluncus* spp. (Gram-negative, anaerobic rods), and various other anaerobic bacteria. These microorganisms inhabit the vagina and rectum of 20 to 40% of healthy women, suggesting an opportunistic etiology; however, some consider the disease to be sexually transmitted because the organisms can be shared through intimate contact. Vaginosis of bacterial origin is typically a mild disease, although it is a risk factor for obstetric infections, various adverse outcomes of pregnancy, and pelvic inflammatory disease.

Vaginosis is characterized by a copious, frothy, fishy-smelling discharge with varying degrees of pain or itching. Diagnosis is based on this fishy odor and the microscopic observation of clue

Figure 39.31 Pseudomembranous Colitis. Endoscopic view of *C. difficile*–associated colitis. The white patches represent inflamed tissue.

MICRO INQUIRY *What cells and tissues make up the pseudomembrane?*

cells in the discharge. Clue cells are sloughed-off vaginal epithelial cells covered with bacteria, mostly *G. vaginalis*. Treatment for bacterial vaginosis is with metronidazole, a drug that kills anaerobic streptococci and the *Mobiluncus* spp. that appear to be needed for the continuation of the disease.

Dental Diseases

Only a few of the symbiotic bacteria in the oral cavity can be considered true opportunistic dental pathogens, or odontopathogens. These few odontopathogens are responsible for the most common bacterial diseases in humans: tooth decay and periodontal disease.

Dental Plaque

The human tooth has a natural defense mechanism against bacterial colonization that complements the protective role of saliva. The hard enamel surface selectively absorbs acidic glycoproteins (mucins) from saliva, forming a membranous layer called the acquired enamel pellicle. This pellicle, or organic covering, contains many sulfate (SO_4^{2-}) and carboxylate (—COO^-) groups that confer a net negative charge to the tooth surface. Because most bacteria also have a net negative charge, there is a natural repulsion between the tooth surface and bacteria in the oral cavity. Unfortunately, this natural defense mechanism breaks down when dental plaque forms.

Dental plaque is one of the densest collections of bacteria in the body—perhaps the source of the microorganisms seen under a microscope by Antony van Leeuwenhoek in the seventeenth century. Dental plaque formation begins with the initial colonization of the pellicle by *Streptococcus gordonii*, *S. oralis,* and *S. mitis* (**figure 39.32**). These bacteria selectively adhere to the pellicle by specific ionic, hydrophobic, and lectinlike interactions. Once the tooth surface is colonized, subsequent attachment of other bacteria results from a variety of specific coaggregation reactions.

S. mutans and *S. sobrinus* become established on the tooth surface by attaching to these initial colonizers (figure 39.32). *S. mutans* and *S. sobrinus* produce extracellular enzymes that polymerize the glucose moiety of sucrose into a heterogeneous group of extracellular, water-soluble, and water-insoluble polysaccharides. These act like a cement that binds bacterial cells together, forming a plaque ecosystem that is also a biofilm. The fructose by-product can be used in fermentation. Once plaque becomes established, the surface of the tooth becomes anoxic. This leads to the growth of strictly anaerobic bacteria (*Bacteroides melaninogenicus, B. oralis,* and *Veillonella alcalescens*), especially between teeth and in the dental-gingival crevices (**figure 39.33**). In addition, bacteria produce lactic and possibly acetic and formic acids from sucrose and other sugars. Because plaque is not permeable to saliva, the acids are not diluted or neutralized, and they demineralize the enamel to produce a lesion on the tooth. It is this chemical lesion that initiates dental decay. ◀◀ *Biofilms are common in nature (section 7.5); Phylum* Bacteroidetes *includes important gut microbiota (section 21.9)*

Dental Decay (Caries)

As fermentation acids move below the enamel surface, they dissociate and react with the hydroxyapatite of the enamel to form soluble calcium and phosphate ions. As the ions diffuse outward, some reprecipitate as calcium phosphate salts in the tooth's surface

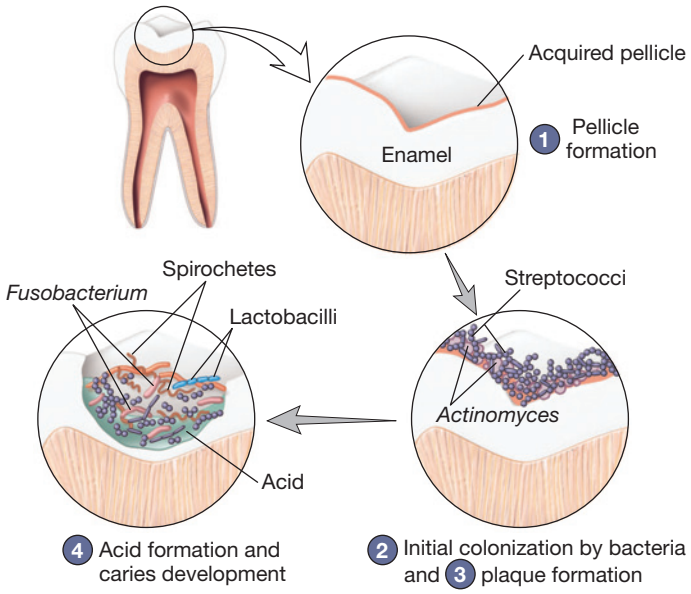

Figure 39.32 Stages in Plaque Development and Cariogenesis. A drawing of a microscopic view of pellicle and plaque formation, acidification, and destruction of tooth enamel.

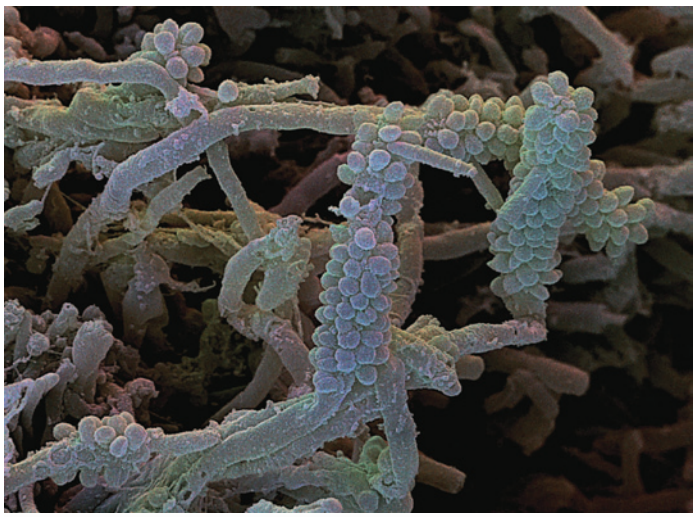

Figure 39.33 The Microscopic Appearance of Plaque. Scanning electron micrograph of plaque with long filamentous forms and "corn cobs" that are the mixed bacterial aggregates.

MICRO INQUIRY *How is tooth enamel demineralized by bacterial growth?*

layer to create an outer layer overlying a porous subsurface area. Between meals and snacks, the pH returns to neutrality and some calcium phosphate reenters the lesion and crystallizes. The result is a demineralization-remineralization cycle.

When an individual eats foods high in sucrose for prolonged periods, acid production overwhelms the repair process, and demineralization is greater than remineralization. This leads to dental decay or **caries** (Latin, rottenness). Once the hard enamel has been breached, bacteria can invade the dentin and pulp of the tooth and cause its death (figure 39.33).

No drugs are available to prevent dental caries. The main strategies for prevention include minimal ingestion of sucrose; daily brushing, flossing, and rinsing with mouthwashes; and professional cleaning at least twice a year to remove plaque. The use of fluorides in toothpaste, drinking water, and mouthwashes or fluoride and sealants applied professionally to the teeth protects against lactic and acetic acids and reduces tooth decay.

Periodontal Disease

Periodontal disease refers to a diverse group of inflammatory diseases that affect the periodontium and is the most common chronic infection in adults. The **periodontium** is the supporting structure of a tooth and includes the cementum, the periodontal membrane, the bones of the jaw, and the gingivae (gums). The gingiva is dense, fibrous tissue and its overlying mucous membrane that surrounds the necks of the teeth. The gingiva helps to hold the teeth in place.

Disease is initiated by the formation of **subgingival plaque,** the plaque that forms at the dentogingival margin and extends down into the gingival tissue. A number of bacterial species contribute to tissue damage. The result is an initial inflammatory reaction known as **periodontitis,** which is caused by the host's immune response to both the plaque bacteria and the tissue destruction. This leads to swelling of the tissue and formation of periodontal pockets. Bacteria colonize these pockets and cause more inflammation, which leads to formation of a periodontal abscess, bone destruction (periodontosis), inflammation of the gingiva (gingivitis), and general tissue necrosis (**figure 39.34**). If the condition is not treated, the tooth may fall out of its socket.

Periodontal disease can be controlled by frequent plaque removal; by brushing, by flossing, and by rinsing with mouthwashes; and at times, by oral surgery of the gums and antibiotics.

Figure 39.34 Periodontal Disease. Notice the plaque on the teeth (arrow), especially at the gingival (gum) margins, and the inflamed gingiva.

Streptococcal Pneumonia

Streptococcal pneumonia is now considered an opportunistic infection because it is often contracted from one's own normal microbiota. It is caused by Gram-positive *Streptococcus pneumoniae*, normally found in the upper respiratory tract. However, disease usually occurs only in those individuals with predisposing factors such as viral infections of the respiratory tract, physical injury to the tract, alcoholism, or diabetes. In addition to pneumonia, *S. pneumoniae* causes other diseases, including acute middle ear infection, bacteremia, and meningitis. About 60 to 80% of all respiratory diseases known as pneumonia are caused by *S. pneumoniae*. An estimated 4 million pneumococcal illnesses occur in the United States annually, and 22,000 deaths result.

The primary virulence factor of *S. pneumoniae* is its capsular polysaccharide, which is composed of hyaluronic acid. The capsule plays an important role in protecting the organism from ingestion and killing by phagocytes. Pathogenesis is due to the rapid multiplication of the bacteria in alveolar spaces. The bacteria also produce the toxin pneumolysin, which destroys host cells. The alveoli fill with blood cells and fluid, and become inflamed. The sputum is often rust-colored because of blood coughed up from the lungs. The onset of clinical symptoms is usually abrupt, with chills; hard, labored breathing; and chest pain. Diagnosis is by chest X ray, Gram stain, culture, and tests for metabolic products. Treatment needs to be based on antibiotic susceptibility, because many strains are resistant to β-lactam and macrolide antibiotics.

Pneumococcal vaccines (PCV-13 and PPSV23) are available for people who are at risk for exposure (e.g., college students, children, the elderly, and people in chronic-care facilities). The pneumococcal conjugate vaccine (PCV) covers 13 pneumococcal serotypes, while the pneumococcal polysaccharide vaccine (PPSV23) covers 23 types of pneumococcal bacteria. These vaccines are effective because they generate antibodies to the strains that cause 88 to 90% of pneumococcal disease. When these antibodies are deposited on the surface of the bacteria, they become opsonic and enhance phagocytosis (*see figure 33.6*).

Retrieve, Infer, Apply

1. Describe the process by which *C. difficile*–associated disease occurs.
2. In both *C. difficile*–associated disease and bacterial vaginosis, the disease begins when the normal microbiota of the tissue site is altered. Why is this?
3. Name some common odontopathogens that are responsible for dental caries, dental plaque, and periodontal disease.

Key Concepts

39.1 Bacteria Can Be Transmitted by Airborne Routes

- A number of infectious diseases are caused by bacteria as a result of their transmission through air.
- Examples of diseases transmitted by airborne dissemination include chlamydial pneumonia (*Chlamydophila pneumoniae*); diphtheria (*Corynebacterium diphtheriae;* **figure 39.1**); Legionnaires' disease (*Legionella pneumophila;* **figure 39.2**); meningitis (*Neisseria meningitidis* [**figure 39.3**] and *Haemophilus influenzae* type b); mycobacterial infections (*M. avium* and *M. intracellulare* pneumonia and *M. tuberculosis;* **figure 39.4**); mycoplasmal pneumonia (*Mycoplasma pneumoniae*); pertussis (*Bordetella pertussis*); and streptococcal diseases (*Streptococcus* spp.; **figures 39.5** and **39.6**).

39.2 Arthropods Can Transmit Bacterial Diseases

- Bacteria can be transmitted to humans as a result of their interaction with arthropod vectors, such as ticks, lice, and fleas.
- Examples of arthropod-borne diseases include Lyme disease (*Borrelia burgdorferi;* **figure 39.7**); plague (*Yersinia pestis;* **figures 39.8** and **39.9**); and Rocky Mountain spotted fever (*Rickettsia rickettsii;* **figure 39.10**).

39.3 Direct Contact Diseases Can Be Caused by Bacteria

- Direct contact of an uninfected human with sources of bacteria (including infected humans) can result in transmission of bacteria and disease. Direct contact of skin, mucous membranes, open wounds, or body cavities can lead to bacterial colonization and disease.
- Examples of direct contact diseases caused by bacteria include gas gangrene or clostridial myonecrosis (*Clostridium perfringens;* **figure 39.11**); group B streptococcal disease (*Streptococcus agalactiae*); mycobacterial infections including leprosy (*Mycobacterium leprae;* **figure 39.12**) and tattoo-associated infections; peptic ulcer disease (*Helicobacter pylori;* **figure 39.13**); sexually transmitted diseases such as chlamydial diseases (*Chlamydia trachomatis;* **figure 39.14**), gonorrhea (*Neisseria gonorrhea;* **figure 39.15**), and syphilis (*Treponema pallidum;* **figures 39.16** and **39.17**); staphylococcal diseases (*Staphylococcus aureus;* **figures 39.18–39.20**), including methicillin-resistant *Staphylococcus aureus* (**figure 39.21**); streptococcal diseases (*Streptococcus pyogenes;* **figure 39.22**); tetanus (*Clostridium tetani*); and trachoma (*Chlamydia trachomatis;* **figure 39.24**).

39.4 Food and Water Are Vehicles for Bacterial Diseases

- Food and water can serve as vehicles that transport bacteria to humans. Ingestion of contaminated food and water often results in infections of the gastrointestinal tract (**tables 39.3** and **39.4**).
- Some common food-borne and waterborne bacterial infectious diseases of the intestinal tract are botulism (*Clostridium botulinum;* **figure 39.25**), *Campylobacter* gastroenteritis (*Campylobacter jejuni*), cholera (*Vibrio cholerae;* **figure 39.26**), *Escherichia coli* gastroenteritis (**figure 39.27**), salmonellosis (various *Salmonella* serovars), typhoid fever (*Salmonella* serovar Typhi), shigellosis (*Shigella* spp.), and staphylococcal food poisoning (*Staphylococcus aureus* enterotoxins).
- Sepsis and septic shock are most commonly caused by Gram-negative bacteria, mediated by the lipid A component of the outer membrane.
- Some diseases are caused by bacterial action on cells of the intestine. Other diseases result from bacterial toxins.

39.5 Zoonotic Diseases Arise from Human-Animal Interactions

- Diseases of animals that are transmitted to humans are called zoonoses (s., zoonosis).
- Important bacterial zoonoses include anthrax (*Bacillus anthracis;* **figure 39.29**); brucellosis (*Brucella* spp.); psittacosis (*Chlamydophila psittaci*); Q fever (*Coxiella burnetii;* **figure 39.30**); and tularemia (*Francisella tularensis*).

39.6 Opportunistic Diseases Can Be Caused by Bacteria

- Normal microbiota can cause disease especially when they are in tissues that are not the regular environment or they overgrow the regular environment; these are opportunists and cause opportunistic diseases.
- Opportunistic diseases include antibiotic-associated colitis (*Clostridium difficile;* **figure 39.31**); bacterial vaginosis (*Gardnerella vaginalis*); dental infections; and streptococcal pneumonia (*Streptococcus pneumoniae*).
- Dental plaque formation begins on a tooth with the initial colonization of the acquired enamel pellicle by *Streptococcus gordonii*, *S. oralis*, and *S. mitis*. Other bacteria then become attached and form a plaque ecosystem (**figures 39.32** and **39.33**). The bacteria produce acids that cause a chemical lesion on the tooth and initiate dental decay or caries.
- Periodontal disease is a group of diverse clinical entities that affect the periodontium. Disease is initiated by the formation of subgingival plaque, which leads to tissue inflammation known as periodontitis and to periodontal pockets. Bacteria that colonize these pockets can cause an abscess, periodontosis, gingivitis, and general tissue necrosis (**figure 39.34**).

Compare, Hypothesize, Invent

1. Describe a typhoid carrier. How does one become a carrier?
2. Many consider cholera as the most severe form of gastroenteritis. Why do you think this is so?
3. Compare the three stages of syphilis and Lyme disease. Why do you think both diseases are so hard to treat once they progress beyond the primary stage?
4. While many *Vibrio cholerae* strains are found in aquatic environments, only a small fraction of these cause human disease. When in aquatic ecosystems, *V. cholerae* is frequently found attached to the exoskeleton of zooplankton, which is made of chitin. Indeed, *V. cholerae* produces an extracellular chitinase, so zooplankton-associated growth presumably provides a good source of organic carbon and nitrogen. Growth on zooplankton and in the human gut shares the requirement for attachment proteins. Remarkably, the same protein, called GbpA, has been shown to bind to both the *N*-acetylglucosamine (GlcNAc) of zooplankton chitin and to epithelial cells. The glycoproteins and lipids on the surface of epithelial cells are commonly modified with GlcNAc.

   How would you show whether or not GbpA binds specifically to epithelial GlnNAc? How would you determine if GbpA is needed for virulence? How would you test the hypothesis that GbpA is produced by pathogenic strains but not, or to a lesser extent, by nonpathogenic strains of *V. cholerae*?

   Read the original paper: Kirn, T. J., et al. 2005. A colonization factor links *Vibrio cholerae* environmental survival and human infection. *Nature* 438:863.
5. The spirochete *Borrelia burgdorferi* causes Lyme disease, which is transmitted to humans when its vector, the deer tick, takes a blood meal. When *B. burgdorferi* is in the gut of the tick, its outer surface protein A (OspA) is expressed at high levels. Once it has been transmitted to a human, OspA production diminishes. However, to complete its infection cycle and return to the tick, *B. burgdorferi* cells must increase OspA synthesis. Microbiologists wanted to determine how the spirochete senses the presence of a feeding tick and thus resumes high levels of OspA production. It was discovered that *B. burgdorferi* specifically binds the host neuroendocrine stress hormones epinephrine and norepinephrine. This enables the microbe to detect the presence of a tick, which results in upregulation of OspA.

   Discuss the role of coevolution in the development of *B. burgdorferi*'s ability to sense and respond to these host compounds. How would you show that among all the mediators of inflammation at the site of a tick bite, the spirochete responds specifically to epinephrine and norepinephrine? Your answer should include some carefully considered control experiments.

   Read the original paper: Schekelhoff, M. R., et al. 2007. *Borrelia burgdorferi* intercepts host hormonal signals to regulate expression of outer surface protein A. *Proc. Natl. Acad. Sci. USA* 104:7247–52.

Human Diseases Caused by Fungi and Protists

Similar to the patient in the opening story, this woman has mucormycosis. The fungus entered her right eye, causing life-threatening disease.

Death by...Mushroom?

Ask Kentuckian Mark Tatum who would win a battle of man versus mushroom and he'll likely bet on the fungus. In 2000 Tatum lost a portion of his face to a severe mucormycosis infection; such infections are often fatal. In fact, the capacity of certain fungi to degrade animal tissues is so legendary that a research fellow at the Massachusetts Institute of Technology is developing a mushroom strain that will be specifically adept at digesting human tissues. In what is known as the "Infinity Burial Project," Jae Rhim Lee is exploring alternatives to the toxic formaldehyde-based burial process. Growing fungi in Petri dishes filled with human hair, skin, nails, and so forth will facilitate the selective breeding of mushrooms that thrive on this macabre media. She has also designed a "mushroom death suit" into which a suspension of mushroom spores will provide mushroom access to its nutrient source (the dead body), and thus accelerate decomposition. Lee states that she is building an acceptance of natural processes, pointing out that cemetery soil already contains many fungal species. Interestingly, among another of her goals is to determine if mushroom-based decomposition will also eliminate some of the more than 200 toxic chemicals that accumulate in the human body.

Ethicists will debate the religious and spiritual issues, while microbial ecologists consider the impact such a strain might have in the environment. For example, do such strains already exist in cemeteries? How will a "man-eating mushroom" change the microbiota of soil? Will mourners be able to visit the cemeteries without fear of hitchhiking spores coming home to dinner? Regardless of the questions yet unanswered, one thing is certain: Fungi are masters at producing extracellular enzymes to digest complex foods into soluble nutrients. Just ask Mark Tatum.

In this chapter, we describe some of the fungi and protists that are pathogenic to humans and discuss the clinical manifestations, diagnosis, epidemiology, pathogenesis, and treatment of the diseases caused by them. The biology and diversity of these organisms are covered in chapters 5, 25, and 26. This chapter follows the format of the previous two chapters in categorizing their diseases by route of transmission (**figure 40.1**).

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Review basic eukaryote cell biology (sections 5.1–5.7)
- ✔ Distinguish between yeast and mold (section 26.1)
- ✔ Identify the major factors supporting growth and reproduction of protists and fungi (sections 25.1 and 26.1)
- ✔ Explain pathogenicity and the infection process (chapter 35)
- ✔ Differentiate different types of vaccines (section 37. 6)

40.1 Relatively Few Fungi and Protists Are Human Pathogens

After reading this section, you should be able to:

- Describe the system used to categorize fungal diseases
- Explain why protist infection is becoming a greater challenge

While there are approximately 1.5 million species of fungi on the Earth, only about 300 produce disease in humans. Medical mycology is the discipline that deals with the fungi that cause human disease. These fungal diseases, known as **mycoses** (s., mycosis; Greek *mykes*, fungus), are typically divided into five groups according to the route of infection: superficial, cutaneous, subcutaneous, systemic, and opportunistic mycoses (**table 40.1**). Superficial, cutaneous, and subcutaneous mycoses are direct contact infections of the skin, hair, and nails. Systemic mycoses are fungal infections that have disseminated to visceral tissues. The fungi that cause systemic or deep mycoses are dimorphic; that is, they exhibit a parasitic yeastlike (single-cell) phase (Y) and a saprophytic mold or mycelial (filamentous) phase (M; *see p. 922*). The switch from growth as a mycelial form at external temperatures to growth as a yeast form at human body temperatures is called the **Y-M shift** and is considered a virulence factor. Most systemic mycoses are acquired by inhalation of spores from soil in which the mold phase of the fungus resides. If a susceptible person inhales enough spores, infection begins as a lung

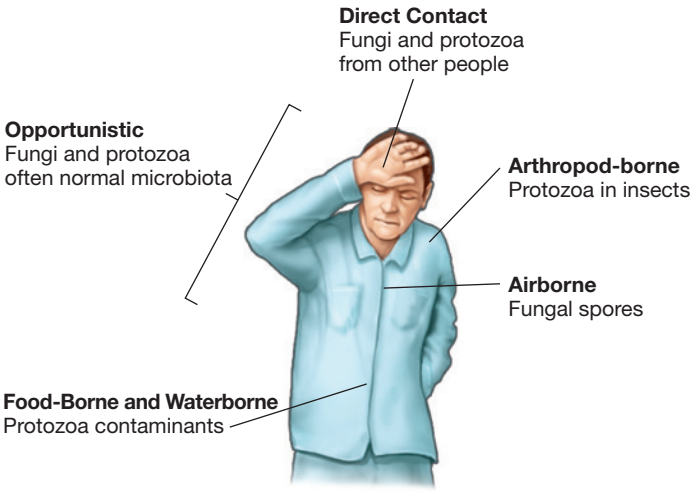

Figure 40.1 Common Routes of Fungal and Protozoan Disease Transmission. Examples of disease-causing fungi and protists are presented in this chapter according to route of transmission.

lesion, becomes chronic, and may spread through the bloodstream to other organs (the target organ varies with the species). Some fungi produce toxins (mycotoxins) that are harmful to humans. We discuss them with other toxins in chapter 35 and in chapter 41 (*see figures 41.5 and 41.6*). ◀◀ Fungi *(chapter 26); Mycotoxins (section 35.2)*

Protozoa have become adapted to practically every type of habitat on Earth, including the human body. Many protists are transmitted to humans by arthropod vectors or in contaminated food or water. However, some protozoan diseases are transmitted by direct contact. Although members of fewer than 20 genera of protists cause disease in humans (**table 40.2**), their impact is formidable. For example, approximately 200 million cases of malaria occur in the world each year. In sub-Saharan Africa alone, malaria is responsible for the deaths of more than half a million children under the age of five annually. It is estimated that there are at least 8,000 cases of trypanosomiasis, 1.3 million cases of leishmaniasis, and over 50 million cases of amebiasis yearly.

Table 40.1 Examples of Some Medically Important Fungi

Disease Category	Pathogen	Location	Disease
Superficial mycoses	*Piedraia hortae*	Scalp	Black piedra
	Trichosporon beigelii	Beard, mustache	White piedra
	Malassezia furfur	Trunk, neck, face, arms	Tinea versicolor
Cutaneous mycoses	*Trichophyton mentagrophytes, T. verrucosum, T. rubrum*	Beard hair	Tinea barbae
	Trichophyton, Microsporum canis	Scalp hair	Tinea capitis
	Trichophyton rubrum	Smooth or bare parts of the skin	Tinea corporis
	Epidermophyton floccosum, T. mentagrophytes, T. rubrum	Groin, buttocks	Tinea cruris (jock itch)
	T. rubrum, T. mentagrophytes, E. floccosum	Feet	Tinea pedis (athlete's foot)
	T. rubrum, T. mentagrophytes, E. floccosum	Nails	Tinea unguium (onychomycosis)
Subcutaneous mycoses	*Phialophora verrucosa, Fonsecaea pedrosoi*	Legs, feet	Chromoblastomycosis
	Madurella mycetomatis	Feet, other areas of body	Maduromycosis
	Sporothrix schenckii	Puncture wounds	Sporotrichosis
Systemic mycoses	*Blastomyces dermatitidis*	Lungs, skin	Blastomycosis
	Coccidioides immitis	Lungs, other parts of body	Coccidioidomycosis
	Cryptococcus neoformans	Lungs, skin, bones, viscera, central nervous system	Cryptococcosis
	Histoplasma capsulatum	Within phagocytes	Histoplasmosis
Opportunistic mycoses	*Aspergillus fumigatus, A. flavus*	Respiratory system	Aspergillosis
	Candida albicans	Skin or mucous membranes	*Candidiasis*
	Pneumocystis jiroveci	Lungs, sometimes brain	*Pneumocystis* pneumonia
	Encephalitozoon, Pleistophora, Enterocytozoon, Microsporidium	Lungs, sometimes brain	Microsporidiosis

Table 40.2 Examples of Medically Important Protozoan Infections

Initial Infection Site	Pathogen	Disease
Blood	*Plasmodium* spp. *Trypanosoma brucei* *Trypanosoma cruzi*	Malaria African sleeping sickness American trypanosomiasis
Intestinal Tract	*Cryptosporidium* spp. *Cyclospora* spp. *Entamoeba histolytica* *Giardia intestinalis* *Toxoplasma gondii*	Cryptosporidiosis Cyclosporidiosis Amebiasis Giardiasis Toxoplasmosis
Lungs	*Balamuthia mandrillaris* *Pneumocystis jiroveci* *Trichomonas tenax*	*Balamuthia* amebic encephalitis *Pneumocystis* pneumonia Pulmonary trichomoniasis
Muscosal Membranes Ears, Eyes, Nose Genitals	*Acanthamoeba* spp. *Naegleria fowleri* *Trichomonas vaginalis*	Amebic meningoencephalitis Amebic meningoencephalitis Trichomoniasis
Skin	*Leishmania braziliensis* *Leishmania donovani* *Leishmania tropica*	Mucocutaneous leishmaniasis Visceral leishmaniasis Cutaneous leishmaniasis

Table 40.3 Water-Based Protozoan Reservoirs

Organism	Reservoir	Comments
Acanthamoeba spp.	Sewage sludge disposal areas	Can cause granulomatous amebic encephalitis, keratitis, corneal ulcers
Cryptosporidium spp.	Many species of domestic and wild animals	Causes acute enterocolitis; important with immunologically compromised individuals; cysts resistant to chemical disinfection; not antibiotic sensitive
Cyclospora cayetanensis	Waters—does not withstand drying; possibly other reservoirs	Causes long-lasting (43 days average) diarrheal illness; infection self-limiting in immunocompetent hosts; sensitive to prompt treatment with sulfonamide and trimethoprim
Giardia intestinalis	Beavers, sheep, dogs, cats	Major cause of early spring diarrhea; important in cold mountain water
Naegleria fowleri	Warm water (hot tubs), swimming pools, lakes	Inhalation in nasal passages; central nervous system infection; causes primary amebic meningoencephalitis

There is also an increasing problem with *Cryptosporidium* and *Cyclospora* contamination of food and water supplies (**table 40.3**). More of our population is elderly, and a growing number of persons are immunosuppressed due to HIV infection, organ transplantation, or cancer chemotherapy. These populations are at increased risk for protozoan infections. ⏮ *Protists (chapter 25)*

While seemingly different, fungi and protists share a number of phenotypic features that serve them in their ability to cause infection: microscopic size, eukaryotic physiology, cell walls or wall-like structures, alternative stages for survival outside of the host, degradative enzymes, and others. Some fungi and protists also share transmission routes. We now discuss diseases of fungi and protists based on how they are acquired by the human host.

40.2 Fungi Can Be Transmitted by Airborne Routes

After reading this section, you should be able to:

- Report the common fungal diseases spread by airborne transmission
- Identify typical signs and symptoms of common airborne fungal diseases

A number of eukaryotic pathogens are transmitted to people through air. These infectious agents are small particles that are carried by air currents and are typically inhaled by unsuspecting hosts. While it is unlikely to find human protozoan disease spread this way, protozoan-containing droplet particles can be

Figure 40.2 Systemic Mycosis: Blastomycosis. Blastomycosis of the hand caused by *Blastomyces dermatitidis*.

MICRO INQUIRY *What is the morphology of* B. dermatitidis *in the environment? In the human host?*

transmitted through the air. Here we present several examples of fungal infectious agents that are acquired through airborne transmission and the diseases they cause.

Blastomycosis

Blastomycosis is the systemic mycosis caused by *Blastomyces dermatitidis*, a fungus that grows as a budding yeast in humans but as a mold on culture media and in the environment. It is found predominately in moist soil enriched with decomposing organic debris, as in the Mississippi and Ohio river basins. *B. dermatitidis* is endemic in parts of the south-central, southeastern, and midwestern United States. Additionally, microfoci have been reported in Central and South America and in parts of Africa. The disease occurs in three clinical forms: cutaneous, pulmonary, and disseminated. The initial infection begins when blastospores are inhaled into the lungs. The fungus can then spread rapidly, especially to the skin, where cutaneous ulcers and abscess formation occur (**figure 40.2**). *B. dermatitidis* can be isolated from pus and biopsy sections. Diagnosis requires the demonstration of thick-walled, yeastlike cells 8 to 15 μm in diameter. Complement fixation, immunodiffusion, and skin tests (blastomycin) are also useful. Amphotericin B, itraconazole, and ketoconazole are the drugs of choice for treatment (*see figure 9.14*). Surgery may be necessary for the drainage of large abscesses. Mortality is about 5%. There are no preventive or control measures. ⏮ *Antifungal drugs (section 9.5)*

Coccidioidomycosis

Coccidioidomycosis, also known as valley fever, San Joaquin fever, or desert rheumatism because of the geographical distribution of the fungus, is caused by *Coccidioides immitis*. *C. immitis* thrives in the semiarid, highly alkaline soils of southwestern United States and parts of Mexico and South America. In the United States about 30,000 people are infected annually, resulting in approximately 200 deaths. Endemic areas have been defined by massive skin testing with the antigen coccidioidin, where upward of 15% positive cases are reported; endemic areas include Arizona, California, Nevada, New Mexico, and Utah. In these areas coccidiodomycosis causes up to 30% of community-acquired pneumonia. In the soil and on culture media, this fungus grows as a mold that forms arthroconidia at the tips of hyphae (*see figure 26.4*). Because arthroconidia are so abundant, immunocompromised individuals can acquire the disease by inhalation as they simply move through these endemic areas. Wind turbulence and even construction of outdoor structures have been associated with increased exposure and infection. In humans, the fungus grows as a thick-walled spherule filled with spores (**figure 40.3**). Most cases of coccidioidomycosis are asymptomatic or indistinguishable from ordinary upper respiratory infections. Most cases resolve in a few weeks, and lasting immunity results. A few infections result in progressive chronic pulmonary disease or disseminated infections of other tissues; the fungus can spread throughout the body, involving almost any organ or site.

Diagnosis is accomplished by identification of the large spherules (approximately 80 μm in diameter) in pus, sputum, and aspirates. Culturing clinical samples in the presence of penicillin and streptomycin on the fungal selective medium Sabouraud agar also is diagnostic. Rapid confirmation methods include testing supernatants of liquid cultures for antigens, serology, and skin testing. Miconazole, itraconazole, ketoconazole, and amphotericin B are the drugs of choice for treatment. Prevention involves reducing exposure to dust (soil) in endemic areas. ⏮ *Antifungal drugs (section 9.5); Identification of microorganisms from specimens (section 36.3)*

Cryptococcosis

Cryptococcosis is a systemic mycosis caused by *Cryptococcus gattii* and *C. neoformans*. These fungi grow as large, budding yeasts in the human host but as smaller yeast cells that undergo monokaryotic or dikaryotic reproduction in the environment, where they are saprophytes with a worldwide distribution. *C. gattii* is responsible for nearly all cryptococcal infections in humans, except where *C. neoformans* infects those with HIV. *C. gattii* disease (primarily pneumonia and meningitis) continues to be an emerging infectious disease in the United States. Worldwide, *C. gatti* kills 13 to 33% of infected individuals. Typically, cryptococci cause disease in the immunocompromised and often cause disease in people with AIDS, cancer, or a recent organ transplant. In fact, cryptococcosis is found in approximately 15% of AIDS patients.

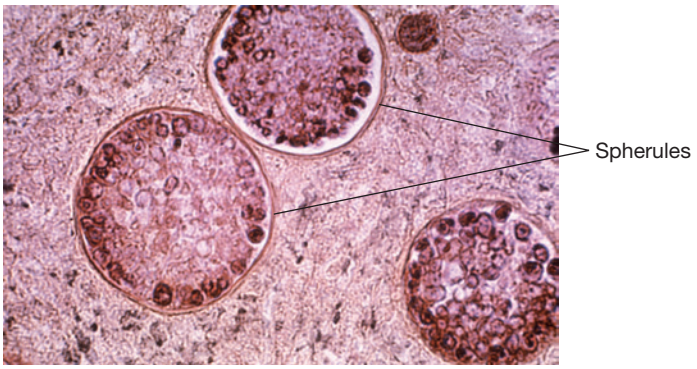

Figure 40.3 Systemic Mycosis: Coccidioidomycosis. *Coccidioides immitis* mature spherules filled with endospores within a tissue section; light micrograph (×400).

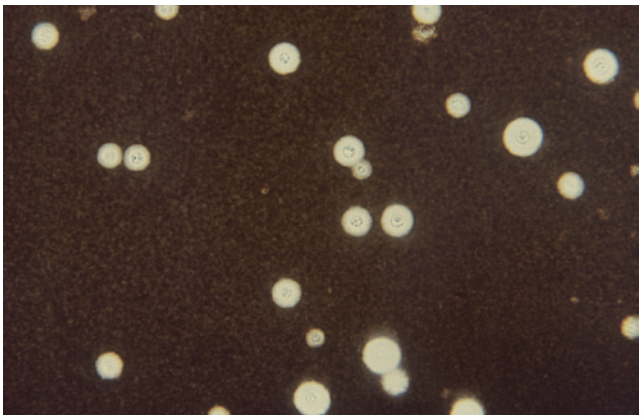

Figure 40.4 Systemic Mycosis: Cryptococcosis. India ink preparation showing *Cryptococcus neoformans*. Note the distinctly outlined capsules surrounding all cells and refractile inclusions in the cytoplasm; light micrograph (×150).

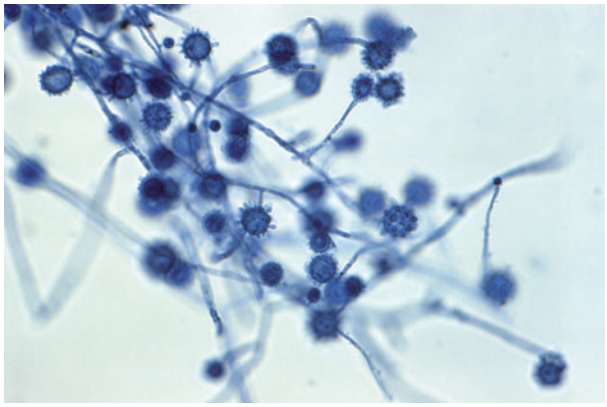
MICRO INQUIRY *Once this microbe is acquired by inhalation, to what other body systems can it spread?*

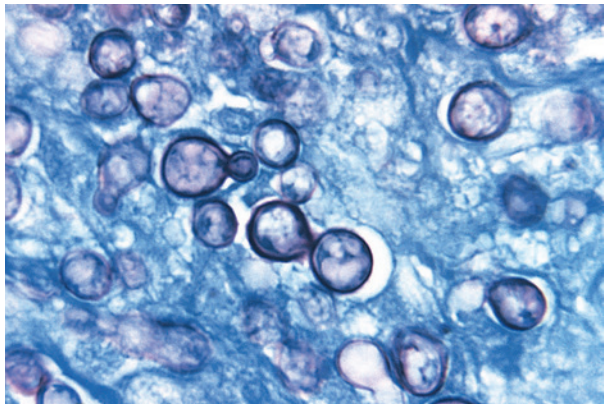
Aged, dried pigeon droppings are an apparent source of infection. The fungi enter the body by the respiratory tract, causing a minor pulmonary infection in most that is usually transitory. In others who inhale the fungi, a pneumonia-like disease with coughing and fever occurs. Some pulmonary infections spread to the skin, bones, viscera, and central nervous system, causing headaches and mental status changes. Once the nervous system is involved, cryptococcal meningitis usually results. Diagnosis is accomplished by detection of the thick-walled, spherical yeast cells in pus, sputum, or cerebral spinal fluid smears using India ink to define the organism (**figure 40.4**). The fungi can be easily cultured on Sabouraud dextrose agar. Identification of the fungus in body fluids is made by immunologic procedures. Treatment for *C. neoformans* includes amphotericin B often with flucytosine. HIV/AIDS patients with a history of infection are treated prophylactically with fluconazole. Prevention of infection with *C. neoformans* is through avoidance of birds and areas contaminated with bird droppings.

Histoplasmosis

Histoplasmosis is primarily a disease of the lungs caused by *Histoplasma capsulatum* var. *capsulatum*, a facultative, parasitic fungus that grows intracellularly. The incubation period for symptomatic patients is approximately 10 days; symptoms include flulike responses such as fever, cough, headaches, and muscle aches. However, infection is often asymptomatic. *H. capsulatum* is a small, budding yeast in humans and on culture media at 37°C (98.6°F). At 25°C (77°F) it grows as a mold, producing microconidia (1 to 5 μm in diameter) that are borne singly at the tips of short conidiophores (*see figure 26.4*). Large macroconidia (8 to 16 μm in diameter) are also formed on conidiophores (**figure 40.5*a***). In humans, the yeastlike form reproduces by budding (figure 40.5*b*). The mycelial form of the fungus is found in soil and is localized in areas that have been contaminated with bird or bat excrement. The microconidia can become airborne



(a)



(b)

Figure 40.5 Morphology of *Histoplasma capsulatum* var. *capsulatum*. (a) Mycelia, microconidia, and chlamydospores as found in the soil. These are the infectious particles; light micrograph (×400). (b) Yeastlike form of *H. capsulatum*.

when contaminated soil is disturbed. Microconidia are thus most prevalent where bird droppings—especially from starlings, crows, blackbirds, cowbirds, sea gulls, turkeys, and chickens—have accumulated. It is noteworthy that the birds themselves are not infected because of their high body temperature; their droppings simply provide the nutrients for this fungus. Only bats and humans demonstrate the disease and harbor the fungus.

Infection ensues when microconidia are inhaled. Histoplasmosis is found worldwide, with Africa, Australia, India, and Malaysia being endemic regions. Within the United States, histoplasmosis is endemic within the Mississippi, Kentucky, Tennessee, Ohio, and Rio Grande river basins. As many as 90% of people who reside these areas have antibodies against the fungus. It has been estimated that in endemic areas of the United States, about 500,000 individuals are infected annually: 50,000 to 200,000 become ill; 3,000 require hospitalization; and about 50 die. The total number of infected individuals may be over 40 million in the United States alone. Histoplasmosis is a common disease among poultry farmers, spelunkers (people who explore caves), and bat guano miners (bat guano is used as fertilizer).

Because *H. capsulatum* grows within macrophages, the fungus can be disseminated to many organs (though rarely) as the infected macrophages circulate throughout the body. Lesions may appear in the lungs and show calcification; thus, the disease may resemble tuberculosis. Most infections resolve spontaneously. Laboratory diagnosis is accomplished by complement fixation tests and isolation of the fungus from tissue specimens.

DISEASE

40.1 A Brief History of Malaria

No other single infectious disease has had the impact on humans that malaria has had. The first references to its periodic fever and chills can be found in early Chaldean, Chinese, and Hindu writings. In the late fifth century BCE, Hippocrates described certain aspects of malaria. In the fourth century BCE, the Greeks noted an association between individuals exposed to swamp environments and the subsequent development of periodic fever and enlargement of the spleen (splenomegaly). In the seventeenth century, the Italians named the disease *mal' aria* (bad air) because of its association with ill-smelling vapors from swamps near Rome. At about the same time, the bark of the quinaquina (cinchona) tree of South America was used to treat the intermittent fevers, although it was not until the mid-nineteenth century that quinine was identified as the active alkaloid. The major epidemiological breakthrough came in 1880, when French army surgeon Charles Louis Alphonse Laveran observed gametocytes in fresh blood. Five years later, the Italian histologist Camillo Golgi observed the multiplication of the asexual blood forms. In the late 1890s, Patrick Manson postulated that malaria was transmitted by mosquitoes. Sir Ronald Ross, a British army surgeon in the Indian Medical Service, subsequently observed developing plasmodia in the intestine of mosquitoes, supporting Manson's theory. Using birds as experimental models, Ross definitively established the major features of the life cycle of plasmodia and received the Nobel Prize in 1902.

Human malaria is known to have contributed to the fall of the ancient Greek and Roman empires. Troops in both the U.S. Civil War and the Spanish-American War also were severely incapacitated by the disease. More than 25% of all hospital admissions during these wars were malaria patients. During World War II, malaria epidemics severely threatened both the Japanese and Allied forces in the Pacific. The same can be said for the military conflicts in Korea and Vietnam.

In the twentieth century, efforts were directed toward understanding the biochemistry and physiology of malaria, controlling the mosquito vector, and developing antimalarial drugs. In the 1960s it was demonstrated that resistance to *P. falciparum* among West Africans was associated with the presence of hemoglobin-S (Hb-S) in their erythrocytes. Hb-S differs from normal hemoglobin-A by a single amino acid, valine, in each half of the Hb molecule. Consequently these erythrocytes—responsible for sickle cell disease—have a low binding capacity for oxygen. Because the malarial parasite has a very active aerobic metabolism, it cannot grow and reproduce within these erythrocytes.

In 1955 the World Health Organization began a worldwide malarial eradication program that collapsed by 1976. Among the major reasons for failure were the development of resistance to the insecticide DDT by mosquitoes and the development of resistance to chloroquine by strains of *Plasmodium*. Scientists are exploring new approaches, such as the development of vaccines and more potent drugs. In 2002 the complete DNA sequences of *P. falciparum* and *Anopheles gambiae* (the mosquito that most efficiently transmits this parasite to humans in Africa) were determined. Together with the human genome sequence, researchers now have in hand the genetic blueprints for the parasite, its vector, and its victim. This has made possible a holistic approach to understanding how the parasite interacts with the human host, leading to new antimalarial strategies, including vaccine design. Overall, no greater achievement for microbiology could be imagined than the control of malaria—a disease that has caused untold misery throughout the world since antiquity and remains one of the world's most serious infectious diseases.

Most individuals with this disease exhibit a hypersensitive state that can be demonstrated by the histoplasmin skin test. Currently the most effective treatment is with amphotericin B, ketoconazole, or itraconazole. Prevention and control involve wearing protective clothing and masks before entering or working in infested habitats. Soil decontamination with 3 to 5% formalin is effective where economically and physically feasible.

40.3 Arthropods Can Transmit Protozoal Disease

After reading this section, you should be able to:

- Report the common protist diseases spread by arthropod transmission
- Identify typical signs and symptoms of arthropod-borne protist diseases
- Correlate arthropod-borne protist infection and disease severity with protist virulence factors

Biting insects, fleas, ticks, and mites can harbor microorganisms that can be subsequently passed to humans. In some cases the arthropod vector is a transient or accidental carrier of the organism, as is the case with fungal diseases that result from passage of spores by flying and crawling insects. In other cases, the vector is an intermediate host in which the microorganism undergoes developmental changes. We discuss viral and bacterial diseases transmitted by arthropods in chapters 38 and 39, respectively. This section discusses several examples of protozoan diseases transmitted by insects.

Malaria

The most important human protozoal pathogens belong to the genus *Plasmodium* and are the causative agents of **malaria** (**Disease 40.1**). A 2014 World Health Organization (WHO) report estimates that there are 3.2 billion people (almost half of the world's population) at risk for malaria. In 2013 there were 198 million people infected worldwide (**figure 40.6**). Although

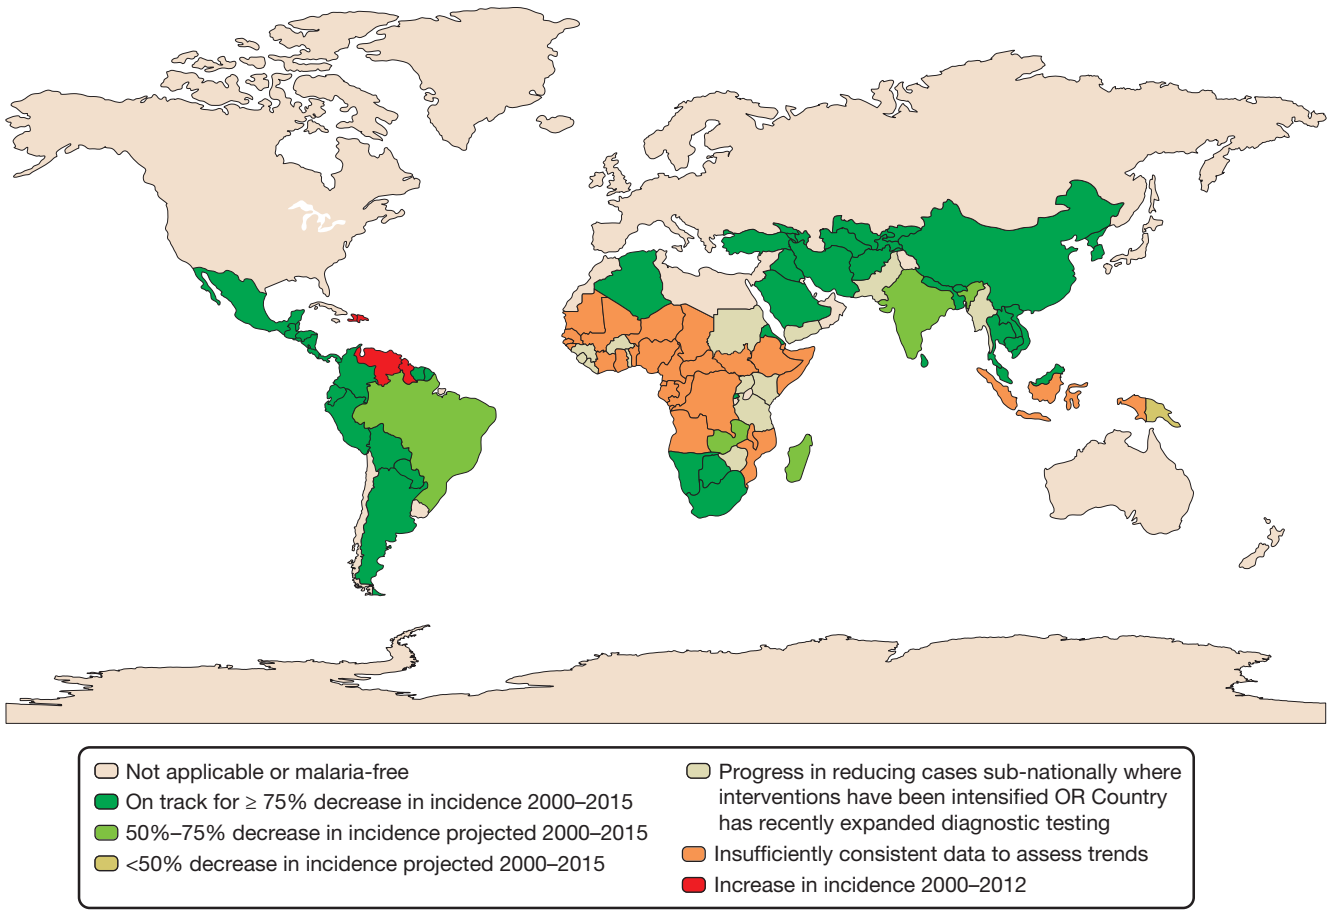


Figure 40.6 **Geographic Distribution of Malaria in 2014.** A country is listed as malaria-endemic if malaria was reported in even a small area of it.

mortality rates have fallen by more than 47% since 2000, 584,000 people died of malaria in 2013; 90% of those deaths were children under the age of five. Indeed, 22% of all childhood deaths in Africa are due to malaria, where about one child dies of malaria every minute. About 1,600 cases are reported each year in the United States, divided between returning U.S. travelers and non-U.S. citizens.

Human malaria is caused by five species of *Plasmodium: P. falciparum, P. malariae, P. vivax*, *P. knowlesi*, and *P. ovale*. The life cycle of plasmodial protists is shown in **figure 40.7**. The parasite first enters the bloodstream through the bite of an infected female *Anopheles* mosquito. As she feeds, the mosquito injects a small amount of saliva containing an anticoagulant along with small haploid sporozoites. The sporozoites in the bloodstream immediately enter hepatic cells of the liver. There they undergo multiple asexual fission (schizogony) and produce merozoites. After being released from hepatocytes, merozoites attach to and penetrate erythrocytes. The incubation period is as short as 7 days (frequently due to *P. falciparum*) and as long as 30 days (usually due to *P. malariae*). ◀◀ Alveolata *(section 25.4)*

Once inside the erythrocyte, the plasmodial cell begins to enlarge as a mononucleate cell termed a trophozoite. The trophozoite's nucleus divides asexually to produce a schizont that has 6 to 24 nuclei. The schizont divides and produces mononucleated merozoites that are released when infected erythrocytes lyse. These then infect other erythrocytes. This erythrocytic stage is cyclic and repeats approximately every 48 to 72 hours or longer, depending on the species of *Plasmodium* involved. The sudden release of merozoites, toxins, and erythrocyte debris into the bloodstream triggers an attack of the chills, fever, and sweats characteristic of malaria. Occasionally, merozoites differentiate into macrogametocytes and microgametocytes, which do not rupture the erythrocyte. When these are ingested by a mosquito during a blood meal, they develop into female and male gametes, respectively. In the mosquito's gut, the infected erythrocytes lyse and the gametes fuse to form a diploid zygote called the ookinete. The ookinete migrates to the mosquito's gut wall, penetrates, and forms an oocyst. In a process called sporogony, the oocyst undergoes meiosis and forms sporozoites, which migrate to the salivary glands of the mosquito. The cycle is now complete, and when the mosquito bites another human host, the cycle begins anew.

The pathological changes caused by malaria involve not only erythrocytes but also the spleen and other organs. Classic symptoms first develop with the synchronized release of merozoites and erythrocyte debris into the bloodstream, resulting in

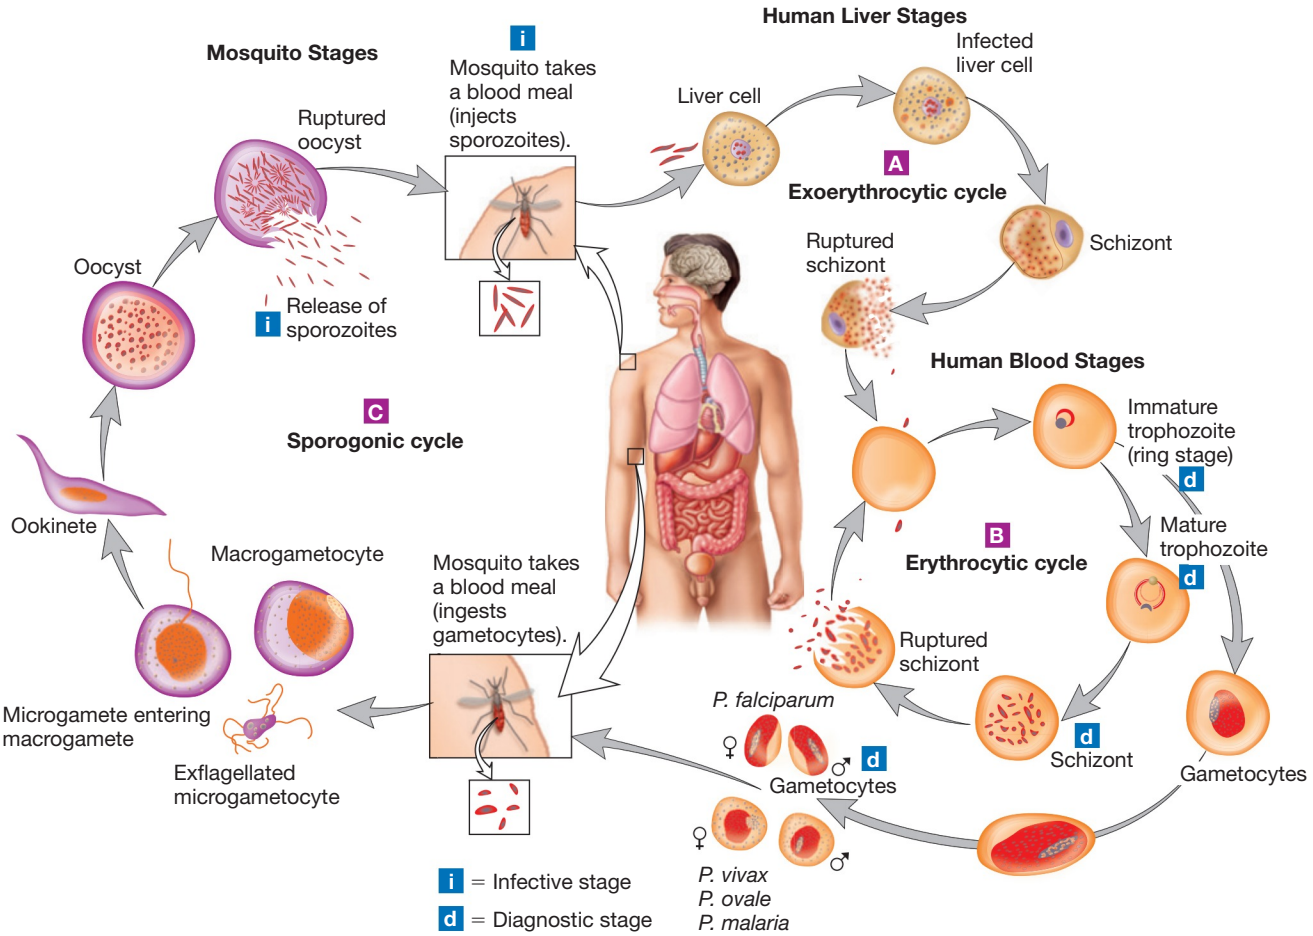

Figure 40.7 Malaria. Life cycle of *Plasmodium vivax*. Note the (A) exoerythrocytic cycle, (B) the erythrocytic cycle, and (C) the sporogonic cycle.

MICRO INQUIRY *How is a schizont formed? What is the cell type that is released from erythrocytes, and where does the protist go next?*

the malarial paroxysms—shaking chills, then burning fever followed by sweating. It may be that the fever and chills are caused partly by a malarial toxin that induces macrophages to release the cytokines TNF-α and interleukin-1; interleukin-1 is a well defined inducer of fever. Several of these paroxysms constitute an attack. If *P. vivax* or *P. ovale* are the causative agents, there is a remission that lasts from a few weeks to several months while dormant protozoa called hypnozooites reside in the liver. This is followed by a relapse. Between paroxysms, the patient feels normal. Anemia can result from the loss of erythrocytes, and the spleen and liver often become enlarged. Children and nonimmune individuals often die of cerebral malaria. ⏮ *Cytokines are chemical messages between cells (section 33.3)*

Diagnosis of malaria is made by demonstrating the presence of parasites within Wright- or Giemsa-stained erythrocytes (**figure 40.8**). When blood smears are negative, serological testing can establish a diagnosis of malaria. Outside the United States, rapid diagnostic tests using species-specific antibodies

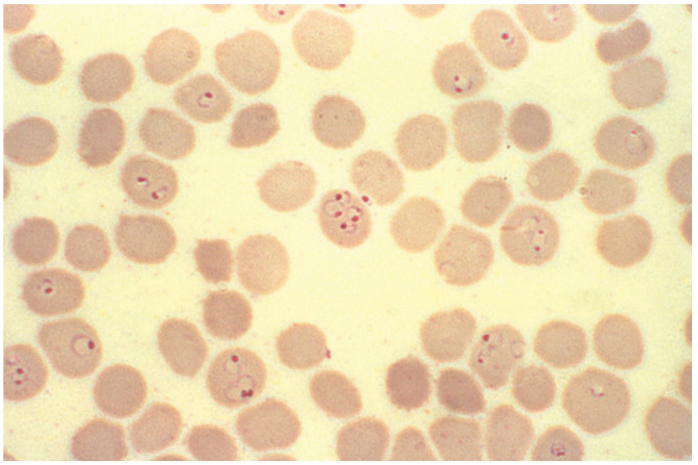

Figure 40.8 Malaria: Erythrocytic Cycle. Trophozoites of *P. falciparum* in circulating erythrocytes; light micrograph (×1,100). The young trophozoites resemble small rings within the erythrocyte cytoplasm.

are commonly used to diagnose malaria; only one of these tests is approved for use by the U.S. Food and Drug Administration (FDA). Also, PCR-based malarial identification and drug resistance testing is available through reference labs. ⏮ *Identification of microorganisms from specimens (section 36.3)*

Specific recommendations for treatment are malaria-region-dependent and include administration of chloroquine, amodiaquine, or mefloquine. In the regions where *P. falciparum* predominates, artemisinin is used for treatment. In fact, artemisinin-based combination therapy (ACT)—combining artemisinin with an antimalarial drug having a different mechanism—is recommended for the treatment of all *P. falciparum* malaria. Implementation of the recommendation has been cost-prohibitive in many regions, but most countries are now starting to adopt this regimen. Artemisinin is not yet approved in the United States, however. These drugs suppress protozoan reproduction and are effective in eradicating erythrocytic asexual stages. Primaquine has proved satisfactory in eradicating the exoerythrocytic stages including hypnozooites. However, because resistance to these drugs is occurring rapidly, more expensive drug combinations are now being used. One example is Fansidar, a combination of pyrimethamine and sulfadoxine. It is worth noting that individuals who are traveling to areas where malaria is endemic (figure 40.6) should receive chemoprophylactic treatment with chloroquine, atovaquone/proguanil, or primaquine.

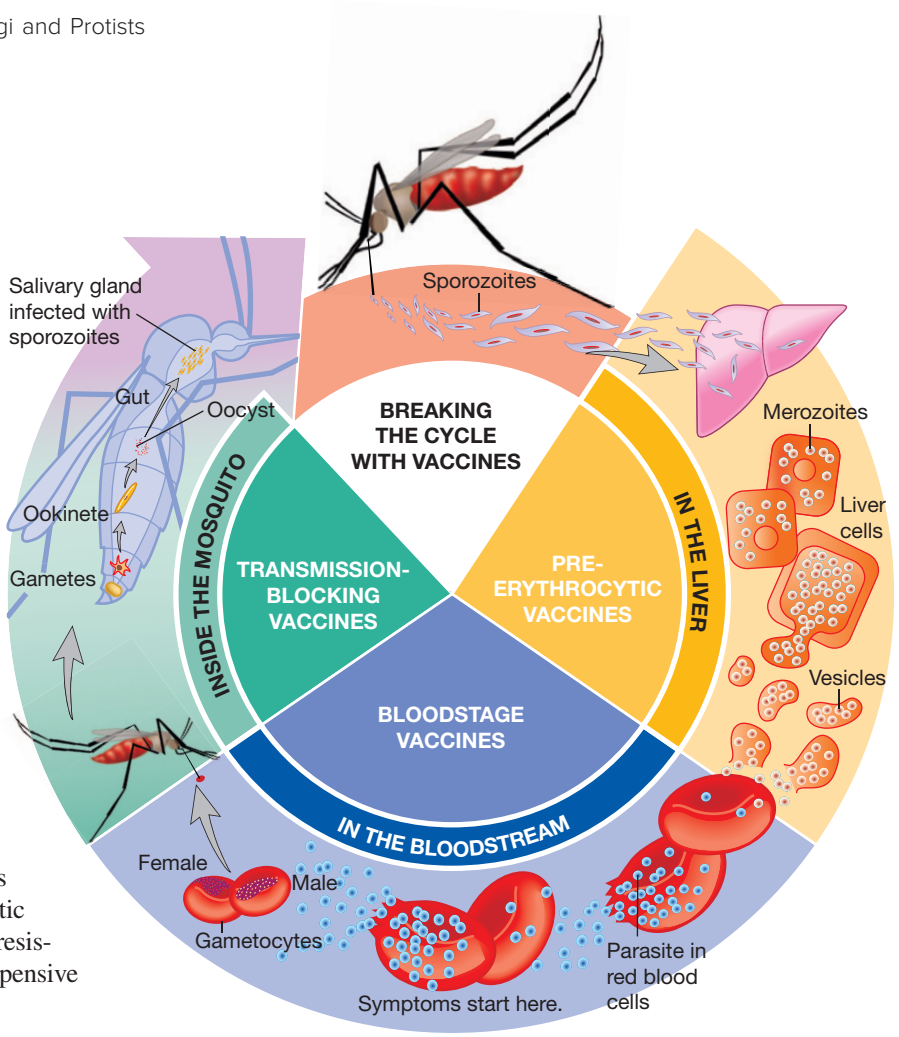

Figure 40.9 Malaria Vaccine Strategies.

MICRO INQUIRY *What is currently the most effective strategy to prevent malaria?*

Control of malaria has been a nagging problem for some time. The ideal approach would be to vaccinate all young children in endemic areas. However, to be effective, a vaccine must interfere with a critical malarial component or process (**figure 40.9**). A number of credible vaccines against malaria have been in clinical trials since 2005. A 2014 report of clinical trials indicated that the pre-erythrocytic, recombinant vaccine Mosquiix, reduced the rates of malaria infection in children by 50% and by 25% in infants. However, until a vaccine that can provide 90 to 95% effectiveness is approved for use, malaria prevention is still best attempted with the use of bed netting and insecticides. ⏮ *Vaccines immunize susceptible populations (section 37.7)*

Leishmaniasis

Leishmanias are flagellated protists that cause a group of several human diseases collectively called **leishmaniasis.** The most common forms of leishmaniasis are cutaneous (skin associated ulcers that heal), diffuse cutaneous (disseminated and chronic skin lesions), mucocutaneous (ulcers of the skin, mouth, nose, and throat), and visceral (affecting liver, spleen, and blood). Co-infection with HIV increases the severity of disease. Worldwide, leishmaniasis is a disease of poverty associated with malnutrition, displacement, poor housing, and discrimination. There are 1.3 million new cases of the cutaneous disease and 400,000 cases of the visceral disease (also called kala-azar) diagnosed around the globe each year. One-tenth of the world's population is at risk of infection; more than 90% of cutaneous disease cases occur in parts of Afghanistan, Algeria, Iran, and the Syrian Arab Republic, as well as Brazil and Colombia, and more than 90% of visceral disease cases occur in parts of Bangladesh, Ethiopia, Sudan, South Sudan, India, and Brazil. About 30,000 people die from leishmaniasis each year, and many more are permanently disfigured (**figure 40.10**).

The primary reservoirs of these parasites are canines and rodents. All species of *Leishmania* use female sand flies such as those of the genera *Lutzomyia* and *Phlebotomus* as intermediate hosts. Sand flies are about one-third the size of a mosquito, so they are hard to see and hear. The leishmanias are transmitted from animals to humans or between humans by sand flies. When an infected sand fly takes a human blood meal, it introduces flagellated promastigotes into the skin of

(a) (b)

Figure 40.10 Leishmaniasis. (a) A person with mucocutaneous leishmaniasis, which has destroyed the nasal septum and deformed the nose and lips. (b) A person with diffuse cutaneous leishmaniasis.

MICRO INQUIRY *What is the primary reservoir of leishmanias? What is the intermediate host?*

the definitive (human) host (**figure 40.11**). Within the skin, the promastigotes are engulfed by macrophages, multiply by binary fission, and form small, nonmotile cells called amastigotes. These destroy the host cell and are engulfed by other macrophages in which they continue to develop and multiply. ⏮ Euglenozoa *(section 25.2)*

A number of species of *Leishmania* are human pathogens. *L. mexicana* is found in the Yucatan Peninsula (Mexico) and has been reported as far north as Texas. In this disease, a relatively small, red papule forms at the site of each insect bite—the inoculation site. These papules are frequently found on the face and ears. They eventually develop into crustated ulcers (figure 40.10*b*). Healing

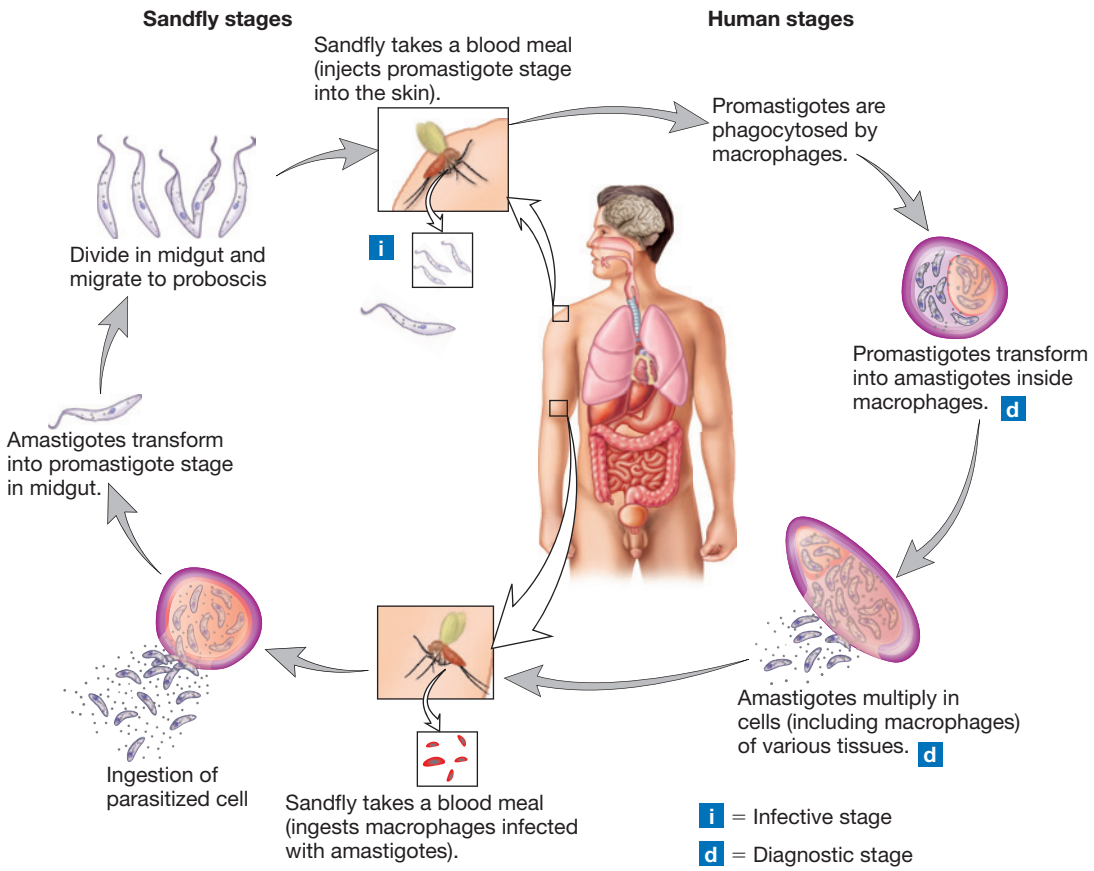

Figure 40.11 ***Leishmania*** **spp. life cycle.** Note the promastigote-to-amastigote cycle.

occurs with scarring and a permanent immunity. *L. donovani* is endemic in large areas within northern China, eastern India, the Sudan, Mediterranean countries, and Latin America. Infection with *L. donovani* results in visceral disease as infected macrophages lodge in various organs where the ongoing cycle of macrophage capture of promastigotes, amastigote development, macrophage death, and amastigote release damages host organs and tissues.

Laboratory diagnosis of leishmaniasis is based on finding the protist within infected macrophages in stained smears from lesions or infected organs. Blood smears and serological tests are also available for diagnosis. Treatment includes pentavalent antimicrobial compounds (e.g., meglumine antimoniate), paromomycin, and liposomal amphotericin B. Vector and reservoir control, and aggressive epidemiological surveillance are the best options for prevention and containment of this disease. As of 2015, there were no approved vaccines against leishmaniasis, although one experimental vaccine induces a 30% skin-positive reaction that appears to be associated with decreased visceral leishmaniasis.

Trypanosomiasis

Another group of flagellated protists called **trypanosomes** cause the aggregate of diseases termed Human African **Trypanosomiasis** (HAT). HAT is also known as African sleeping sickness. There are two forms of HAT, each referring to the subspecies of trypanosome causing the disease. Gambiense HAT is caused by *Trypanosoma brucei* subspecies *gambiense*, which is distributed over western and central countries and causes over 95% of reported cases. The remaining cases (rhodesiense HAT) are caused by *T. brucei* subspecies *rhodesiense*, found in the upland savannas of eastern and southern Africa. Reservoirs for these trypanosomes are domestic cattle and wild animals, within which they cause severe malnutrition. Both species use tsetse flies (genus *Glossina*) as intermediate hosts.

Trypanosomiasis is such a problem in parts of Africa that millions of hectares are not fit for human habitation. New cases of HAT have been declining since 2009, with approximately 7,000 reported to WHO annually. However, it is likely that the majority of cases are not reported due to the lack of public health infrastructure in endemic regions. As a result, more than 20,000 new cases per year are likely, among an estimated 70 million people at risk.

The parasites are transmitted to humans by the bite of the fly (**figure 40.12**; *also see figure 25.6*). The protists pass through the lymphatic system, enter the bloodstream, and replicate by binary fission as they pass to other body fluids. The tsetse fly bite is painful and can develop into a chancre. Patients may exhibit

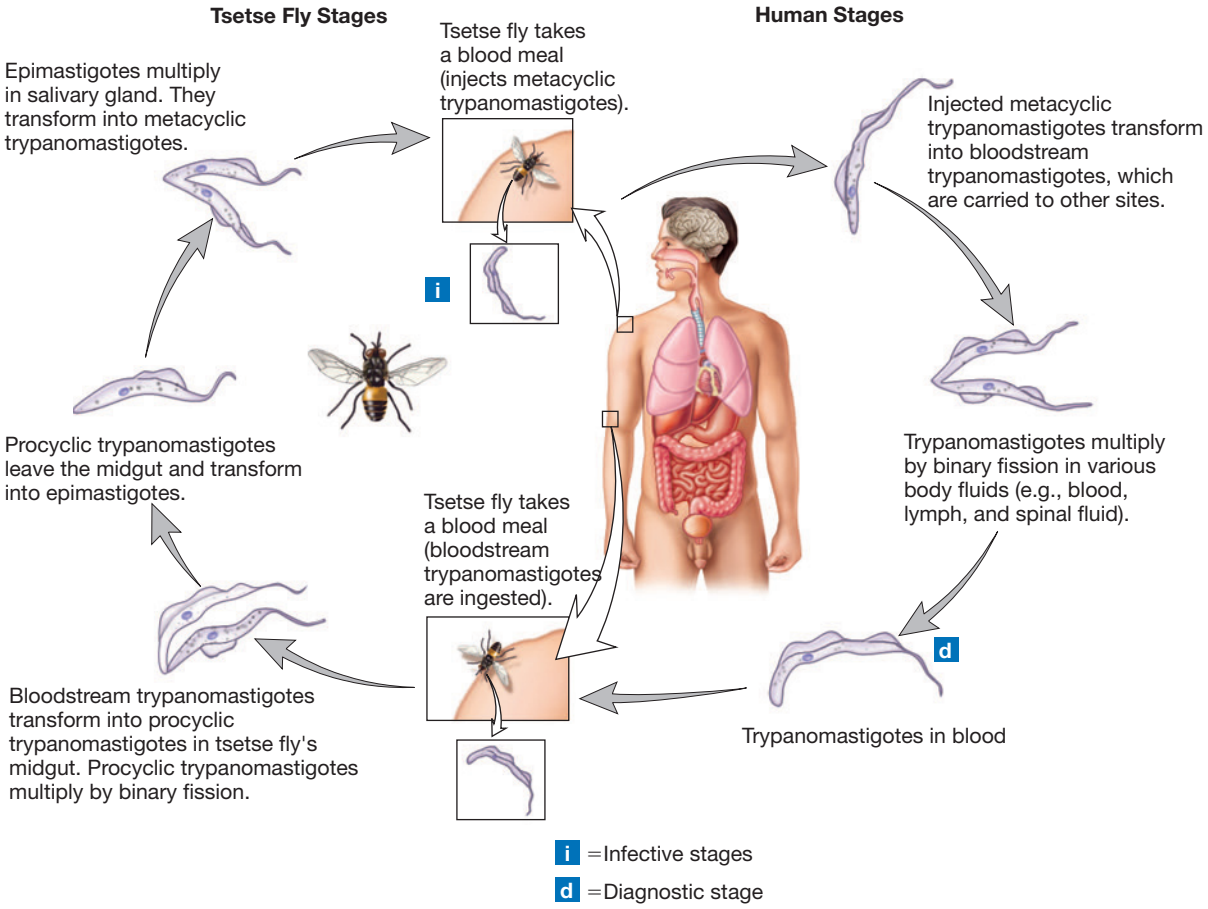

Figure 40.12 Life Cycle of *Trypanosoma brucei*.

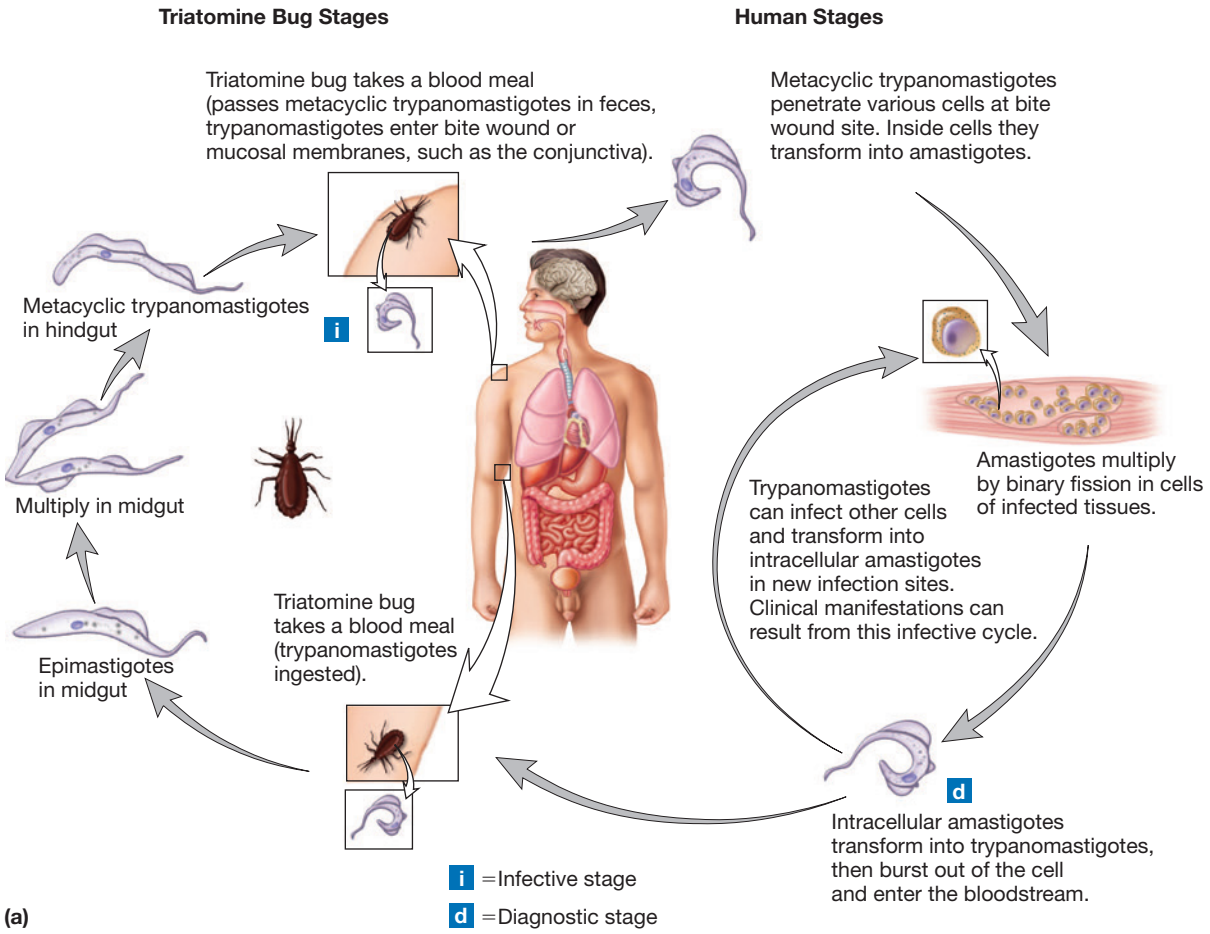

(b)

Figure 40.13 ***Trypanosoma cruzi* Infection.** (a) *T. cruzi* life cycle. (b) The triatomine bug.

symptoms of fever, severe headaches, extreme fatigue, muscle and joint aches, irritability, and swollen lymph nodes. Some patients develop a skin rash. The disease gets its name from the fact that patients exhibit lethargy—characteristically lying prostrate, drooling from the mouth, and insensitive to pain; they also exhibit progressive confusion, slurred speech, seizures, and personality changes. The protists cause interstitial inflammation and necrosis within the lymph nodes and small blood vessels of the brain and heart. Rhodesiense HAT develops so rapidly that infected individuals often die within a year. *T. brucei* subspecies *gambiense* causes necrotic damage within the central nervous system that leads to a variety of nervous disorders, including the characteristic sleeping sickness. Sleeping sickness is curable with medication; it is otherwise fatal within 2 to 3 years.

T. cruzi causes **American trypanosomiasis** (**Chagas' disease**), which occurs in the tropics and subtropics of the continental Americas (southern United States, Central America and northern South America). The parasite uses the triatomine (kissing) bug as a vector (**figure 40.13**). As the triatomine bug takes a blood meal, protists are discharged in the insect's feces, which contain an irritant that stimulates the victim to scratch. This enables trypanosomes to enter the bloodstream and invade the liver, spleen, lymph nodes, and central nervous system; disease occurs immediately after infection, lasting weeks or months (acute phase). Cell invasion stimulates the trypanosome's transformation into amastigotes, resulting in clinical manifestations of infection. The bloodstream trypanomastigotes do not replicate, however, until they enter a cell (becoming amastigotes) or are

ingested by the arthropod vector (becoming epimastigotes). A chronic indeterminate (asymptomatic) phase of the disease follows the acute phase. During this phase, a high percentage of heart and gastrointestinal disease occurs due to parasitized cardiac and intestinal cells, respectively. There are approximately 8 million infected people globally, with 28,000 new cases per year and 12,000 annual deaths.

Trypanosomiasis is diagnosed by finding motile protists in fresh blood, spinal fluid, or skin biopsy and by serological testing. Treatment depends on the infecting trypanosome species and the stage of infection. Pentamidine isethionate and suramin are used to treat the hemolymphatic stages of HAT. Melarsoprol is used to treat late disease with central nervous system involvement caused by both trypanosomes. Benznidazole or nifurtimox are used to treat Chagas' disease, but effectiveness is best when administered during the acute phase of infection. Vaccines are not useful because the parasite is able to change its protein coat **(antigenic variation)** to evade the immunologic response.

40.4 Direct Contact Diseases Can Be Caused by Fungi and Protists

After reading this section, you should be able to:

- Report the common fungal and protist diseases spread by direct contact
- Identify typical signs and symptoms of fungal and protist diseases spread by direct contact
- Correlate direct contact fungal infection and disease severity with fungal virulence factors
- Correlate direct contact protist infection and disease severity with protist virulence factors

Transmission of eukaryotic pathogens by direct contact results in a number of infectious diseases of the skin and reproductive organs. The direct contact diseases caused by fungi can be classified by their penetration into the host; superficial, cutaneous, and subcutaneous fungal infections are known. Diseases caused by protists can occur through hand-to-mouth/nose exchange, as well as their transfer through body fluids. We discuss the fungal pathogens first and then protist pathogens.

Fungal Pathogens

Fungi responsible for infections limited to the outer surface of hair and skin cause superficial mycoses. Superficial mycoses are extremely rare in the United States; most occur in the tropics. The fungi that cause these diseases remain above the basement membrane of skin, consuming keratin as their primary carbon source. Infections of the hair shaft are collectively called **piedras** (Spanish for stone because they are associated with the hard nodules formed by mycelia on the hair shaft). For example, black piedra is caused by *Piedraia hortae* and forms hard, black nodules on the hairs of the scalp. White piedra is caused by the yeast *Trichosporon beigelii* and forms light-colored nodules on the beard and mustache. Some superficial mycoses are called **tineas** (Latin for grub, larva, worm); the specific type is designated by a modifying term. Tineas involve the outer layers of the skin, nails, and hair. Tinea versicolor is caused by the yeast *Malassezia furfur,* which forms brownish-red scales on the skin of the trunk, neck, face, and arms. Treatment involves removal of the skin scales with a cleansing agent and removal of the infected hairs. Good personal hygiene prevents these infections.

Tinea barbae (Latin *barba*, the beard) is an infection of beard hair caused by *Trichophyton mentagrophytes* or *T. verrucosum*. It is predominantly a disease of men who live in rural areas and acquire the fungus from infected animals. Tinea capitis (Latin *capita*, the head) is an infection of the scalp hair (**figure 40.14*a***). It is characterized by hair loss, inflammation, and scaling. Tinea capitis is primarily a childhood disease caused by *Trichophyton* or *Microsporum* species. Person-to-person transmission of the fungus occurs frequently when poor hygiene and overcrowded conditions exist. The fungus also occurs in domestic animals, which can transmit it to humans. A Wood's lamp (an ultraviolet [UV] light) can help with the diagnosis of tinea capitis because fungus-infected hair fluoresces when illuminated by UV radiation (figure 40.14*b*).

Other fungi can infect skin cells; they cause diseases known as cutaneous mycoses. Cutaneous mycoses—also called **dermatomycoses, ringworms,** or tineas—occur worldwide and represent the most common fungal diseases in humans. Members of three genera of cutaneous fungi, or dermatophytes, are involved in these mycoses: *Epidermophyton, Microsporum*, and *Trichophyton*. Diagnosis is by microscopic examination of biopsied areas of the skin cleared with 10% potassium hydroxide and by culture on Sabouraud dextrose agar. Treatment is with topical ointments such as miconazole, tolnaftate, or clotrimazole for 2 to 4 weeks. Griseofulvin and itraconazole are the only agents proven to be effective in treating dermatophytoses. Infections by dermatophytes may be insidious; the desquamated (shed) skin cells can contain viable fungi for months or years. Thus any treatment plan should also include thorough cleaning of bedding, carpets, and any other substrates that could hold desquamated skin cells.

MICRO INQUIRY *What is the difference between a piedra and a tinea? Which is shown here?*

Tinea corporis (Latin *corpus*, the body) is a dermatophytic infection that can occur on any part of the skin (**figure 40.15*a***). The disease is characterized by circular, red, well-demarcated, scaly, vesiculopustular lesions accompanied by itching. Tinea corporis is caused by *Trichophyton rubrum, T. mentagrophytes, T. concentricum,* or *Microsporum canis*. Fungi are transmitted by direct contact with infected animals and humans or by indirect contact through fomites (inanimate objects).

Tinea pedis (Latin *pes*, the foot), also known as athlete's foot, and tinea manuum (Latin *mannus*, the hand) are dermatophytic infections of the feet (figure 40.15*b*) and hands, respectively. Clinical symptoms vary from a fine scale to a pimplelike eruption. Itching is frequently present. Warmth, humidity, trauma, and occlusion increase susceptibility to infection. Most

(c)

Figure 40.15 Cutaneous Mycosis. (a) Tinea corporis. Ringworm of the body (shoulder) caused by *Trichophyton concentricum*. (b) Tinea pedis caused by *Trichophyton rubrum*. (c) Tinea unguium of the nails caused by *Trichophyton rubrum*.

infections are caused by *T. rubrum, T. mentagrophytes*, or *E. floccosum*. Tinea pedis and tinea manuum occur throughout the world, are most commonly found in adults, and increase in frequency with age.

Tinea unguium (Latin *unguis*, nail) is a dermatophytic infection of the nail bed (figure 40.15*c*). In this disease, the nail becomes discolored and then thickens. The nail plate rises and separates from the nail bed. *Trichophyton rubrum* or *T. mentagrophytes* is the causative fungus.

The dermatophytes that infect underneath the skin cause subcutaneous mycoses, such as sporotrichosis, chromoblastomycosis, and maduromycosis. These fungi are normally saprophytic inhabitants of soil and decaying vegetation. Because they are unable to penetrate the skin, they must be introduced into the subcutaneous tissue by a puncture wound. Most infections involve barefooted agricultural workers. Once in the subcutaneous tissue, the disease develops slowly—often over a period of years. During this time, the fungi produce a nodule that eventually ulcerates, and the organisms spread along lymphatic channels, producing more subcutaneous nodules. At times, the nodules drain to the skin surface. Griseofulvin, terbinafine, itraconazole, and fluconazole are common therapeutic options. The administration of oral 5-fluorocytosine, iodides, or amphotericin B, and surgical excision may be used for stubborn infections. Diagnosis is accomplished by culture of the infected tissue.

Sporotrichosis is the subcutaneous mycosis caused by the dimorphic fungus *Sporothrix schenckii*. The disease occurs throughout the world and is the most common subcutaneous mycotic disease in the United States. The fungus can be found in the soil; on living plants, such as barberry shrubs and roses; or in plant debris, such as sphagnum moss, baled hay, and pine-bark mulch. Infection occurs by a puncture wound from a thorn or splinter contaminated with the fungus. The disease is an occupational hazard for florists, gardeners, and forestry workers. It is not spread from person to person. After an incubation period of 1 to 12 weeks, a small, red papule arises and begins to ulcerate (**figure 40.16**). New lesions appear along lymph channels and can remain localized or spread throughout the body, producing extracutaneous sporotrichosis.

Sporotrichosis is typically treated by oral itraconazole for 3 to 6 months. Systemic or severe disease is treated with a lipid formulation of amphotericin B or ingestion of supersaturated potassium iodide until the lesions are healed, usually over several weeks. Preventative measures include gloves and other protective clothing, as well as avoidance of contaminated landscaping materials, especially sphagnum moss.

Chromoblastomycosis, a disease in which dark brown nodules are formed, is caused by the black molds *Phialophora verrucosa* and *Fonsecaea pedrosoi*. These fungi exist worldwide, especially in tropical and subtropical regions. Most infections involve the legs and feet (**figure 40.17**). **Maduromycosis** is caused by *Madurella mycetomatis*, which is distributed worldwide and is especially prevalent in the tropics. Because the fungus destroys subcutaneous tissue and produces serious deformities, the resulting infection is often called a **eumycotic mycetoma,** or fungal tumor. One form of mycetoma, known as Madura foot, occurs through skin abrasions acquired while walking barefoot on contaminated soil.

Protist Pathogens

Very few human pathogenic protists are transmitted through direct contact. Thus we only discuss one such disease, trichomoniasis.

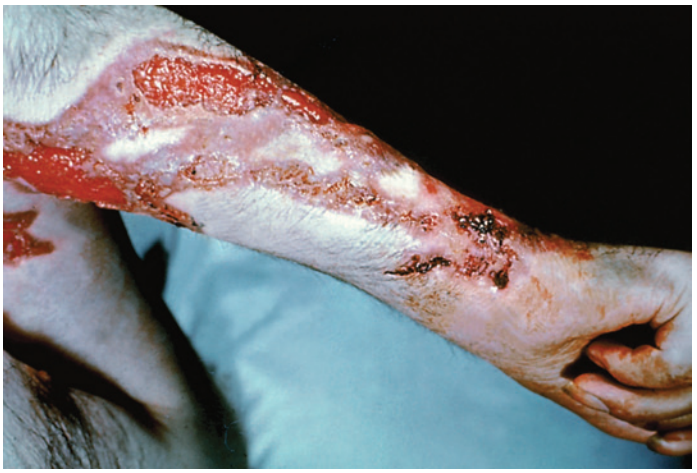

Figure 40.16 Subcutaneous Mycosis: Sporotrichosis. Sporotrichosis of the arm caused by *Sporothrix schenckii.*

MICRO INQUIRY *How do fungi causing subcutaneous mycoses gain access to tissue below the skin surface?*

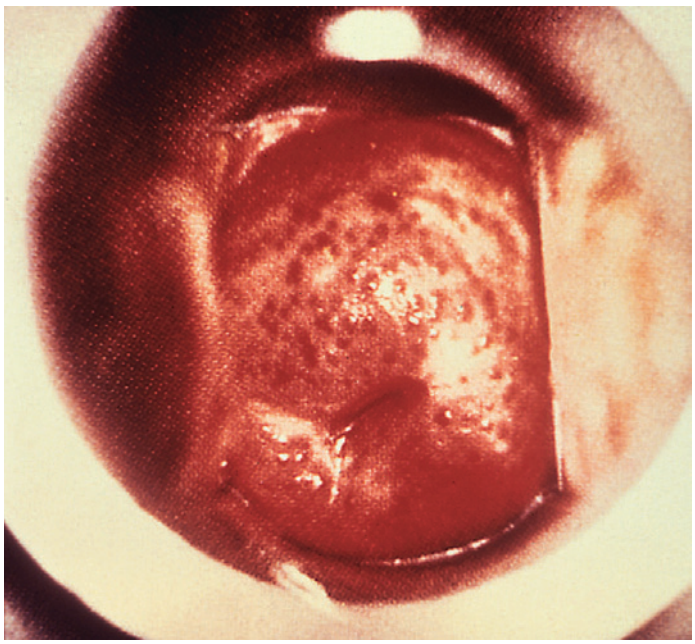

Figure 40.18 Trichomoniasis. *Trichomonas vaginalis* infection of the cervix causing hemorrhages, papules, and vesicles ("strawberry cervix").

Trichomoniasis is a sexually transmitted disease caused by the protozoan flagellate *Trichomonas vaginalis* (*see figure 25.4*). Humans are the only known host of *T. vaginalis*. Infection with this protist is often found with other sexually transmitted infections (STIs) and may increase the risk of acquiring other STIs. It is one of the most common STIs, with an estimated 2.3 million cases (women aged 14–49) annually in the United States and 160 million cases annually worldwide. In response to the protist, the body accumulates leukocytes at the site of infection. In females, this usually results in a profuse, purulent vaginal discharge that is yellowish to light cream in color and characterized by a disagreeable odor. The discharge is accompanied by itching. The cervical mucosa is covered with punctate hemorrhages, papules, and vesicles, referred to as "strawberry cervix" (**figure 40.18**). Males are generally asymptomatic because of the trichomonacidal action of prostatic secretions; however, at times a burning sensation occurs during urination. Diagnosis is made in females by microscopic identification of the protozoan. Infected males demonstrate protozoa in semen or urine. Treatment is by administration of metronidazole to all sexual contacts. ⏮ Parabasalia *(section 25.2)*

40.5 Food and Water Are Vehicles of Protozoal Diseases

After reading this section, you should be able to:

- Report the common food-borne and waterborne fungal and protist diseases
- Identify typical signs and symptoms of common food-borne and waterborne fungal and protist diseases
- Correlate vehicle-borne protist infection and disease severity with protist virulence factors
- Explain in specific terms why access to clean water is considered a basic human right

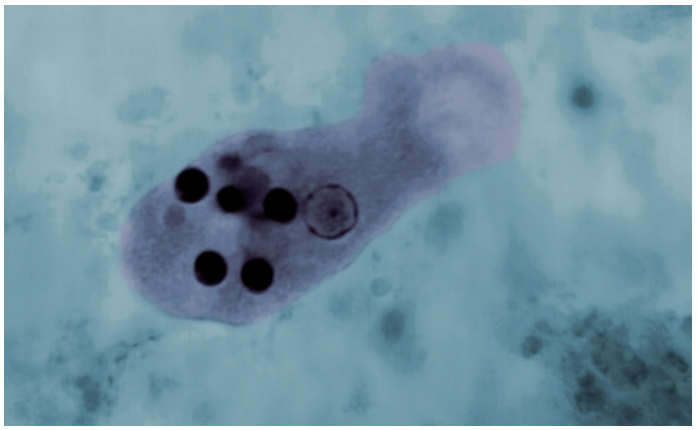
With advancing genomic studies, a number of infectious agents transmitted by food and water have been reclassified from fungi to protozoa. Thus we discuss food-borne and waterborne diseases using protist examples.

Amebiasis

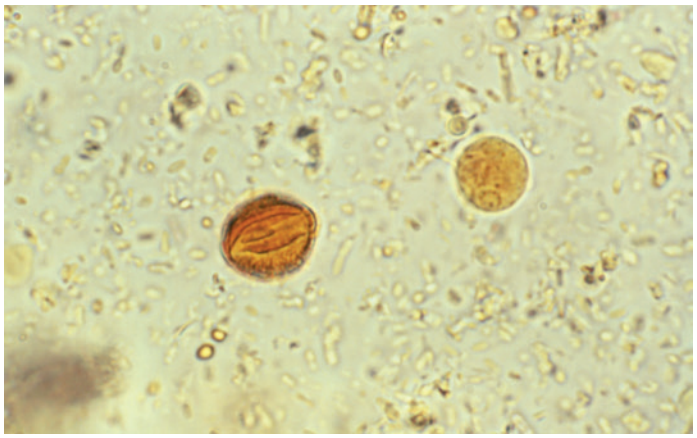
Worldwide there are approximately 500 million people infected with *Entamoeba* protozoa. It is now accepted that two species of *Entamoeba* infect humans: *E. dispar* and *E. histolytica*, which causes approximately 10% of invasive amebiasis; both are responsible for **amebiasis** (**amebic dysentery**). These very common parasites are endemic in warm climates where adequate sanitation is lacking. Within the United States, about 3,000 to 5,000 cases are reported annually. However, it is a major cause of parasitic death worldwide; as many as 100,000 die of amebiasis each year. However, this may represent the tip of an iceberg since only 10–20% of infected individuals are symptomatic and thus seek diagnosis and treatment. ⏮ Entamoebida *(section 25.3)*

Infection occurs by ingestion of mature cysts from fecally contaminated water, food, or hands, or from fecal exposure during sexual contact. After excystation in the lower region of the small intestine, the metacyst divides rapidly to produce eight small trophozoites (**figure 40.19**). These trophozoites move to the large intestine, where they can invade the host tissue, live as commensals in the lumen of the intestine, or undergo encystation. In many hosts, the trophozoites remain in the intestinal lumen, resulting in an asymptomatic carrier state with cysts shed in feces.

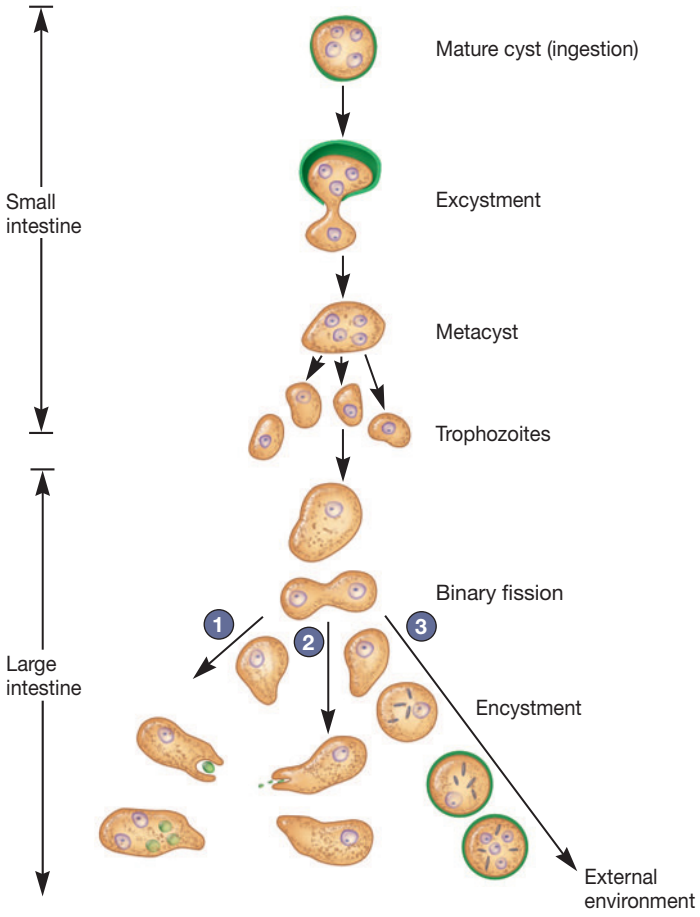
If the infective trophozoites invade intestinal tissues, they multiply rapidly and spread laterally, while feeding on erythrocytes, bacteria, and yeasts. The invading trophozoites destroy the epithelial lining of the large intestine by producing a protease that plays a role in intestinal invasion by degrading the extracellular matrix and circumventing the host immune response by cleaving secretory immunoglobulin A (sIgA), IgG, and complement factors. The protease is encoded by at least seven genes, several of which are found in *E. histolytica* but not *E. dispar*. Lesions (ulcers) are characterized by minute points of entry into the mucosa and extensive enlargement of the lesion after penetration into the submucosa. *E. histolytica* also may invade and produce lesions in other tissues, especially the liver, to cause hepatic



(a)



(b)



(c)

Figure 40.19 **Amebiasis Caused by *Entamoeba histolytica*.** Light micrographs of (a) a trophozoite (×1,000) and (b) a cyst (×3,100). (c) Life cycle. Infection occurs by ingestion of a mature cyst. Excystment occurs in the lower region of the small intestine, and the metacyst rapidly divides to give rise to eight small trophozoites (only four are shown). These enter the large intestine, undergo binary fission, and may (1) invade host tissues, (2) live in the lumen of the large intestine without invasion, or (3) undergo encystment and pass out of the host in feces.

amebiasis. However, all extraintestinal amebic lesions are secondary to those established in the large intestine. The symptoms of amebiasis are highly variable, ranging from an asymptomatic infection to fulminating dysentery (exhaustive diarrhea accompanied by blood and mucus), appendicitis, and abscesses in the liver, lungs, or brain. ⏮ *Antibodies are proteins that bind to specific 3-D molecules (section 34.7)*

Laboratory diagnosis of amebiasis can be difficult and is based on finding trophozoites in fresh, warm stools and cysts in ordinary stools. Serological testing for *E. histolytica* is available but often unreliable. The therapy for amebiasis is complex and depends on the location of the infection within the host and the host's condition. Asymptomatic carriers who are passing cysts should always be treated with iodoquinol or paromomycin because they represent the most important reservoir of the protozoan. In symptomatic intestinal amebiasis, paromomycin, metronidazole and iodoquinol are the drugs of choice. Prevention and control of amebiasis are achieved by practicing good personal hygiene and avoiding water or food that might be contaminated with human feces. Viable cysts in water can be destroyed by hyperchlorination or iodination. ⏮ *Antiprotozoan drugs (section 9.7)*

Amebic Meningoencephalitis and Keratitis

Free-living amoebae of the genera *Naegleria* and *Acanthamoeba* are facultative parasites responsible for causing two clinically distinct central nervous system diseases in humans: primary amoebic meningoencephalitis (PAM) and **keratitis** (inflammation of the cornea), respectively. *Naegleria fowleri* causes PAM, a disease that is typically fatal in 3 to 10 days after infection. They are among the most common protists found in freshwater (including natural and treated pools and hot tubs), drinking water systems, ventilation and air-conditioning systems, and moist soil. In 2011 several deaths were attributed to *Naegleria* infections acquired through the use of neti pots (similar to gravy boats) to "rinse the sinuses." In each case, tap water was reported to be contaminated with the protist. Meningoencephalitis occurred when the protist traversed the thin cell layer between the sinus and the brain.

In addition, several species of *Acanthamoeba* are known to cause encephalitis and to infect the eye, causing a chronically progressive, ulcerative *Acanthamoeba* keratitis that may result in blindness. Wearers of soft contact lenses may be predisposed to this infection and should take care to prevent contamination of their lens-cleaning and soaking solutions. Diagnosis of these infections is by demonstration of amoebae in clinical specimens.

Most freshwater amoebae are resistant to commonly used antimicrobial agents. These amoebae are reported in fewer than 100 human disease cases annually in the United States, although the incidence (especially of *Acanthamoeba keratitis*) is likely higher.

Cryptosporidiosis

A number of cryptosporidial species infect humans and other animals. *Cryptosporidium* ("hidden spore cysts") spp. are found in about 90% of sewage samples, in 75% of river waters, and in 28% of drinking waters. *C. parvum* is a common protist found in the intestine of many birds and mammals. When these animals defecate, oocysts are shed into the environment. If a human ingests food or water that is contaminated with the oocysts, excystment occurs within the small intestine, and sporozoites enter epithelial cells and develop into merozoites. Some of the merozoites subsequently undergo sexual reproduction to produce zygotes, which differentiate into thick-walled oocysts. Oocysts released into the environment begin the life cycle again. ⏮ Alveolata *(section 25.4)*

Major problems for public health arise from the fact that (1) oocysts are small, only 4 to 6 μm in diameter—much too small to be easily removed by the sand filters used to purify drinking water; (2) they have a low infectious dose, around 10 to 100 oocysts; and (3) *Cryptosporidium* spp. also are extremely resistant to disinfectants such as chlorine and oocysts may remain viable for 2 to 6 months in moist environments.

The incubation period for cryptosporidiosis ranges from 5 to 28 days. Diarrhea, which characteristically may be cholera-like (i.e., very watery, without blood), is the most common symptom. Other symptoms include abdominal pain, nausea, fever, and fatigue. The pathogen is routinely diagnosed by fecal concentration and acid-fast stained smears. Treatment of people with healthy immune systems is with nitazoxanide along with rehydration. Although the disease usually is self-limiting in healthy individuals, patients with late-stage AIDS or who are immunocompromised in other ways may develop prolonged, severe, and life-threatening diarrhea.

Cyclosporiasis

Cyclosporiasis is caused by the unicellular protist *Cyclospora cayetanensis*, first isolated in 1979. The disease is most common in tropical and subtropical environments, although it has been reported in most countries. In Canada and the United States, cyclosporiasis has been responsible for affecting over 3,600 people in at least 11 food-borne outbreaks since 1990, with 304 confirmed cases in 2014. A number of cyclosporiasis outbreaks have been linked to contaminated produce.

The disease presents with frequent, sometimes explosive, diarrhea. Often the patient exhibits loss of appetite, cramps, and bloating due to substantial gas production, nausea, vomiting, fever, fatigue, and substantial weight loss. Patients may report symptoms for days to weeks with decreasing frequency and then relapses. The protozoa infect the small intestine with a mean incubation period of approximately 1 week. Cyclosporan oocysts in freshly passed feces are not infective (**figure 40.20**). Thus direct oral-fecal transmission does not occur. Instead, the oocysts must differentiate into

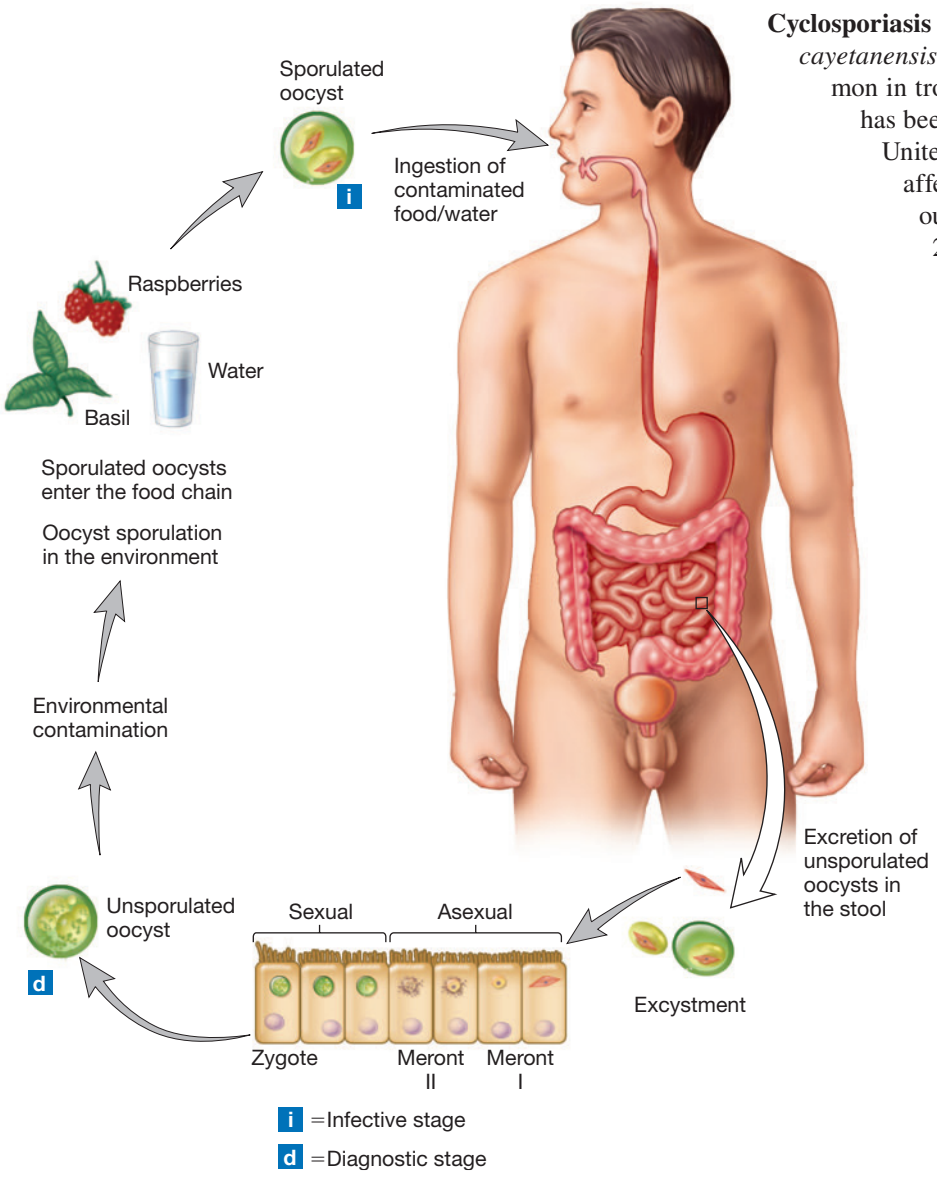


Figure 40.20 **Life Cycle of *Cyclospora cayetanensis*.** Unsporulated oocysts, shed in the feces of infected animals, sporulate and contaminate food and water. Once ingested, the sporulated oocysts excyst, penetrate host cells, and reproduce by binary fission (merogony). Sexual stages unite to form zygotes, resulting in new oocysts (unsporulated) that are shed in feces.

Some of the elements in this figure were created based on an illustration by Ortega, et al. Cyclospora cayetanensis. *In:* Advances in Parasitology: Opportunistic protozoa in humans. *San Diego: Academic Press; 1998. pp. 399–418.*

sporozoites after days or weeks at temperatures between 22 and 32°C (71.6–89.6°F). Sporozoites often enter the food chain when oocyst-contaminated water is used to wash fruits and vegetables prior to their transport to market. Once ingested, the sporozoites are freed from the oocysts and invade intestinal epithelial cells, where they replicate asexually. Sexual development is completed when sporozoites mature into new oocysts and are released into the intestinal lumen to be shed with feces.

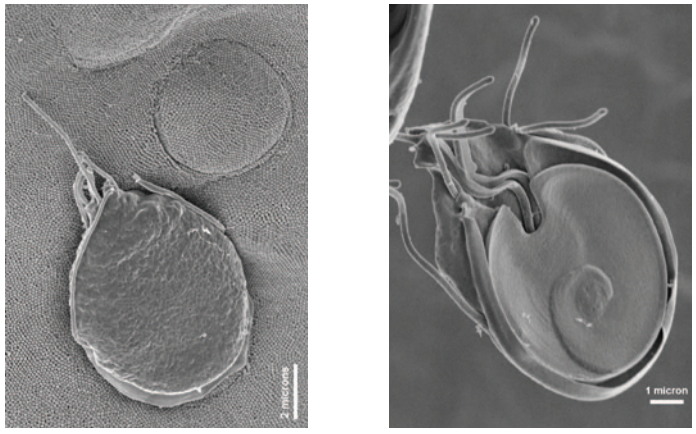
Laboratory diagnosis of cyclosporiasis is by the identification of oocysts in feces. Identification may require several specimens over several days. Treatment is with a combination of trimethoprim and sulfamethoxazole, and fluids to restore water lost through diarrhea. Prevention of cyclosporiasis is by avoidance of contaminated food and water. No vaccine is available.

Giardiasis

Giardia intestinalis is a flagellated protist that causes the very common intestinal disease **giardiasis,** which is worldwide in distribution and affects children more seriously than adults. In the United States, this protist is the most common cause of epidemic waterborne diarrheal disease (about 30,000 cases yearly). Approximately 7% of the population are asymptomatic carriers who shed cysts in their feces. *G. intestinalis* is endemic in child day-care centers in the United States, with estimates of 5 to 15% of diapered children being infected. Transmission occurs most frequently by cyst-contaminated water supplies. Epidemic outbreaks have been recorded in wilderness areas, suggesting that humans may be infected from stream water with *G. intestinalis* harbored by rodents, deer, cattle, or household pets. This implies that human infection also can be a zoonosis. As many as 200 million humans may be infected worldwide by ingesting as few as 10 cysts.

Following ingestion, *Giardia* cysts undergo excystment in the duodenum, forming trophozoites. The trophozoites inhabit the upper portions of the small intestine, where they attach to the intestinal mucosa by means of their sucking disks (**figure 40.21**; *also see figure 25.4*). The ability of the trophozoites to adhere to the intestinal epithelium accounts for the fact that they are rarely found in stools. It is thought that the trophozoites feed on mucous secretions and reproduce to become such a large population that they interfere with nutrient absorption by the intestinal epithelium. Giardiasis varies in severity, and asymptomatic carriers are common. Symptoms of giardiasis typically begin 1 week after infection and can last 6 to 8 weeks or longer if untreated. The disease can be acute or chronic. Acute giardiasis is characterized by severe diarrhea, epigastric pain, cramps, voluminous flatulence ("passing gas"), and anorexia. Chronic giardiasis is characterized by intermittent diarrhea, with periodic appearance and remission of symptoms.

Laboratory diagnosis is based on the identification of trophozoites—only in the severest of diarrhea—or cysts in stools. A commercial ELISA test is also available for the detection of *G. intestinalis* antigen in stool specimens. Tinidazole, nitazoxanide, and metronidazole are the drugs of choice for adults, and furazolidone is used for children because it is available in a liquid suspension. Prevention and control involve proper treatment of community water supplies, especially the use of slow sand filtration because the cysts are highly resistant to chlorine treatment. ▶▶| *Purification and sanitary analysis ensure safe drinking water (section 43.1); Wastewater treatment (section 43.2)*



(a) (b)

Figure 40.21 Giardiasis. (a) Scanning electron micrograph (SEM) depicting a *Giardia muris* protozoan adhering itself to the microvillous border of an intestinal epithelial cell. Each small circular profile under the protozoan represents the rounded tip of a single microvillous, and it is estimated that 2000 to 3000 microvilli cover the surface of a single intestinal epithelial cell. The two circular lesions above the protozoan are impressions made by the ventral adhesive disk of other *G. muris* organisms. (b) This SEM reveals the ultrastructural morphology of a *Giardia* protozoan's ventral adhesive disk. This disk acts like a suction cup, facilitating the organism's attachment to the intestinal surface.

Toxoplasmosis

Toxoplasmosis is a worldwide disease caused by the protist *Toxoplasma gondii.* It infects nearly 90% of people over the age of twelve, although most of those infected do not exhibit symptoms of the disease because the immune system usually prevents illness. More than 60 million U.S. citizens are asymptomatically infected. The natural reservoir of *T. gondii* is wild rodents, birds, and other small animals. Cats are an important factor in the transmission of *T. gondii* to humans; cats are the definitive (final) host and are required for completion of the sexual cycle (**figure 40.22**). Kittens especially shed oocysts of the protist in their feces for several weeks after infection. The protist is ubiquitous and finds its way into the food supply; toxoplasmosis can be transmitted by the ingestion of raw or undercooked meat. In fact, the CDC lists toxoplasmosis as the third leading cause of death due to food-borne infection. Oocysts enter the human host by way of the nose or mouth, and the parasites colonize the intestine. Congenital transfer, blood transfusion, or a tissue transplant also can transmit the protist. Originally toxoplasmosis gained public notice when it was discovered that the protist can infect a pregnant woman's fetus, causing serious congenital defects or death. It follows that pregnant women are advised not to empty cat litter boxes. Adults usually complain of an "infectious mononucleosis-like" syndrome.

Acute toxoplasmosis is usually accompanied by lymph node swelling (lymphadenopathy) with white blood cell enlargement. Pulmonary necrosis, myocarditis, and hepatitis caused by tissue necrosis are common. Retinitis (inflammation of the retina of the

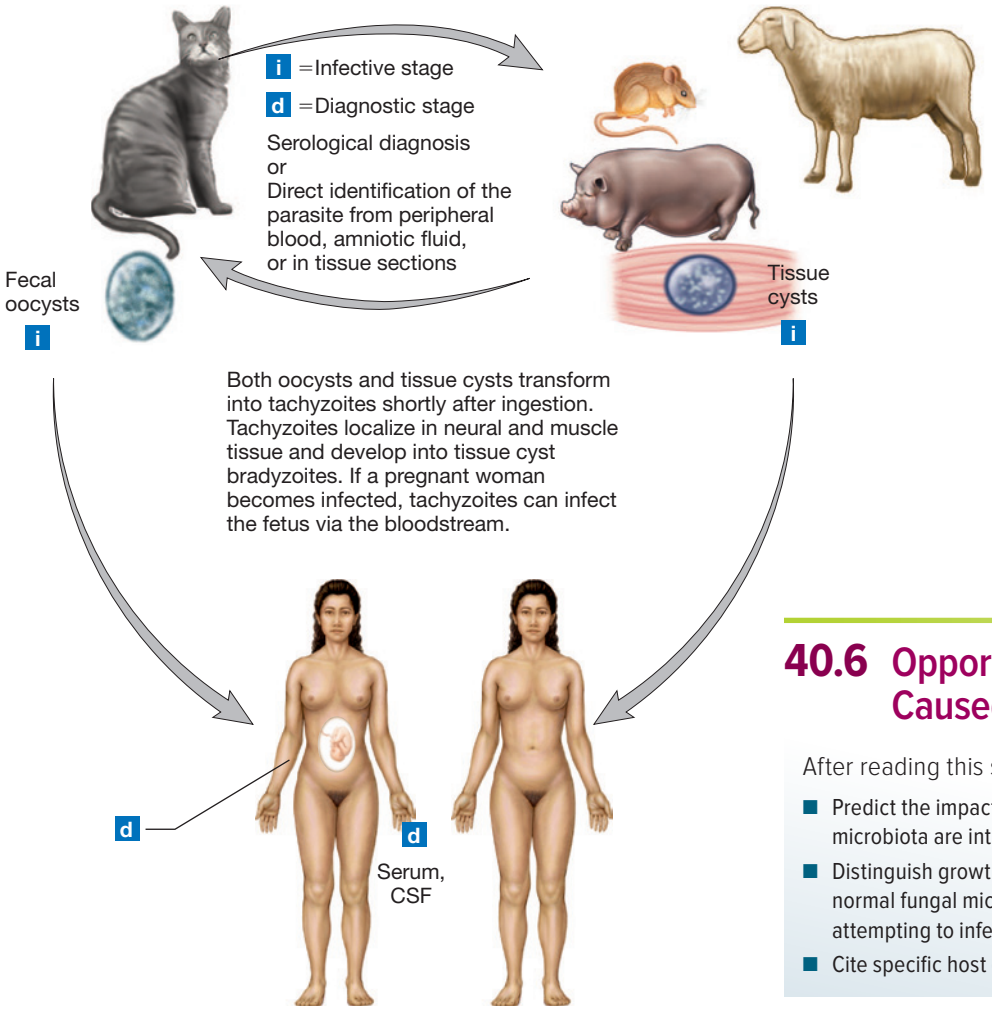


Figure 40.22 Life Cycle of *Toxoplasma gondii*. *Toxoplasma gondii* is a protozoan parasite of numerous mammals and birds. However, a cat, the definitive host, is required for completion of the sexual cycle. Oocysts are shed in the feces of infected animals, where they may be ingested by another host. Ingested oocysts transform into tachyzoites, which migrate to various tissue sites via the bloodstream.

MICRO INQUIRY *Upon entry into the human host by the nose or mouth, where do* T. gondii *colonize?*

eye) is associated with necrosis due to proliferation of the parasite within retinal cells. *T. gondii* in the immunocompromised, such as AIDS or transplant patients, can produce a unique encephalitis with necrotizing lesions in the brain accompanied by inflammatory infiltrates. *T. gondii* continues to cause more than 3,000 congenital infections per year in the United States. In immunocompromised or immunosuppressed individuals, infection frequently results in fatal disseminated disease with heavy cerebral involvement. ⏮ Alveolata *(section 25.5)*

Laboratory diagnosis of toxoplasmosis is by serological tests. Epidemiologically, toxoplasmosis is ubiquitous in all higher animals. Treatment of toxoplasmosis is with a combination of pyrimethamine and sulfadiazine. Prevention and control require minimizing exposure by the following: avoiding eating raw meat and eggs, washing hands after working in soil, cleaning cat litter boxes daily, keeping household cats indoors if possible, and feeding cats commercial food.

40.6 Opportunistic Diseases Can Be Caused by Fungi and Protists

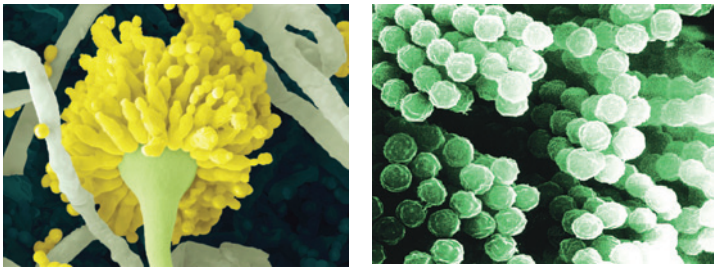
After reading this section, you should be able to:

- Predict the impact to the host resulting when normal fungal microbiota are introduced to a new host environment
- Distinguish growth and reproduction challenges experienced by normal fungal microbiota and ubiquitous environmental fungi when attempting to infect a human
- Cite specific host conditions that promote fungal infection

Recall that an opportunistic microorganism can be a member of the resident microbiota that is generally harmless in its normal environment; it becomes pathogenic when (1) introduced to a new environment, (2) outcompetes the other resident microbes, or (3) the host becomes (immuno-) compromised. A compromised host is seriously debilitated and has lowered resistance to infection. There are many causes of this condition: malnutrition, alcoholism, cancer, diabetes, another infectious disease (e.g., HIV/AIDS), trauma from surgery or injury, an altered microbiota from prolonged use of antibiotics (e.g., in vaginal candidiasis), and immunosuppression (e.g., by drugs, hormones, genetic deficiencies, cancer chemotherapy, and old age). Opportunistic mycoses may start as normal microbiota or ubiquitous environmental contaminants. The importance of opportunistic fungi and protozoa is increasing because of the expansion of the immunocompromised patient population. Here we discuss a few opportunistic fungal pathogens.

Aspergillosis

Of all the fungi that cause disease in human hosts, none is as widely distributed in nature as members of the genus *Aspergillus*. These filamentous fungi are omnipresent: they are found wherever organic debris occurs, especially in soil, decomposing plant



(a) (b)

Figure 40.23 Cause of an Opportunistic Mycosis. (a) Conidiophores of *Aspergillus flavus*. (b) SEM of *Aspergillus* spores.

matter, household dust, building materials, some foods, and water. In fact, it is almost impossible to avoid daily inhalation of *Aspergillus* spores (**figure 40.23**). In people with healthy immune systems, *Aspergillus* fungi do not often cause disease. However, infection results when healthy immune functions deteriorate.

Aspergillus fumigatus is apparently more common in air, and is also the usual cause of pulmonary **aspergillosis.** *A. flavus* is the most common cause of both superficial infection and invasive disease of immunosuppressed patients. *A. flavus* is more common in some locations such as hospitals. Invasive disease typically results in pulmonary infection (with fever, chest pain, and cough) that disseminates to the brain, kidney, liver, bone, or skin. Invasive aspergillosis has a mortality rate of 50 to 100%. ⏮ Ascomycota *includes yeasts and molds (section 26.5)*

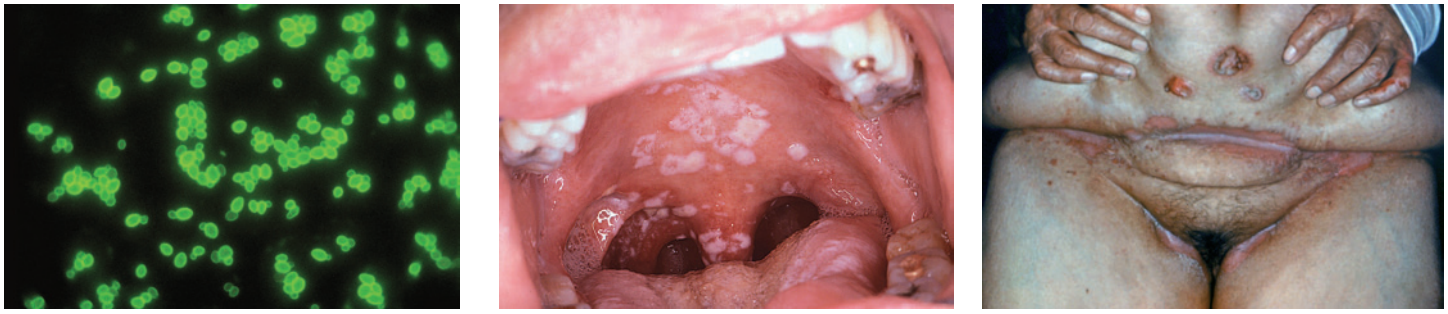
The major portal of entry for *Aspergillus* spp. is the respiratory tract. Inhalation of conidiospores can lead to several types of pulmonary aspergillosis. One type is allergic aspergillosis. Infected individuals may develop an immediate allergic response and suffer asthma attacks when exposed to fungal antigens. In bronchopulmonary aspergillosis (another potential response to *Aspergillus* spp.), patients with underlying pulmonary disease (tuberculosis, asthma, cystic fibrosis) suffer the major clinical manifestation of bronchitis resulting from both type I and type III hypersensitivities. Although tissue invasion seldom occurs in bronchopulmonary aspergillosis, the fungus often can be cultured from sputum. Finally, the most common manifestation of pulmonary involvement is the occurrence of colonizing aspergillosis, in which fungal colonies form within the lungs and develop into "fungus balls" called aspergillomas. These consist of a tangled mass of hyphae growing in a circumscribed area. From the lung, the fungus may spread, producing disseminated aspergillosis in a variety of tissues and organs. In patients whose resistance is severely compromised, invasive aspergillosis may occur and fill the lung with fungal hyphae. Rarely, aspergillomas (or tumor-like growths of fungal spores) can form, as well. ⏮ *Hypersensitivities (section 34.10)*

Laboratory diagnosis of aspergillosis depends on identification either by direct examination of pathological specimens or by isolation and characterization of the fungus. An enzyme immunoassay that detects galactomannan (an exoantigen of *Aspergillus* spp.) can be used to screen suspected cases of aspergillosis. Treatment for invasive disease is with voriconazole, while allergic-type aspergillosis is treated with itraconazole and corticosteroids. However, successful therapy depends on treatment of the underlying disease so that host resistance increases. ⏮ *Antifungal drugs (section 9.5)*

Candidiasis

Candidiasis is a mycosis caused by dimorphic fungi of the genus *Candida*. Recall that some fungi can exist as single cells (yeast) or as filaments (molds) adapting to their environmental conditions. Candida spp. use this Y-M shift to disseminate within a human host depending on their need to invade through body fluids (as yeast) or tissues (as molds). There are over 20 species of *Candida* that can cause infection in humans, most notably *C. albicans* (**figure 40.24*a***) and *C. glabrata*. In contrast to other pathogenic fungi, *C. albicans* and *C. glabrata* are members of the normal microbiota within the gastrointestinal tract, respiratory tract, vaginal area, and mouth. In healthy individuals, they do not produce disease because growth is suppressed by other microbiota and host resistance mechanisms. However, if anything upsets the normal microbiota and immune competency, these fungi may multiply rapidly and produce candidiasis. *Candida* species are important nosocomial pathogens. In some hospitals, they may represent almost 10% of nosocomial bloodstream infections. Because these fungi can be transmitted sexually, candidiasis is also listed by the CDC as a sexually transmitted disease.

No other mycotic pathogens produce as diverse a spectrum of disease in humans as do *Candida* spp. Most infections involve the



(a) (b) (c)

Figure 40.24 Opportunistic Mycoses Caused by *Candida albicans*. (a) Fluorescent antibody (FA) stain revealing the oval budding of the yeast form. (b) Thrush, or oral candidiasis, is characterized by the formation of white patches on the mucous membranes of the tongue and elsewhere in the oropharyngeal area. These patches form a pseudomembrane composed of spherical yeast cells, leukocytes, and cellular debris. (c) Intertriginous candidiasis involves those areas of the body, usually opposed skin surfaces, that cause irritation, inflammation, and areas of cutaneous ulceration.

skin or mucous membranes. This occurs because *Candida* spp. are strict aerobes and find such surfaces very suitable for growth. Cutaneous involvement usually occurs when the skin becomes overly moist or damaged. For instance, paronychia and onychomycosis are associated with infections of the subcutaneous tissues of the digits and nails, respectively. These infections usually result from continued immersion of the appendages in water.

Oropharyngeal candidiasis, or **thrush** (figure 40.24*b*), is a fairly common disease in newborns, persons with dentures, and people who use inhaled steroids. A weakened immune system predisposes people to candidiasis, which appears as many small, white flecks that cover the tongue and mouth. At birth, newborns do not have a normal microbiota in the oropharyngeal area. If the mother's vaginal area is heavily colonized with *Candida* spp., the upper respiratory tract of the newborn becomes colonized during passage through the birth canal. Once the newborn has developed his or her own normal oropharyngeal microbiota, thrush becomes uncommon.

Intertriginous candidiasis involves those areas of the body, usually opposed skin surfaces, that are warm and moist: axillae, groin, skin folds (figure 40.24*c*). Napkin (diaper) candidiasis is typically found in infants whose diapers are not changed frequently and therefore are not kept dry. **Candidal vaginitis** can result as a complication of diabetes, antibiotic therapy, oral contraceptives, pregnancy, or any other factor that compromises the female host. Normally the omnipresent vaginal lactobacilli create a low pH, which limits fungal growth. However, if the numbers of lactobacilli are decreased by any of the aforementioned factors, yeast may proliferate, causing a curdlike, yellow-white discharge from the vagina. *C. albicans* and *C. glabrata* can be transmitted to males during intercourse and lead to **balanitis.** Balanitis is an infection of the male glans penis and occurs primarily in uncircumcised males. The disease begins as vesicles on the penis that develop into patches and are accompanied by severe itching and burning.

Diagnosis of candidiasis is sometimes difficult because (1) these fungi are frequent secondary invaders in diseased hosts, (2) a mixed microbiota is most often found in the diseased tissue, and (3) no completely specific immunologic procedures for the identification of *Candida* spp. currently exist. Mortality is almost 50% when the fungi invade the blood or disseminate to visceral organs, as occasionally seen in immunocompromised patients.

There is no one satisfactory treatment for candidiasis. Cutaneous lesions can be treated with topical agents such as sodium caprylate, sodium propionate, nystatin, miconazole, and trichomycin. Clotrimazole lozenges and nystatin swishing are used to treat oropharyngeal candidiasis. Similar drugs are used to treat genital/vulvovaginal and rectal candidiasis. Ketoconazole, amphotericin B, fluconazole, itraconazole, and flucytosine also can be used for systemic candidiasis.

Microsporidiosis

More than 1,200 species of *Microsporidia* have been catalogued, in 143 genera; at least 14 species are known to be human pathogens. Several domestic and feral animals appear to be reservoirs for several species that infect humans. Increasingly recognized as opportunistic infectious agents, microsporidia infect a wide range of vertebrate and invertebrate hosts. **Microsporidiosis** is an infectious disease found mostly in HIV patients, however. One unifying characteristic of microsporidia is their production of a highly resistant spore, capable of surviving long periods of time in the environment. Spore morphology varies with species, but most superficially resemble enteric bacteria. Microsporidial spores recovered from human infections are oval to rodlike, measuring 1 to 4 μm. Microsporidia also possess a unique organelle known as the polar tubule, which is coiled within the spore (**figure 40.25**; *also see figure 26.17*). ◀◀ Microsporidia *(section 26.7)*

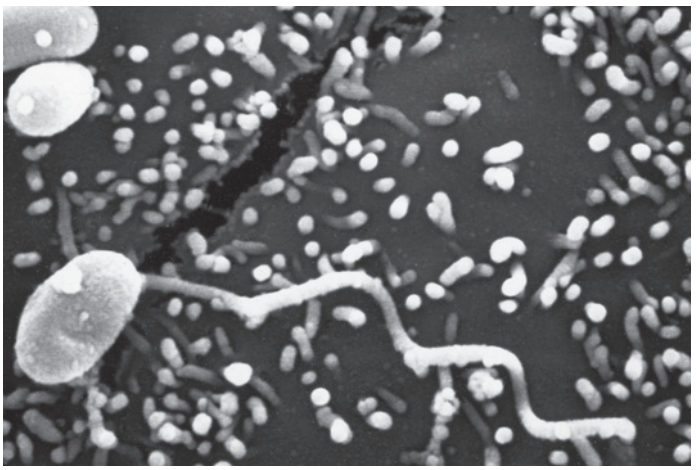


Figure 40.25 Microsporidia. Scanning electron micrograph of a microsporidian spore with an extruded polar tubule inserted into a eukaryotic cell. The spore injects the infective sporoplasms through its polar tubule.

Infection of a host cell results when a microsporidial spore extrudes its polar tubule, which bores through the target cell's plasma membrane. A sudden increase in spore calcium results in the injection of the sporoplasm (cytoplasm-like contents) through the polar tubule into the host cell. Inside the cell, the sporoplasm condenses and undergoes asexual multiplication. Multiplication of the sporoplasm is species-specific, occurring within the host cytoplasm or within a vacuole, and is usually completed through binary (merogony) or multiple (schizogony) fission. Once the sporoplasm has multiplied, it directs the development of new spores (sporogony) by first encapsulating meronts or schizonts (products of asexual multiplication) within a thick spore coating. New spores increase until the host cell membrane ruptures, releasing the progeny.

Microsporidia infections can result in a wide variety of symptoms. These include hepatitis, pneumonia, skin lesions, diarrhea, weight loss, and wasting syndrome. Diagnosis is based on clinical manifestations and identification of microsporidia in fecal smears stained by the "Quick-Hot Gram-Chromotrope technique," also known as the Chromotrope 2R method. Where possible by electron microscopy, identification can be made based on the characteristic polar tubule coiled within a spore. Molecular identification is also possible using PCR and primers to the small subunit ribosomal RNA (*see figure 19.3*). Treatment of microsporidiosis is not well defined. However, some successes have been reported with the use of albendazole (which inhibits tubulin and ATP synthesis in helminths), itraconazole, metronidazole, thalidomide (a toxic, immunosuppressant drug), and fumagillin (an amebicide).

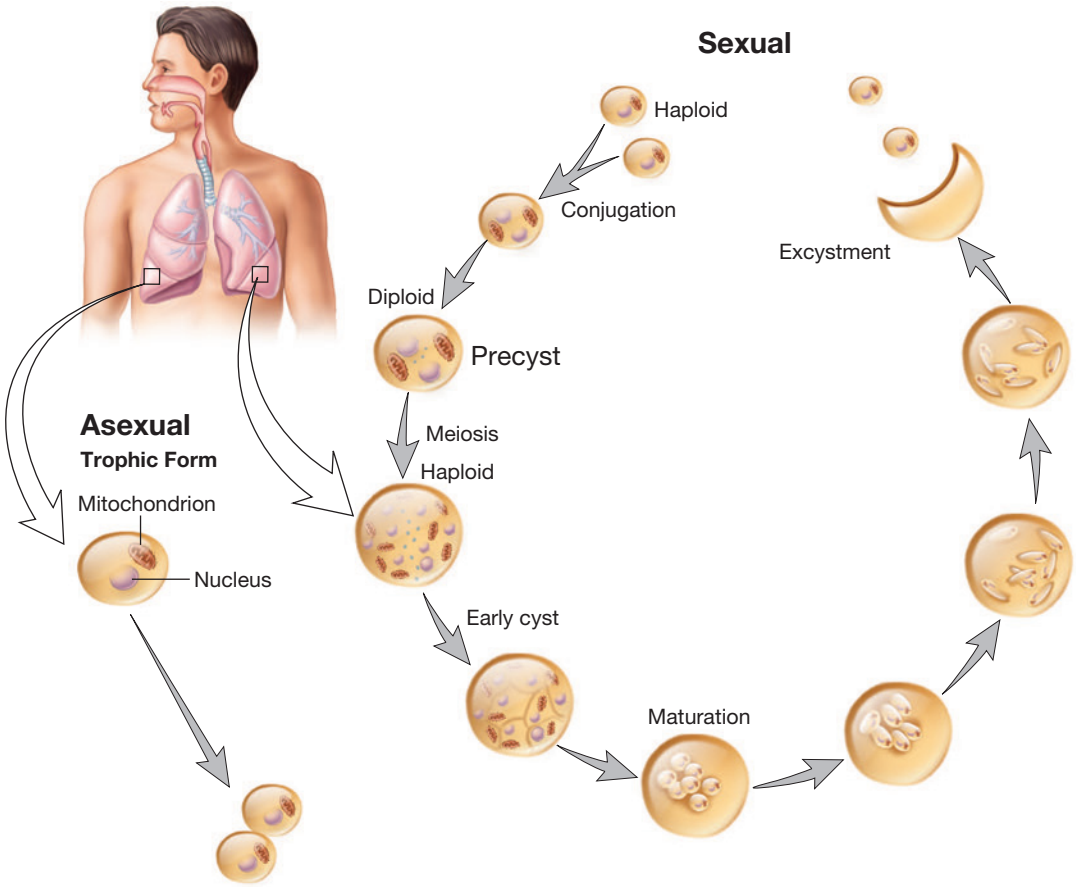

Figure 40.26 **Life Cycle of *Pneumocystis jiroveci*.** This fungus exhibits both sexual and asexual reproductive stages. Sexual reproduction occurs when haploid cells undergo conjugation followed by meiosis. Asexual reproduction occurs by binary fission. Both forms of reproduction can occur within the human host.

Pneumocystis Pneumonia

Pneumocystis jiroveci is a fungus found in the lungs of a wide variety of mammals. Although it was previously classified as a protist, its rRNA, DNA sequences (from several genes), and biochemical analyses have shown that it is more closely related to fungi than to protists. The life cycle of *P. jiroveci* is presented in **figure 40.26**, although some aspects of its development are not well known. The disease that this fungus causes has been called *Pneumocystis* pneumonia or *Pneumocystis carinii* pneumonia (PCP). Its name was changed to *Pneumocystis jiroveci* in honor of the Czech parasitologist, Otto Jirovec, who first described this pathogen in humans. In recent medical literature, the acronym PCP for the disease has been retained despite the loss of the old species epithet (*carinii*). PCP now stands for *Pneumocystis* pneumonia.

Serological data indicate that most humans are exposed to *P. jiroveci* by age three or four. However, PCP occurs almost exclusively in immunocompromised hosts. Extensive use of immunosuppressive drugs and irradiation for the treatment of cancers and following organ transplants accounts for the formidable prevalence rates for PCP. This pneumonia also occurs in premature, malnourished infants and in more than 80% of HIV-positive patients who have progressed to AIDS. Both the organism and the disease remain localized in the lungs—even in fatal cases. Within the lungs, *P. jiroveci* causes the alveoli to fill with a frothy exudate.

Laboratory diagnosis of *Pneumocystis* pneumonia can be made definitively only by microscopically demonstrating the presence of the microorganisms in infected lung material or by a PCR analysis. Treatment is by means of oxygen therapy and either a combination of trimethoprim and sulfamethoxazole, atovaquone, or trimetrexate. Prevention and control are through prophylaxis with drugs, such as fluconazole, in susceptible persons.

Retrieve, Infer, Apply

1. How do infections caused by *Entamoeba histolytica* occur?
2. What is the most common cause of epidemic waterborne diarrheal disease?
3. In what two ways does *Toxoplasma* affect human health?
4. Why are some mycotic diseases of humans called opportunistic mycoses?
5. What parts of the human body can be affected by *Candida* infections?
6. Describe the infection process used by microsporidia.
7. When is *Pneumocystis* pneumonia likely to occur in humans?

Key Concepts

40.1 Relatively Few Fungi and Protists Are Human Pathogens

- Human fungal diseases, or mycoses, can be divided into five groups according to the level and mode of entry into the host (**figure 40.1**). These are the superficial, cutaneous, subcutaneous, systemic, and opportunistic mycoses (**table 40.1**).
- Protozoa are responsible for some of the most serious human diseases that affect hundreds of millions of people worldwide (**table 40.2**) and can also be grouped by route of disease transmission.

40.2 Fungi Can Be Transmitted by Airborne Routes

- Most systemic mycoses that occur in humans are acquired by inhaling the spores from the soil where the free-living fungi are found.
- Four types can occur in humans: blastomycosis (**figure 40.2**), coccidioidomycosis (**figure 40.3**), cryptococcosis, (**figure 40.4**), and histoplasmosis (**figure 40.5**).

40.3 Arthropods Can Transmit Protozoal Disease

- The most important human protozoan pathogen is *Plasmodium*, the causative agent of malaria (**figures 40.6–40.9**). Human malaria is caused by five species of *Plasmodium: P. falciparum, P. vivax, P. malariae, P. knowlesi,* and *P. ovale*.
- Flagellated protozoa are transmitted by arthropods and infect the blood and tissues of humans. Two major groups occur: the leishmanias, which cause the diseases collectively termed leishmaniasis (**figures 40.10** and **40.11**), and the trypanosomes (**figures 40.12** and **40.13**), which cause trypanosomiasis.

40.4 Direct Contact Diseases Can Be Caused by Fungi and Protists

- Superficial mycoses of the hair shaft are collectively called piedras. Two major types are black piedra and white piedra. Tinea versicolor is a third common superficial mycosis.
- The cutaneous fungi that parasitize the hair, nails, and outer layer of the skin are called dermatophytes, and their infections are termed dermatophytoses, ringworms, or tineas. At least seven types can occur in humans: tinea barbae (ringworm of the beard), tinea capitis (ringworm of the scalp; **figure 40.14**), tinea corporis (ringworm of the body; **figure 40.15*a***), tinea pedis (ringworm of the feet; figure 40.15*b*), and tinea unguium (ringworm of the nails; figure 40.15*c*).
- The dermatophytes that cause the subcutaneous mycoses are normal saprophytic inhabitants of soil and decaying vegetation. Three types of subcutaneous mycoses can occur in humans: chromoblastomycosis (**figure 40.16*a***), maduromycosis, and sporotrichosis (**figure 40.17**).
- Trichomoniasis is a sexually transmitted disease caused by the protozoan flagellate *Trichomonas vaginalis*. *T. vaginalis* causes bleeding and pustules (**figure 40.18**).

40.5 Food and Water Are Vehicles of Protozoal Diseases

- *Entamoeba histolytica* is the amoeboid protozoan responsible for amebiasis. This is a very common disease in warm climates throughout the world. It is acquired when cysts are ingested with contaminated food or water (**figure 40.19**).
- Freshwater parasites such as *Naegleria* and *Acanthamoeba* can cause primary amebic meningoencephalitis.
- *Cryptosporidium parvum* is a common coccidial apicomplexan parasite that causes severe diarrheal disease. It is acquired from contaminated food or water.
- *Cyclospora cayetanensis* is shed in the feces of a current host and can only infect the gastrointestinal tract of a new host after it has developed at 22 to 32°C for several days or weeks. It can be acquired from contaminated water used to rinse fruit or vegetables (**figure 40.20**).
- *Giardia intestinalis* is a flagellated protozoan that causes the common intestinal disease giardiasis (**figure 40.21**). This disease is distributed throughout the world, and in the United States, it is the most common cause of waterborne diarrheal disease.
- Toxoplasmosis is a disease caused by the protozoan *Toxoplasma gondii*. It is one of the major causes of death in AIDS patients (**figure 40.22**).

40.6 Opportunistic Diseases Can Be Caused by Fungi and Protists

- An opportunistic organism is one that is generally harmless in its normal environment but can become pathogenic in a compromised host.
- The most important opportunistic mycoses affecting humans include systemic aspergillosis (**figure 40.23**), candidiasis (**figure 40.24**), and *Pneumocystis* pneumonia (**figure 40.26**).
- An emerging opportunistic fungal disease, especially of the immunocompromised, is caused by the group of unique microbes known as the microsporidia. They live as a spore form and have a unique organelle used for infecting new host cells (**figure 40.25**).

Compare, Hypothesize, Invent

1. What is one distinct feature of fungi that could be exploited for antibiotic therapy?
2. Why do you think most fungal diseases in humans are not contagious?
3. Trypanosomes are notorious for their ability to change their surface antigens frequently. Given the kinetics of a primary immune response (primary antibody production), how often would the surface antigen need to be changed to stay "ahead" of the antibody specificity?
4. The initial, nonsymptomatic liver stage (LS) of *Plasmodium* spp. is considered very promising for prophylactic drug and vaccine development (figure 40.9). However, technical obstacles in obtaining LS protists has hindered analysis of gene and protein expression. Tarun and her colleagues developed a rodent model whereby LS protists could be studied. They identified a set of proteins expressed only in the LS, including enzymes involved in metabolic pathways active only in LS, as well as exported proteins.

   Examine the *P. vivax* life cycle in figure 40.7. Why do you think the metabolic requirements of LS protists are so unique? Having identified these proteins, what would be the next step in identifying drugs that might be effective against LS protozoa? How might this information assist in vaccine development?

   Read the original paper: Tarun, A. S., et al. 2008. A combined transcriptome and proteome survey of malaria parasite liver stages. *Proc. Natl. Acad. Sci. USA* 105:305.
5. Infection with the fungal pathogen *Cryptococcus gattii* can be devastating to immunocompromised individuals, yet not much is known about its natural habitat. To explore its association with plants, model systems were developed between *C. gattii* and the mustard plant *Arabidopsis* and *Eucalyptus*. It was discovered that *C. gattii* grows well on these plants and is a plant pathogen only when plants are infected with strains of opposite mating types. In addition, two compounds produced by the plants, myoinositol and indole acetic acid, were found to promote fungal mating.

   Why is it important to understand the fungal niche in nature? List two questions these results raise concerning the transmission of *Cryptococcus* to human hosts. How would you go about addressing these questions?

   Read the original paper: Xue, C., et al. 2007. The human fungal pathogen *Cryptococcus* can complete its sexual life cycle during a pathogenic association with plants. *Cell Host Microbe* 1:263.

Microbiology of Food

Beer brewing started in prehistoric times and has been continuously refined. Now the introduction of genetically modified grain has some brewers and consumers wondering if this is progress.

The Art, Science, and Genetics of Brewing Beer

Beer has a long history. Prehistoric nomads probably learned to make beer from grains and water before they figured out how to bake bread. Beer was on Noah's list of provisions. Six-thousand-year-old Babylonian tablets describe beer recipes. Ancient Chinese, Egyptians, and Romans brewed beer. It is even rumored that the Pilgrims made landfall in Plymouth in 1620 because their beer supply was running low. Apart from water, beer is now considered the most frequently consumed liquid. With a global population of about 7 billion, that's a lot of beer.

There are three essential steps to making beer. First, barley is soaked in warm water to trigger germination. Once germinated, the grain produces the enzymes gluconase, which breaks down plant cell walls, and amylase to degrade the plant starch to a sugar fermentable by yeast. Next the sprouted grain is heated and dried, denaturing the enzymes. This mixture is called malt, and it is flushed with warm water so yeast can begin fermenting the starch to ethanol and CO_2 (section 41.5).

Predictably, many modifications have been made to the art and science of beer brewing. Since the mid-1990s, this has included the development of genetically modified (GM) ingredients. Most breweries find it more cost effective to add gluconases and amylases collected from bacteria that have been genetically engineered to produce these enzymes. Likewise, GM yeasts can be used to increase the brewing efficiency. Herbicide-resistant rice and corn have been used for a number of years by many larger breweries. However, the genetic modification of barley has lagged behind that of other grains.

Australia has become an emerging leader in the production of GM grain, where drought and heat have fostered the development of stress-tolerant crops. Trials are underway to test GM barley with resistance to two species of pathogenic fungi (*Rhizoctonia solani* and *R. oryzae*), as well as GM barley that uses nitrogen more efficiently, and barley that produces heat-stable gluconase.

What is the likely fate of GM barley? Public fear of GM foods is thought to be diminishing as it is realized that for over a decade, 70 to 80% of foods in the United States contain at least one GM ingredient without resulting in public health problems. Other countries are gradually increasing their growth and consumption of GM foods, particularly soy, corn, and cotton. Thus it is likely that GM barley will quietly find its way into much of the world's beer (including yours).

As the history of beer illustrates, humankind long ago figured out how to harness microorganisms to transform raw foods into gastronomic delights, including chocolate, cheeses, pickles, sausages, soy sauce, and wines. It was not until the late nineteenth century, however, that the role microorganisms play in food spoilage was appreciated. This illustrates the two opposing roles of microorganisms in food production and preservation. This chapter begins with an overview of microbial spoilage of food; the second half discusses the importance of other microbes in food and beverage production.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ List environmental factors that influence microbial growth (section 7.4)
- ✔ Compare and contrast the growth and physiology of obligate aerobes, facultative anaerobes, and strict anaerobes (section 7.4)
- ✔ Review physical and chemical agents commonly used to control microbial growth (sections 8.4 and 8.5)
- ✔ Describe the capacity of a bacterial spore to survive in nature, and list example bacteria that form endospores (sections 3.9, 23.1, and 23.3)
- ✔ Summarize the possible fates of pyruvate in fermentation (section 11.8)
- ✔ Explain the principles of a toxin-mediated disease (section 35.2)
- ✔ Predict methods used to test for food-borne microorganisms (sections 29.2, 36.3, and 36.4)
- ✔ Discuss the typical bacterial, viral, fungal, and protist diseases transmitted by food (sections 38.4, 39.4, and 40.5)

41.1 Microbial Growth Can Cause Food Spoilage

After reading this section, you should be able to:

- Differentiate between intrinsic and extrinsic factors that influence food spoilage
- Explain how the composition of a food item helps determine the kind of microbial growth that might occur
- List two physical and two biological features of a food that influence spoilage

Just as foods nourish the people who consume them, so too can they support the growth of microorganisms. Microbial growth is controlled by factors related to the food itself, called intrinsic factors; by extrinsic factors, which include the environment in which the food is stored; and by any preservatives that may have been added. Here we review the most important intrinsic and extrinsic factors involved in food spoilage. *Food Spoilage*

Intrinsic Factors

Food composition is a critical intrinsic factor that influences microbial growth (**table 41.1**). If a food consists primarily of carbohydrates, microbial spoilage will most likely occur at some point in time. Foods with high water activity (p. 931) including some fruits and vegetables first show spoilage by fungi. For instance, even the slightest bruising of the tomato skin, exposing the interior, will result in rapid fungal growth. This affects the quality of tomato products, including tomato juices and ketchup. Molds also produce enzymes that weaken and penetrate the protective outer skin of fruits and vegetables. Once molds degrade carbohydrates within the skin, bacteria can colonize the food. Colonizing bacteria include those that cause soft rots, such as *Erwinia carotovora,* which produce hydrolytic enzymes such as pectinase. ⏮ *Solutes affect osmosis and water activity (section 7.4)*

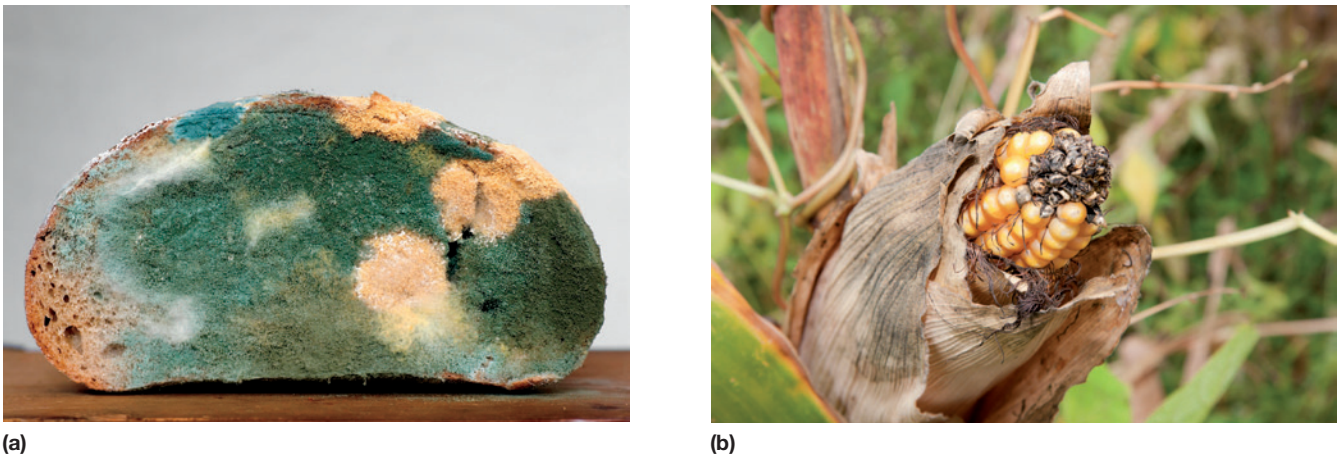
Molds can rapidly grow on grains and corn when these products are stored in moist conditions. The moldy bread pictured in **figure 41.1*a*** shows extensive fungal hyphal development and sporulation. Contamination of grains by the ascomycete *Claviceps purpurea* causes ergotism, a toxic condition (*see figure 26.12*). Hallucinogenic alkaloids produced by this fungus can lead to altered behavior, abortion, and death if infected grains are eaten.

In contrast to carbohydrates, when foods contain large amounts of proteins or fats (e.g., meat and dairy products), bacterial growth can produce a variety of foul odors. The production of

Table 41.1 Differences in Spoilage Processes in Relation to Food Characteristics

Substrate	Food Example	Chemical Reactions or Processes[1]	Typical Products (and Effects)
Pectin	Fruits	Pectinolysis	Methanol, uronic acids (loss of fruit structure, soft rots)
Proteins	Meat	Proteolysis, deamination	Amino acids, peptides, amines, H_2S, ammonia, indole (bitterness, souring, bad odor, sliminess)
Carbohydrates	Starchy foods	Hydrolysis, fermentations	Organic acids, CO_2, mixed alcohols (souring, acidification)
Lipids	Butter	Hydrolysis, fatty acid degradation	Glycerol and mixed fatty acids (rancidity, bitterness)

1 Other reactions also occur during the spoilage of these substrates.



(a) (b)

Figure 41.1 Food Spoilage. Typical examples of fungal spoilage include (a) bread, most likely supporting the growth of *Penicllium* sp. (green hyphae) and other fungi, and (b) ear rot in corn, which can result in major economic losses.

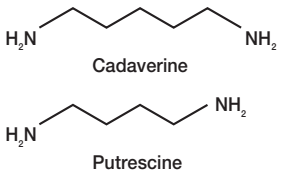


Figure 41.2 Cadaverine and Putrescine. These foul-smelling amines are the products of protein degradation.

short-chained fatty acids from fats renders butter rancid. The anaerobic breakdown of proteins is called **putrefaction.** It yields foul-smelling amine compounds such as cadaverine (imagine the origin of that name) and putrescine (**figure 41.2**). Unpasteurized milk, which contains fats, protein, and carbohydrates, provides a good example of microbial succession during spoilage: acid production by *Lactococcus lactis* subspecies *lactis* is followed by additional acid production associated with the growth of more acid-tolerant organisms such as *Lactobacillus.* Next, yeasts and molds become dominant and degrade the accumulated lactic acid, and the acidity gradually decreases. Eventually protein-digesting bacteria become active, resulting in a putrid odor and bitter flavor. The milk, originally opaque, eventually becomes clear because the proteins and fats have become coagulated (**figure 41.3**).

The pH and oxidation-reduction (redox) potential of a food also are critical intrinsic factors. A low pH favors the growth of yeasts and molds. In neutral or alkaline pH foods, such as meats, bacteria are more dominant in spoilage and putrefaction. Furthermore, when meat products, especially broths, are cooked, they present a reducing environment for microbial growth. These products, with their readily available amino acids, peptides, and growth factors, are ideal media for the growth of anaerobes, including clostridia.

Figure 41.3 Milk Spoilage. Fresh (left) and curdled (right) milk are shown. The spoilage process produces acidic conditions that denature and precipitate the milk casein to yield separated curds and whey.

The physical structure of a food also can affect the course and extent of spoilage. Grinding and mixing of foods such as sausage and hamburger increase the food surface area and distribute contaminating microorganisms throughout the food. This can result in rapid spoilage if such foods are stored improperly.

Many foods contain natural antimicrobial substances, including complex chemical inhibitors and enzymes. Coumarins found in fruits and vegetables have antimicrobial activity. Cow's milk and eggs also contain antimicrobial substances. Eggs are rich in the enzyme lysozyme, which lyses the cell walls of contaminating Gram-positive bacteria (*see figure 33.4*). Herbs and spices, which were once the mainstay of food preservation, often possess significant antimicrobial substances; generally fungi are more sensitive than bacteria to these compounds. Sage and rosemary are two of the most antimicrobial spices. Aldehydic and phenolic compounds that inhibit microbial growth are found in cinnamon, mustard, and oregano. Other important inhibitors are garlic, which contains allicin; cloves, which have eugenol; and basil, which contains rosmarinic acid. Nonetheless, spices can sometimes contain pathogenic and spoilage organisms. Enteric bacteria, *Bacillus cereus, Clostridium perfringens,* and *Salmonella enterica* have been detected in spices. Microorganisms can be eliminated or reduced by ethylene oxide sterilization. This treatment can result in *Salmonella*-free spices and herbs and a 90% reduction in the levels of general spoilage organisms. ⏮ *Microorganisms are controlled with chemical control agents (section 8.5)*

Extrinsic Factors

Extrinsic factors are more easily controlled than intrinsic factors and are therefore frequently the basis for food preservation. Temperature is an important extrinsic factor in determining whether a food will spoil. For instance, spoilage problems can occur with minimally processed, concentrated frozen citrus products. These were once prepared with little or no heat treatment, and Gram-positive bacteria and yeasts in the genera *Saccharomyces* and *Candida* could grow upon thawing and dilution with water. Today most frozen concentrates are pasteurized (p. 931), filtered, and then concentrated by heating under vacuum. Vitamin C and other flavors are added back to the product before packaging. Ready-to-serve juices are routinely pasteurized, even though this results in some flavor loss.

Humidity is also a key factor in controlling food spoilage. At higher relative humidities, microbial growth is initiated more rapidly, even at lower temperatures (especially when refrigerators are not maintained in a defrosted state). When drier foods are placed in moist environments, moisture absorption can occur on the food surface, promoting microbial growth.

The atmosphere in which food is stored also is important. This is especially true with shrink-wrapped foods because many plastic films allow oxygen diffusion, which results in increased growth of surface-associated microorganisms. Excess CO_2 can decrease the solution pH, inhibiting microbial growth. Storing

meat in a high CO_2 atmosphere inhibits Gram-negative bacteria, resulting in a population dominated by the lactobacilli.

Retrieve, Infer, Apply

1. What are some intrinsic factors that influence food spoilage and how do they exert their effects?
2. How would the spoilage of bread differ from that of a high-fat food like butter?
3. Why do sausage and other ground meat products provide a better environment for the growth of food spoilage organisms than solid cuts of meats?
4. What extrinsic factors can determine whether food spoilage will occur?

41.2 Various Methods Are Used to Control Food Spoilage

After reading this section, you should be able to:

- Review the limitations of refrigeration
- Explain why canning is not always a fail-safe means of preserving food
- Compare and contrast two pasteurization methods
- Describe the principle of water availability and how it can be used to preserve foods
- Explain how commonly used chemicals preserve food
- Defend an informed opinion on the safety and efficacy of food irradiation
- Describe two microbe-based food preservatives
- Examine the packaging of food you frequently consume and assess its capacity to prevent spoilage

Foods can be preserved by a variety of methods. The goal of each method is to eliminate or reduce the populations of spoilage and disease-causing microorganisms while maintaining food quality. We now briefly discuss some of these techniques.

Filtration

Microorganisms can be removed from water, wine, beer, juices, soft drinks, and other liquids by filtration. This can keep bacterial populations low or eliminate them entirely. Removal of large particulates by prefiltration and centrifugation maximizes filter life and effectiveness. Several major brands of beer are filtered rather than pasteurized to better preserve flavor and aroma.

Low Temperature

Refrigeration at 5°C retards microbial growth, although with extended storage, microorganisms eventually grow and produce spoilage. Of particular concern is the growth of *Listeria monocytogenes,* which can grow at temperatures used for refrigeration. It should be kept in mind that refrigeration slows the metabolic activity of most microbes, but it does not lead to significant decreases in existing microbial populations.

High Temperature

Controlling microbial populations in foods by means of high temperatures can significantly limit disease transmission and spoilage. Heating processes, first used by Nicholas Appert in 1809, provide a safe means of preserving foods, particularly when carried out in commercial canning operations (**figure 41.4**). Canned food is heated in special containers called retorts at about 115°C for intervals ranging from 25 to over 100 minutes. The precise time and temperature depend on the nature of the food. Sometimes canning does not kill all microorganisms but only those that will spoil the food, because growth of remaining bacteria is inhibited by an intrinsic property of the food, such as pH. After heat treatment, cans are cooled as rapidly as possible, usually with cold water. ⏮ *Physical control methods alter microorganisms to make them nonviable (section 8.4)*

Despite efforts to eliminate spoilage microorganisms during canning, canned foods may become spoiled. This may be due to spoilage before canning, underprocessing during canning, and leakage of contaminated water through seams during cooling. Spoiled canned food is often recognized by changes in color, texture, odor, and taste (although sampling is not advisable). Organic acids, sulfides, and gases (particularly CO_2 and H_2S) may be produced. If spoilage microorganisms produce gas, both ends of the can will bulge outward. Sometimes the swollen ends can be moved by thumb pressure (soft swells); in other cases, the gas pressure is so great that the ends cannot be dented by hand (hard swells). However, swelling is not always due to microbial

Figure 41.4 Food Preparation for Canning. Microbial control is important in processing and preserving many foods. Here a worker is pouring peas into a large, clean vat during the preparation of vegetable soup. After preparation, the soup is transferred to cans. Each can is heated for a short period, sealed, processed at temperatures from 110 to 121°C in a canning retort to destroy spoilage microorganisms, and finally cooled.

MICRO INQUIRY *Canned products such as vegetable soup often contain salt. Other than serving as a flavoring, what is the purpose of salt in the canned product?*

Table 41.2 Methods of Pasteurization

Type of Pasteurization	Temperature and Duration of Heating	Products Pasteurized
Low-temperature holding (LTH)	68.2°C, 30 minutes	Beer, fruit juice, smaller volumes of milk
High-temperature short-time (HTST)	72°C, 15 seconds	Industry standard for milk and other dairy products in the United States
Ultra-high temperature (UHT)	138°C, 3 seconds	Milk that does not require refrigeration until opened

spoilage; acid in low pH foods may react with iron in the can to release hydrogen and generate a hydrogen swell.

Pasteurization involves heating food to a temperature that kills disease-causing microorganisms and substantially reduces the levels of spoilage organisms. There are three types of pasteurization, which differ by temperature and length of time the product is heated (**table 41.2**). Shorter-term processing results in improved flavor and extended product shelf life. These require stainless steel heat exchangers specifically designed to rapidly heat and cool the liquid being pasteurized. The duration of pasteurization is based on the statistical probability that the number of remaining viable microorganisms will be below a certain level after a particular heating time at a specific temperature. These calculations are discussed in detail in section 8.4. *Food Pathogens and Temperature*

Water Availability

The presence and availability of water also affect the ability of microorganisms to colonize foods. Simply by drying a food, one can slow or prevent spoilage processes; this is commonly seen in dried fruit, which does not require refrigeration. Water can be made less available by adding solutes such as sugar and salt. Water availability is measured in terms of **water activity** (a_w). This represents the ratio of relative humidity of the air over a test solution compared with that of distilled water, which has an a_w of 1. When large quantities of salt or sugar are added to food, most microorganisms are dehydrated by the hypertonic conditions and cannot grow. Even under these adverse conditions, osmophilic and xerophilic microorganisms may spoil food. In contrast to most spoilage bacteria that thrive at an a_w of about 0.9, these microbes grow best at an a_w of 0.6 to 0.7. Osmophilic (Greek *osmus,* impulse, and *philein,* to love) microbes grow best in or on media with a high osmotic concentration (e.g., jams and jellies), whereas xerophilic (Greek *xerosis,* dry, and *philein,* to love) microorganisms thrive in low a_w environments (e.g., cereals) and may not grow under high a_w conditions. Dehydration, such as lyophilization to produce freeze-dried foods, is a common means of preventing microbial growth. Freeze-drying increases the osmolarity of the product while at the same time reducing the a_w so microbial growth is retarded.

Chemical-Based Preservation

Various chemical agents can be used to preserve foods; these substances are closely regulated by the U.S. Food and Drug Administration (FDA) and are listed as being "*g*enerally *r*ecognized *a*s *s*afe" or **GRAS** (**table 41.3**). They include simple organic acids, sulfite, ethylene oxide as a gas sterilant, sodium nitrite, and ethyl formate. These chemical agents may damage the microbial plasma membrane or denature various cell proteins. Other compounds interfere with the functioning of nucleic acids, thus inhibiting cell reproduction.

Sodium nitrite is an important chemical used to help preserve ham, sausage, bacon, and other cured meats by inhibiting the growth of *Clostridium botulinum* and the germination of its spores. This protects against botulism and reduces the rate of spoilage. Besides increasing meat safety, nitrite decomposes to nitric acid, which reacts with heme pigments to keep the meat red in color. However there is concern about nitrite because it can react with amines to form carcinogenic nitrosamines. *Botulism (section 39.4)*

Low pH can also be used to hinder microbial spoilage. For example, acetic and lactic acids inhibit growth of *Listeria monocytogenes* Organic acids (1–3%) can be used to treat meat carcasses, and poultry can be cleansed with 10% lactic acid/sodium lactate buffer (pH 3) prior to packaging. In addition, low pH can increase the activity of other chemical preservatives. Sodium propionate is most effective at lower pH values, where it is primarily undissociated. Breads, with their low pH values, often contain sodium propionate as a preservative. The use of citric acid is also common. *Organic acids (section 42.1)*

High Hydrostatic Pressure

In the last decade, the use of high hydrostatic pressure (HHP) has grown as an alternative way to preserve food. HHP is the application of pressures from 100 to 800 millipascals (mPa) without significant changes in temperature. Pressures typically range from 350 to 600 mPa for 5 to 15 minutes at temperatures from 5 to 35°C. HHP is most detrimental to cell membranes, thus eukaryotic microbes are more susceptible. Predictably, Gram-positive bacteria, particularly endospores, are harder to kill than Gram-negative bacteria. At present, there is no industry standard for the HHP conditions that are considered effective for various foods and their microbial contaminants.

Radiation

Although the public is wary of food radiation, it is an effective way to prevent food spoilage. Unfortunately, there is the common misperception that food becomes radioactive upon radiation.

Table 41.3 Major Groups of Chemicals Used in Food Preservation

Preservatives	Approximate Maximum Use	Organisms Affected	Foods
Benzoic acid/benzoates	0.1%	Yeasts and molds	Margarine, pickle relishes, apple cider, soft drinks, tomato ketchup, salad dressings
Dehydroacetic acid	65 ppm	Insects	Pesticide on strawberries, squash
Ethylene/propylene oxides	700 ppm	Yeasts, molds, vermin	Fumigant for spices, nuts
Ethyl formate	15–200 ppm	Yeasts and molds	Dried fruits, nuts
Parabens[1]	0.1%	Yeasts and molds	Bakery products, soft drinks, pickles, salad dressings
Propionic acid/propionates	0.32%	Molds	Bread, cakes, some cheeses; inhibitor of ropy bread dough
Sodium diacetate	0.32%	Molds	Bread
Sodium nitrite	120 ppm	Clostridia	Cold cuts, hot dogs, sausages
Sorbic acid/sorbates	0.2%	Molds	Hard cheeses, figs, syrups, salad dressings, jellies, cakes
SO_2/sulfites	200–300 ppm	Insects and microorganisms	Molasses, dried fruits, wine, lemon juice (not used in meats or other foods recognized as sources of thiamine)

1 *Methyl, propyl, and heptyl esters of p-hydroxybenzoic acid.*

This would be similar to thinking that you become radioactive following a chest or dental X ray. ⏮ *Radiation (section 8.4)*

Gamma irradiation of food most often uses a cobalt-60 source; however, cesium-137 is employed in some facilities. Gamma radiation has excellent penetrating power but must be used with moist foods because radiation is effective only if it generates reactive oxygen species from water in the microbial cells, resulting in oxidation of nucleic acids, lipids, and proteins. This process of **radappertization,** named after Nicholas Appert, can extend the shelf life of seafoods, fruits, and vegetables. Unlike canning, radappertization does not heat the food product. To sterilize meat products, 4.5 to 5.6 megarads are commonly used.

Microbial Product–Based Inhibition

Interest is increasing in the use of bacteriocins for the preservation of foods. **Bacteriocins** are proteins secreted by certain bacteria that kill closely related microbes by binding to specific sites on the target cell. They often affect plasma membrane integrity and function. The only bacteriocin currently approved for food preservation is nisin, a small amphiphilic peptide produced by some strains of *Lactococcus lactis.* It is nontoxic to humans and affects Gram-positive bacteria by binding to lipid II during peptidoglycan synthesis and forming pores in the plasma membrane (*see figure 12.10*). Nisin was added to the GRAS list of food additives about 45 years ago. This means that it can be added directly to foods such as packaged meats, cheese, eggs, and canned vegetables. Nisin is effective in low-acid foods, where it improves inactivation of *Clostridium botulinum* during the canning process and inhibits germination of any surviving spores. ⏮ *Bacteriocins (section 33.3)*

Interestingly, a preparation of six strains of **bacteriophages** that specifically infect and kill *Listeria monocytogenes* is used to spray ready-to-eat meats such as hot dogs and lunch meats. The spray is applied to the surface of the meats prior to packaging. The phages are present in equal concentration; using multiple phage types significantly reduces the development of phage-resistant strains.

Packaging

Gases present in the atmosphere within a food storage package can have a significant affect on microbial growth. This has led to the development of **modified atmosphere packaging** (**MAP**). Modern shrink-wrap materials and vacuum technology make it possible to package foods with controlled atmospheres. These materials are largely impermeable to oxygen. This prolongs shelf life by a factor of two to five times compared to the same product packaged in air. With a CO_2 content of 60% or greater in the atmosphere surrounding a food, spoilage fungi will not grow, even if low levels of oxygen are present. High-oxygen MAP is also effective because it triggers the formation of superoxide anions within microbial cells. Some products currently packaged using MAP technology include delicatessen meats and cheeses, pizza, grated cheese, some bakery items, and dried products such as coffee.

Retrieve, Infer, Apply

1. Describe the major approaches used in food preservation.
2. What types of chemicals can be used to preserve foods?
3. What cellular component does HHP target? What is radappertization?
4. How does nisin function? What bacterial genus produces this important peptide?
5. Consider the fact that *Listeria* phages must be propagated in the pathogen prior to producing an anti-*Listeria* spray. What safeguards do you think must be instituted to ensure the safety of the spray?
6. What are the major gases involved in MAP? How are their concentrations varied to inhibit microbial growth?

41.3 Food-Borne Disease Outbreaks

After reading this section, you should be able to:

- Summarize a major food-borne infection that had substantial health and economic consequences
- Describe the origin and consequences of a major food intoxication event in the United States
- Explain why these cases of food-borne disease outbreaks serve as cautionary tales for government regulatory agencies, food producers, and consumers
- Contrast and compare aflatoxins and fumonisins

Most food-borne illnesses are neither recognized nor reported. The source and the identity of a food pathogen are only discovered if it causes an illness dire enough that the victim visits a physician or hospital. That said, the Centers for Disease Control and Prevention (CDC) estimates that are about 48 million cases of food-related illness annually in the United States, 128,000 hospitalizations, and about 3,000 deaths. Of these, only 14 million can be attributed to known pathogens. *Salmonella enterica* serovars causes the most reported illnesses, while noroviruses, *Campylobacter jejuni, Escherichia coli* O157:H7, and *Listeria monocytogenes* are other major causes of food-borne diseases. ⏮ *Food and water are vehicles for viral diseases (section 38.4); Food and water are vehicles for bacterial diseases (section 39.4)*

All food-borne illnesses are transmitted by the fecal-oral route. While the "4-Fs"—feces, fingers, food, and flies—are critical for fecal-oral transmission, fomites, such as faucets, drinking cups, and cutting boards, also play a role in the maintenance of the fecal-oral route of contamination. Here we review several major outbreaks of food-borne diseases that illustrate the personal, economic, and societal impacts of tainted food. We divide our coverage into the two primary types of food-related diseases: food-borne infections and food intoxications. The individual food-borne diseases are covered in sections 38.4, 39.4, and 40.5.

Food-Borne Infection

A **food-borne infection** involves ingestion of the pathogen, followed by its growth in the host, including tissue invasion or the release of toxins. The most common microbes involved are summarized in **table 41.4** (*also see table 39.3*).

Listeriosis, caused by *Listeria monocytogenes,* was responsible for the largest meat recall in U.S. history. In 2002 a seven-state listeriosis outbreak was linked to deli meats and hot dogs produced at a single meat-processing plant in Pennsylvania. Pregnant women, the young and the old, and immunocompromised individuals are especially vulnerable to *L. monocytogenes* infections. In this outbreak, 7 deaths, 3 stillbirths, and 46 illnesses were caused by consumption of contaminated meats. Microbiologists matched the strain of *L. monocytogenes* found in the contaminated food products with samples obtained from floor drains in a Wampler, Inc., packaging plant. This prompted the recall of 27.4 million pounds of meats that had been distributed over a 5-month period to stores, restaurants, and school lunch programs. Following the outbreak, the plant closed for a month and the Wampler brand name was phased out. This episode prompted the U.S. Department of Agriculture (USDA) to step up its environmental testing program for *L. monocytogenes* so that it now tests plants that do not regularly submit data to the USDA. It also performs surprise inspections of those that do. The USDA advises people at risk of contracting listeriosis to avoid eating soft cheeses (e.g., feta, Brie, Camembert), refrigerated smoked meats such as lox, as well as deli meats and undercooked hot dogs. In 2006 the Wampler plant in Pennsylvania was closed, having never recovered from the $100 million cost and the damage to its reputation caused by the 2002 outbreak. Thus a single outbreak resulted in death, illness, bankruptcy, and changes to food safety inspection policy.

Food Intoxication

Microbial growth in food products also can result in **food intoxication** (table 41.4). Intoxication produces symptoms shortly after the food is consumed because growth of the disease-causing microorganism is not required. The classic example is picnickers vomiting 4 to 6 hours after consuming salad contaminated with *Staphylococcus aureus* enterotoxin. While in this case, the consumption of *S. aureus* cells is not necessary, toxins produced in the food can be associated with microbial cells or can be released by microbes growing in the host. Thus the division between food-borne infection and intoxication is not always clear-cut.

For example, the enterohemorrhagic microbe *E. coli* O157:H7 blurs the line between infection and intoxication as the microbe must first replicate in the host before sufficient toxin is produced to cause illness. *E. coli* O157:H7 produces a toxin known as Shiga-like toxin, which is responsible for a potentially life-threatening complication known as hemolytic uremic syndrome, most commonly seen in children and the elderly. The first U.S. outbreaks of *E. coli* O157:H7 (in the 1980s) occurred in individuals who had consumed undercooked hamburgers. This microbe

Table 41.4 Some Food-Borne Bacteria That Cause Acute Bacterial Vomiting and Diarrhea

Organism	Incubation Period (Hours)	Vomiting	Diarrhea	Fever	Food Source
Staphylococcus aureus	1–6	+++[1]	+	Rare	Meats, cold cuts, and salads (e.g., tuna, egg, pasta), cream-filled bakery goods
Bacillus cereus	1–6 (intoxication); 8–16 (infection)	+++	++	–[2]	Reheated fried rice, sprouts, cucumber
Clostridium perfringens	8–16	±[3]	+++	–	Rewarmed meat dishes
Clostridium botulinum	18–24	±	Rare	–	Canned goods contaminated during processing or packaging, raw honey
Escherichia coli (enterohemorrhagic)	3–5 days	±	++	±	Undercooked hamburger, unpasteurized fruit juices, raw vegetables
Escherichia coli (enterotoxigenic strain)	16–72	±	++	–	Contaminated drinking water; major cause of traveler's diarrhea.
Vibrio parahaemolyticus	6–96	+	++	±	Shellfish, particularly clams and oysters
Vibrio cholerae	24–72	+	+++	–	Contaminated water; shellfish
Shigella spp.	24–72	±	++	+	Salads, sandwiches, produce, contaminated water
Salmonella spp. (gastroenteritis)	8–48	±	++	+	Poultry, eggs, meats, dairy, produce, peanut butter
Salmonella enterica serovar Typhi (typhoid fever)	10–14 days	±	±	++	Spread from a healthy carrier to food via fecal-oral transmission.
Campylobacter jejuni	2–10 days	–	+++	++	Poultry, produce, raw milk
Yersinia enterocolitica	3–14 days	±	+	+	Pork, milk

inhabits the intestines of a variety of mammals, and ground beef contaminated with cattle feces during slaughter and processing continues to be a common cause of these outbreaks. ◀◀ Escherichia coli *gastroenteritis (section 39.4)*

More recently other types of foods have been found to be contaminated with *E. coli* O157:H7. One example is minimally processed, ready-to-eat fresh salad greens, which have become a popular convenience and represent a multibillion-dollar business in the United States and Europe. The produce is repeatedly washed, then dried and packed into plastic bags. When transported, the produce must be kept cool. Unfortunately, this healthy approach to consuming vegetables is not always without risk. In the past decade, over a dozen outbreaks of enterohemorrhagic *E. coli* O157:H7 were traced to minimally processed produce. The largest and most well publicized was a spinach-associated outbreak in 2006, which sickened more than 200 people. This outbreak prompted intense investigation, and it was determined that contamination occurred while the spinach was still in the field. Surveillance studies determined that the most likely source was feral swine that burrowed under fences and traveled across the spinach fields. This finding raises more questions than it answers, including: how can thousands of agricultural fields be protected from wild animals; why didn't the postharvest washing procedure cleanse the spinach of the *E. coli*; and what factors were in play that allowed the initial bacterial inoculum on the plants to grow by at least a factor of 10? This single event prompted efforts by both government and industry to ensure that minimally processed produce remains a convenience, not a sporadic source of disease.

Three Gram-positive, endospore-forming rods are important sources of food intoxications and infections: *Clostridium botulinum, C. perfringens,* and *Bacillus cereus*. *C. botulinum* intoxication is discussed in chapter 39. There are typically 30 or fewer cases of botulism reported each year in the United States, and most are associated with home canning. *C. perfringens* typically causes a 24-hour infection. It has a relatively high infectious dose (10^8 cells) and results in abdominal cramps and diarrhea 8 to 22 hours after consumption. *B. cereus* causes two types of intoxication, each the result of a different toxin. Food poisoning

following ingestion of *B. cereus*–contaminated meats, fish, or vegetables can cause a diarrheal illness that is very similar to that of *C. perfringens*. *B. cereus* intoxication, characterized by acute (less than 24 hours) vomiting, is generally associated with consumption of contaminated starchy foods such as rice or pastries.

Some fungus-derived toxins have a more insidious health effect. The most potent are the fungal carcinogens aflatoxins and fumonisins. **Aflatoxins** are produced by *Aspergillis flavus* and *A. parasiticus*. These fungi grow and release toxin in moist grains and nuts. Aflatoxin consumption is most common in developing countries where these products are stored in suboptimal conditions and are consumed with little or no post-harvest processing. Aflatoxins are planar, ringed compounds that wedge between strands of DNA (intercalate), thereby causing frameshift mutations that can cause cancer. This occurs primarily in the liver, where they are converted to unstable derivatives. Currently a total of 18 aflatoxins are known. The most important are shown in **figure 41.5**. Of these, aflatoxin B_1 is the most common and the most potent carcinogen. After ingestion by lactating animals (e.g., dairy cows), aflatoxins B_1 and B_2 are modified in the liver to yield the aflatoxins M_1 and M_2. If cattle consume aflatoxin-contaminated feeds, aflatoxins can contaminate milk and dairy products. Besides their importance in grains, aflatoxins have also been found in beer, cocoa, raisins, peanut butter, and soybean meal.

Diet appears to be related to aflatoxin exposure: the average aflatoxin intake in the typical European-style diet is 19 ng/day, whereas for some Asian diets it is estimated to be 103 ng/day. Aflatoxin sensitivity also can be influenced by prior disease exposure. Individuals who have had hepatitis B have a 30-fold higher risk of liver cancer upon exposure to aflatoxins than individuals who have never had this disease. It has been observed that prevention of hepatitis B infections by vaccination and reduction of carrier populations help control the potential effects of aflatoxins.

The **fumonisins** are fungal contaminants of corn that were first isolated in 1988. They are produced by *Fusarium moniliforme* and cause leukoencephalomalacia in horses (also called "blind staggers"—it is fatal within 2 to 3 days), pulmonary edema in pigs, and esophageal cancer in humans. Fumonisins inhibit ceramide synthase, a key enzyme for the proper use of fatty substances in the cell. This disrupts synthesis and metabolism of sphingolipids, important compounds that influence a wide variety of cell functions. At least 10 different fumonisins exist; the basic structures of fumonisins FB1 and FB2 are shown in **figure 41.6**. Corn and corn-based feeds and foods, including cornmeal and corn grits, can be contaminated. Thus it is extremely important to store corn and corn products under dry conditions, where these fungi cannot develop.

Other eukaryotic microorganisms also synthesize potent toxins. For example, algal toxins contaminate fish and thereby affect the health of marine animals higher in the food chain; they also contaminate shellfish and finfish, which are later consumed by humans. These toxins are produced during harmful algal blooms, as discussed in section 30.2.

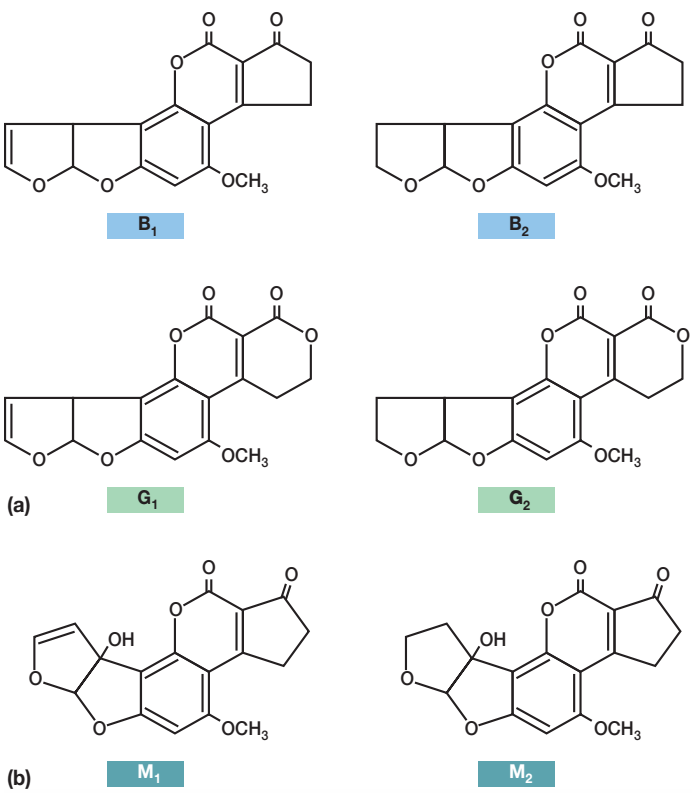

Figure 41.5 Aflatoxins. When *Aspergillus flavus* and related fungi grow on foods, carcinogenic aflatoxins can be formed. These have four basic structures. (a) The letter designations refer to the color of the compounds under ultraviolet light after extraction from the grain and separation by chromatography. The B_1 and B_2 compounds fluoresce with a blue color, and the G_1 and G_2 appear green. (b) The two type M aflatoxins are found in the milk of lactating animals that have ingested type B aflatoxins.

MICRO INQUIRY *What foods are most prone to aflatoxin contamination?*

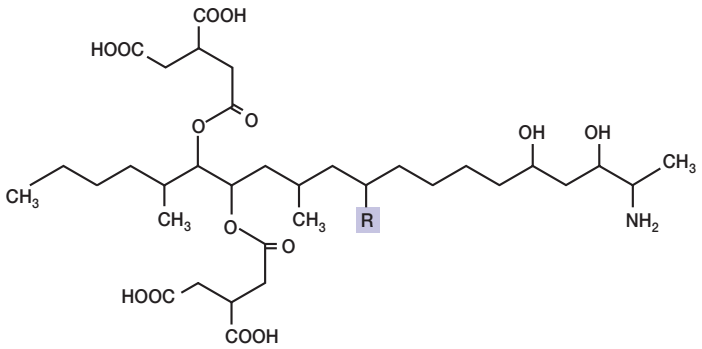

Figure 41.6 Fumonisin Structure. The basic structure of fumonisins FB1 and FB2 produced by *Fusarium moniliforme,* a fungal contaminant that can grow in improperly stored corn. A total of at least 10 different fumonisins have been isolated. These are strongly polar compounds that cause diseases in domestic animals and humans. FB1, R = OH; FB2, R = H.

1. What is the difference between a food-borne infection and a food intoxication? Which do you think is harder to prevent? Explain your answer.
2. What practical recommendations regarding food preparation could you make to someone concerned about *E. coli* O157:H7 contamination?
3. Aflatoxins are produced by members of which fungal genus? How do they damage animals that eat the contaminated food?
4. Members of what microbial genus produce fumonisins and why are these compounds of concern? If improperly stored, what are the major foods and feeds in which these chemicals might be found?

41.4 Detection of Food-Borne Pathogens Requires Government-Industry Cooperation

After reading this section, you should be able to:

- List the principles that guide the development of food testing strategies
- Describe how a food-borne pathogen consumed by an individual might be traced back to the food source

In 1905 Upton Sinclair's novel *The Jungle* exposed the horrific state of the meat packaging industry. The following year, the first in a series of federal and state laws was enacted in the United States aimed at improving safety of the food supply. In 2001 the FDA Food Safety Modernization Act was passed. This was the first major piece of food safety legislation to be enacted since 1938. It has a number of key provisions; the goal is to change the focus of federal regulators from responding to food contamination to preventing it. Although most look to the government to keep food safe, food safety is a shared responsibility, as precautions must be defined and in place during production, transport, sale, and consumption of any food item. The length and complexity of the chain from producer to consumer has increased dramatically in the last 20 years with the rise in food imports and exports, making ensuring food safety even more complicated.

Here we provide a broad overview of food pathogen detection. Unfortunately it is impossible to test each food item for every potential pathogen. Apart from the logistical implications, such an approach is economically untenable. For example, if the U.S. dairy industry were to test all dairy products daily at each farm with a $5-per-sample assay, it would cost about $150 million annually. Checking each milk tanker truck as it enters a processing plant reduces the cost to about $21 million—a savings of $129 million each year. So the challenge in developing a testing strategy involves identifying which pathogens to detect, as well as when and where to detect them.

Several principles guide the development of the technologies, protocols, and policies used to keep foods safe. These include (1) specificity and sensitivity for the given pathogen—any given test should not have a high level of false negatives or positives (specificity) and the pathogen in question should be detected even in low concentrations (sensitivity); (2) speed, which is particularly important for fresh produce awaiting distribution; and (3) simplicity: foods should be tested with limited sample preparation. Furthermore, the goal of each detection strategy should be clearly defined. Ideally "testing to prevent," that is, to confirm food is safe before it leaves the farm or processing plant, is the goal. When this is unreasonable due to logistics and cost, then the next level is "testing to protect," which involves analysis before the food is accessible for consumption. These strategies are designed to avoid "testing to recover," when an outbreak has occurred and the origin of the contaminated food must be identified.

The most common approach to detecting food-borne pathogens involves using selective media to culture the microbe followed by the use of biochemical and/or immunological assays for strain identification. Fluorescent antibody tagging and *e*nzyme-*l*inked *i*mmuno*s*orbant *a*ssays (ELISAs; *see figure 36.12*) are frequently employed. A variety of molecular methods are also used. Unlike culture-based assays, molecular techniques can detect viruses that cannot be grown conveniently, microbes that are present in very small numbers, and slow-growing or nonculturable pathogens. In addition, results are usually obtained much faster. For instance, although the important pathogen *E. coli* O157:H7 can be isolated and identified using selective culture media, the application of multilocus sequence typing, serotype-specific probes, and polymerase chain reaction (PCR) enables the rapid detection of a few target cells in large populations of background microorganisms. Several molecular techniques have been specifically developed to ensure food safety; here we mention three. (1) PCR has been combined with restriction fragment length polymorphism (RFLP) analysis. Here, rather than visualizing genomic fragments that have been cleaved, PCR amplifies the variable regions to generate a cleaner genomic fingerprint in a relatively short period of time. (2) Pathogen-specific PCR primers. For instance, different species of *Campylobacter* can be detected by amplifying a region of the gene encoding gyrase B. (3) Microarray technology in which oligonucleotides representing housekeeping and virulence genes are used as probes to which DNA extracted directly from the food item can be hybridized. Note that unlike most microarray procedures, it is not necessary to make cDNA from mRNA because one is looking only for the presence or absence of a given pathogen's genome, not relative levels of gene expression. Microarrays are especially attractive because, unlike some other molecular techniques, there is no need to first enrich for the pathogen by culture-based techniques. ⏮ *Polymerase chain reaction amplifies targeted DNA (section 17.2); Transcriptome analysis (section 18.5); Microbial taxonomy and phylogeny are largely based on molecular characterization (section 19.3)*

The CDC oversees a program called **PulseNet** for the early detection of food-borne pathogens, particularly during an

Figure 41.7 PulseNet. This network operates throughout the United States to identify microbes causing food-borne disease using pulsed-field gel electrophoresis of genomes extracted from contaminating microbes. Shown here, a food microbiologist examines the electrophoretic pattern, or fingerprint, generated by a bacterial pathogen.

MICRO INQUIRY *Why is it important that PulseNet coordinate the identities of food-borne pathogens on a national level?*

outbreak. The basis for this program is the use of pulsed-field gel electrophoresis (PFGE) under carefully controlled and duplicated conditions. PFGE generates a strain-specific DNA electrophoresis pattern, or fingerprint, for each bacterial pathogen (**figure 41.7**). PFGE is similar to standard DNA gel electrophoresis but is capable of separating very large fragments of DNA. This requires periodic switching of the voltage supply in three different directions: the central axis of the gel and two that run at a 120° angle on either side. The duration of each pulse is the same but can be increased over the duration of the run. Because PFGE can resolve large (Mb) pieces of DNA, whole genomes can be cut with restriction enzymes that cleave in only a few places to generate a DNA fingerprint. The patterns obtained for each strain of food-borne pathogen are found in a national database maintained by the CDC. This enables strain-specific identification of new isolates through comparison with the database. ⏮ *Restriction enzymes (section 17.1); Gel electrophoresis (section 17.1)*

PulseNet also fosters real-time communication between community, state, and federal health agencies. With this uniform procedure, it is possible to link pathogens associated with disease outbreaks in different parts of the world to a specific food source. For example, a *Shigella* outbreak in three different areas of North America was traced to Mexican parsley that had been tainted with polluted irrigation water. This program has resulted in the rapid establishment of epidemiological linkages, thereby decreasing additional cases of food-borne disease.

The 2011 outbreak of a novel *E. coli* pathogen in Germany brought the detection and analysis of food-borne pathogens into the twenty-first century. In less than a month, the entire genomes of several *E. coli* O104:H4 strains recovered from patients were sequenced using next-generation sequencing techniques. This outbreak illustrates that the pressing need for food safety combined with the rapid pace of innovation ensures the introduction of newer, faster, and highly accurate techniques will continue. ⏮ *Next-generation DNA sequencing (section 18.1);* Escherichia coli *gastroenteritis (section 39.4)*

1. How are most food-borne pathogens detected?
2. Why is it advantageous to omit the pre-enrichment step in microarray and PCR-based approaches?
3. How is PulseNet used in the surveillance of food-borne diseases?
4. Compare how you might implement the testing of a meat product (e.g., hot dogs) with that of a vegetable (e.g., spinach). Consider the pathogen(s) to be detected, in addition to when and where testing should occur.

41.5 Microbiology of Fermented Foods: Beer, Cheese, and Much More

After reading this section, you should be able to:

- Compare and contrast mesophilic and thermophilic fermentations
- Differentiate between a yeast-lactic and a mold-lactic fermentation
- Outline the process by which cheese is made
- List some fermented meats
- Provide an overview of the production of wine, champagne, beer, and distilled spirits.
- Describe a fermented food item not commonly eaten in the United States

Fermentation has been used to process food for thousands of years; the earliest records date as far back as 6,000 BCE. Microbial growth, either of natural or inoculated populations, causes chemical or textural changes to form a product that can be stored for extended periods. The fermentation process also is used to create pleasing food flavors and odors—such as cheese, yogurt, and chocolate (**Techniques & Applications 41.1**).

The major fermentations used in food microbiology (which are named by their principle end product) are lactic, propionic, and alcoholic fermentations. These fermentations are carried out by a wide range of microbes, many of which have not been characterized. ⏮ *Fermentation does not involve an electron transport chain (section 11.8)*

Fermented Milks

Although we are most familiar with yogurt, at least 400 different fermented milks are produced around the world. The majority of fermented milk products rely on **lactic acid bacteria** (**LAB**),

TECHNIQUES & APPLICATIONS

41.1 Chocolate: The Sweet Side of Fermentation

Chocolate could be characterized as the "world's favorite food," but few people realize that fermentation is an essential part of chocolate production. The Aztecs were the first to develop chocolate fermentation, serving a chocolate drink made from the seeds of the chocolate tree, *Theobroma cacao* (Greek *theos,* god, and *broma,* food, or "food of the gods"). Chocolate trees now grow in Africa as well as South America.

The process of chocolate fermentation has changed very little over the past 500 years. Each tree produces large pods that each hold 30 to 40 seeds in a sticky pulp (**box figure**). Ripe pods are harvested and slashed open to release the pulp and seeds. The sooner the fermentation begins, the better the product, so fermentation occurs on the farm where the trees are grown. The seeds and pulp are placed in "sweat boxes" or in heaps in the ground and covered, usually with banana leaves.

Like most fermentations, this process involves a succession of microbes. First, a community of yeasts, including *Candida rugosa* and *Kluyveromyces marxianus,* hydrolyzes the pectin that covers the seeds and ferments sugars to release ethyl alcohol and CO_2. As the temperature and the alcohol concentration increase, the yeasts are inhibited and lactic acid bacteria increase in number. Lactic acid production drives the pH down, encouraging the growth of bacteria that produce acetic acid as a fermentation end product. Acetic acid is critical to the production of fine chocolate because it kills the sprout inside the seed and releases enzymes that cause further degradation of proteins and carbohydrates, contributing to the overall taste of the chocolate. In addition, acetate esters, derived from acetic acid, are important for the development of good flavor. Fermentation takes 5 to 7 days. An experienced cocoa grower knows when fermentation is complete: if it is stopped too soon, the chocolate will be bitter and astringent; if it lasts too long, microbes start growing on the seeds instead of in the pulp. "Off tastes" arise when Gram-positive bacteria in the genus *Bacillus* and filamentous fungi belonging to the genera *Aspergillus, Penicillium*, and *Mucor* hydrolyze lipids in the seeds to release short-chain fatty acids. As the pH begins to rise, bacteria of the genera *Pseudomonas, Enterobacter*, and *Escherichia* also contribute to bad tastes and odor.

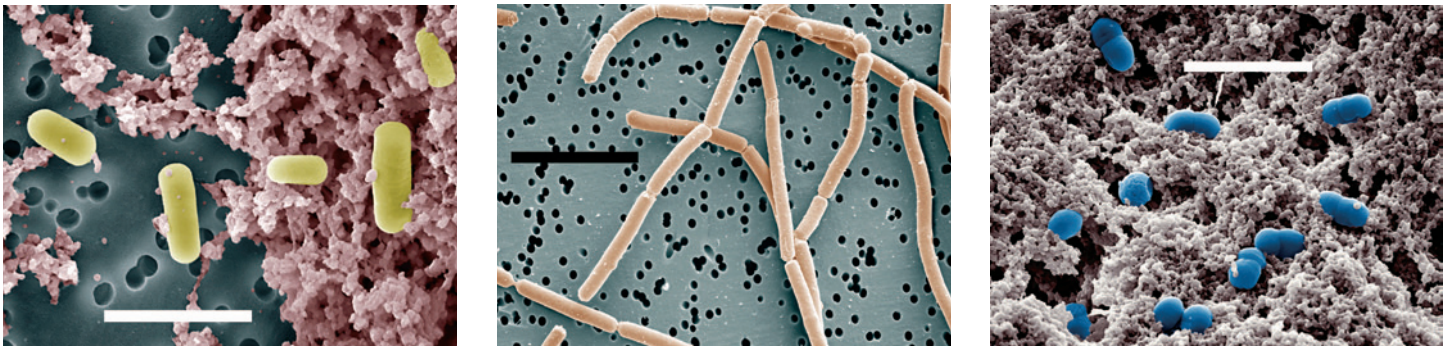
(a)

(b)

Cocoa Fermentation. (a) Cocoa pods growing on the cocoa tree. Each pod is 13 to 15 cm in length and contains 30 to 40 seeds in a sticky white pulp. (b) Seeds and pulp are fermented in boxes commonly covered with banana leaves for 5 to 7 days and then dried in the sun. Chocolate cannot be produced without fermentation.

After fermentation, the seeds, now called beans, are spread out to dry. The dried beans are brown and lack pulp. They are bagged and sold to chocolate manufacturers, who first roast the beans to further reduce the bitter taste and kill most of the microbes. The beans are then ground and the nibs—the inner part of each bean—are removed. The nibs are crushed into a thick paste called a chocolate liquor, which contains cocoa solids and cocoa butter but no alcohol. Cocoa solids are brown and have a rich flavor, and cocoa butter has a high fat content and is off-white in color. The two components are separated, and the cocoa solids can be sold as cocoa, while the cocoa butter is used to make white chocolate or sold to cosmetics companies for use in lipsticks and lotions. However, the bulk of these two components will be used to make chocolate. The cocoa solids and butter are reunited in controlled ratios, and sugar, vanilla, and other flavors are added. The better the fermentation, the less sugar needs to be added (and the more expensive the chocolate).

The final product, delicious chocolate, is a combination of over 300 different chemical compounds. This mixture is so complex that no one has yet been able to make synthetic chocolate that can compete with the natural fermented plant. Microbiologists and food scientists are studying the fermentation process to determine the role of each microbe. But like chemists, they have had little luck in replicating the complex, imprecise fermentation that occurs on cocoa farms. In fact, the finest, most expensive chocolate starts as cocoa on farms where the details of fermentation have been handed down through generations. Chocolate production is truly an art as well as a science, while eating it is simply divine.



(a) (b) (c)

Figure 41.8 Lactic Acid Bacteria (LAB). Colorized scanning electron micrographs of LAB used as starter cultures. (a) *Lactobacillus helveticus.* (b) *Lactobacillus delbrueckii* subspecies *bulgaricus.* (c) *Lactococcus lactis.* The bacteria are supported by filters, seen as holes in the background. Scale bar = 5 μm.

MICRO INQUIRY *Can you name at least two features that make these bacteria well suited for milk fermentations?*

which include species belonging to the genera *Lactobacillus, Lactococcus, Leuconostoc,* and *Streptococcus* (**figure 41.8**). These firmicutes tolerate acidic conditions, are nonsporing, and are aerotolerant with a strictly fermentative metabolism. ◀◀ *Order Lactobacillales (section 23.3)*

Regardless of the type of milk product, **starter cultures** of LAB are added to begin fermentation. For example, *Lactococcus lactis* and *Streptococcus cremoris* are used in cheese production and various *Leuconostoc* species are used to start buttermilk fermentation. A vexing problem for the dairy industry is the presence of bacteriophage that destroy starter cultures. Lactic acid production from a heavily phage-infected starter culture can cease within 30 minutes. Overcoming this problem has revealed that many reliable starter cultures consist of bacteria that prevent phage infection by a variety of mechanisms, such as preventing adsorption or phage DNA entry, the activity of restriction modification, or the use of a CRISPR-Cas system. Nonetheless, various phage control measures are available, and still more are in development. ◀◀ *Restriction enzymes cut DNA at specific sequences (section 17.1); The CRISPR/Cas System (section 27.2)*

Mesophilic Fermentations

Mesophilic milk fermentation results in the production of buttermilk and sour cream. This type of fermentation relies on the acidic products of fermentation to denature milk protein. To carry out the process, milk is typically inoculated with the desired starter culture and is then incubated at an optimum growth temperature (approximately 20 to 30°C). Microbial growth is stopped by cooling, and *Lactobacillus* spp. and *Lactococcus lactis* cultures are used for aroma and acid production. *Lactococcus lactis* subspecies *diacetylactis* converts CO_2 and milk citrate to diacetyl, which gives a richer, buttery flavor to the finished product.

Thermophilic Fermentations

Despite the name, thermophilic fermentations are not carried out at extremely hot temperatures, rather they are conducted around 45°C. An important example is yogurt production. In commercial production, milk is pasteurized, cooled to 43°C or lower, and inoculated with a 1:1 ratio of *Streptococcus salivarius* subspecies *thermophilus* (*S. thermophilus*) and *Lactobacillus delbrueckii* subspecies *bulgaricus* (*L. bulgaricus*). *S. thermophilus* grows more rapidly at first and renders the milk anoxic and weakly acidic. *L. bulgaricus* then acidifies the milk even more. Acting together, the two species ferment almost all of the lactose to lactic acid and flavor the yogurt with diacetyl (*S. thermophilus*) and acetaldehyde (*L. bulgaricus*). Many yogurts now contain probiotic bacterial strains (p. 944), but these do not necessarily contribute to the fermentation process. Fruits or fruit flavors are pasteurized separately and then combined with the yogurt. Freshly prepared yogurt contains about 10^9 bacteria per gram.

Yeast-Lactic Fermentation

Yeast-lactic fermentations include kefir, a product with an ethanol concentration of up to 2%. This fermented milk originated in the Caucasus Mountains and is produced east into Mongolia. Kefir products tend to be foamy due to active carbon dioxide production. This process is based on the use of kefir "grains" as a starter culture. These are coagulated lumps of casein (milk protein) that contain yeasts, lactic acid bacteria, and acetic acid bacteria, which are recovered at the end of the fermentation. Originally kefir was produced in leather sacks hung by the front door during the day, and passers-by were expected to push and knead the sack to mix and stimulate the fermentation. Fresh milk could be added occasionally to replenish nutrients and maintain activity.

Mold-Lactic Fermentation

Mold-lactic fermentation results in a unique Finnish fermented milk called *viili*. Milk is inoculated with a mixture of the fungus *Geotrichum candidum* and lactic acid bacteria. The cream rises to the surface, and after incubation at 18 to 20°C for 24 hours, lactic acid reaches a concentration of 0.9%. The fungus forms a velvety layer across the top of the final product, which also can be made with a bottom fruit layer.

Table 41.5 Major Types of Cheese and Microorganisms Used in Their Production

	CONTRIBUTING MICROORGANISMS[1]	
Cheese (Country of Origin)	Earlier Stages of Production	Later Stages of Production
Soft, unripened Cottage	*Lactococcus lactis*	*Leuconostoc cremoris*
Cream	*Lactococcus cremoris, L. diacetylactis, Streptococcus thermophilus, L. delbrueckii* subspecies *bulgaricus*	
Mozzarella (Italy)	*S. thermophilus, L. bulgaricus*	
Soft, ripened Brie (France)	*Lactococcus lactis, Lactococcus cremoris*	*Penicillium camemberti, P. candidum, Brevibacterium linens*
Camembert (France)	*L. lactis, Lactococcus cremoris*	*Penicillium camemberti, B. linens*
Semisoft Blue, Roquefort (France)	*L. lactis, Lactococcus cremoris*	*P. roqueforti*
Brick, Muenster (United States)	*L. lactis, Lactococcus cremoris*	*B. linens*
Limburger (Belgium)	*L. lactis, Lactococcus cremoris*	*B. linens*
Hard, ripened Cheddar, Colby (Britain)	*L. lactis, Lactococcus cremoris*	*Lactobacillus casei, L. plantarum*
Swiss (Switzerland)	*L. lactis, L. helveticus, S. thermophilus*	*Propionibacterium shermanii, P. freudenreichii*
Very hard, ripened Parmesan (Italy)	*L. lactis, Lactococcus cremoris, S. thermophilus*	*L. delbrueckii* subspecies *bulgaricus*

1 *Lactococcus lactis* stands for *L. lactis* subspecies *lactis*. *Lactococcus cremoris* is *L. lactis* subspecies *cremoris*, *Lactococcus diacetylactis* is *L. lactis* subspecies *diacetylactis*, and *Streptococcus thermophilus* is *Streptococcus salivarius* subspecies *thermophilus*.

Cheese Production

Cheese is one of the oldest foods, probably developed roughly 8,000 years ago. About 2,000 distinct varieties of cheese are produced throughout the world, representing approximately 20 general types (**table 41.5**).

The production of cheese varies with the type of cheese, but a general outline includes the following steps. First, the milk may be pasteurized to remove spoilage microorganisms. It must then be cooled to 32°C so that starter cultures can be added. The mixture is held at this temperature for 30 minutes. This ripening step allows fermentation to begin and the pH to decline as acidic fermentation products accumulate. Next, rennet is added; rennet is a mixture of enzymes produced by mammals to aid in the digestion of milk. Rennin is the key enzyme in rennet because it catalyzes a complex reaction that results in hydrolysis of milk protein (casein), converting the milk to solid curds. The curds set for about 30 minutes to allow the formation of a firm coagulum. Further fermentation of curds continues until the pH reaches 6.4, at which point the cheese is cut into small pieces and heated to 38°C, which helps separate remaining liquid (whey) from the curd. After the whey is completely drained from the curd, the process of cheddaring begins (**figure 41.9**). Here curd is stacked and occasionally flipped over; this process helps expel residual whey and allows further fermentation. When the curd mats, now knitted together, reach a pH of 5.1 to 5.5, they are cut into smaller pieces. Depending on what kind of cheese is being made, salt will either be added (e.g., cheddar cheese) or the cheese will be rolled in loaves and placed in a salt solution called brine (e.g., mozzarella). The next step is to take the salted cheese and form it into blocks so it can age for weeks to years. This will, in part, determine the final hardness and texture of the cheese. Finally it will be packaged or waxed (e.g., Jarlsberg cheese).

Lactococcus lactis is used as a starter culture for a number of cheeses. Starter culture density is often over 10^9 colony-forming units (CFU) per gram of cheese curd before ripening. However, the high salt, low pH, and temperatures that characterize the cheese microenvironment quickly reduce these numbers. This enables other bacteria, sometimes called nonstarter lactic

Figure 41.9 Cheddar Cheese Production. Cheddar, a village in England, has given its name to a cheese made in many parts of the world. "Cheddaring" is the process of turning and piling the curd to expel whey and develop the desired cheese texture.

acid bacteria (NSLAB), to grow; their numbers can reach 10^7 to 10^9 CFU/g after several months of aging. Thus both starter and nonstarter LAB contribute to the final taste, texture, aroma, and appearance of the cheese.

In some cases, molds are used to further enhance the cheese. Obvious examples are Roquefort and blue cheese. For these cheeses, *Penicillium roqueforti* spores are added to the curds just before final cheese processing. Sometimes the surface of an already formed cheese is inoculated at the start of ripening; for example, Camembert cheese is inoculated with spores of *Penicillium camemberti.*

Meat and Fish

A variety of meat products can be fermented: sausage, country-cured hams, salami, cervelat, Lebanon bologna, fish sauces (processed by halophilic *Bacillus* species), *izushi,* and *katsuobushi*. *Pediococcus acidilactici* and *Lactobacillus plantarum* are most often involved in sausage fermentations. *Izushi* is based on the fermentation of fresh fish, rice, and vegetables by *Lactobacillus* spp.; *katsuobushi* results from the fermentation of tuna by *Aspergillus glaucus*. These latter two fermentations originated in Japan.

Wines and Champagnes

Wine production, the focus of **enology** (Greek *oinos,* wine, and *ology,* the science of), starts with the collection of grapes, which are then crushed so the liquid, called **must,** can be fermented. Wine production concludes with a variety of storage and aging steps (**figure 41.10**). All grapes have white juices. To make a red wine, skins of red grapes are allowed to remain in contact with the must before fermentation. Wines can be produced by using the natural grape skin microorganisms, but this natural mixture of bacteria and yeasts gives unpredictable fermentation results. To avoid this, fresh must is treated with a sulfur dioxide fumigant and a desired strain of the yeast *Saccharomyces cerevisiae* or *S. ellipsoideus* is added. After inoculation, the juice is fermented

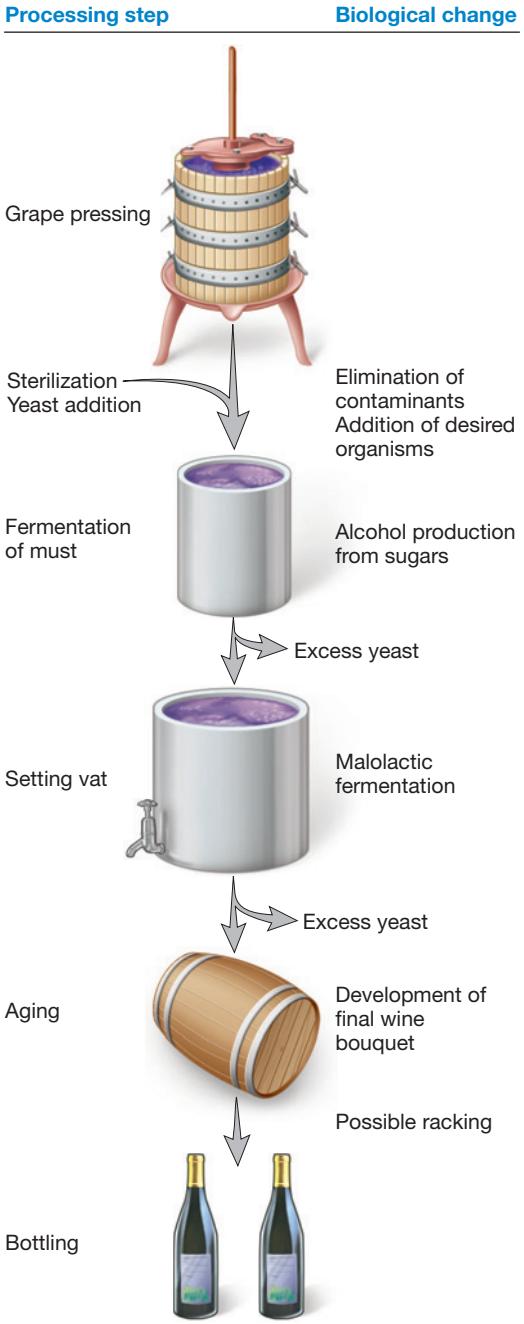

Figure 41.10 Wine Making. Once grapes are pressed, the sugars in the juice (the must) can be immediately fermented to produce wine. Must preparation, fermentation, and aging are critical steps.

for 3 to 5 days at temperatures between 20 and 28°C. Depending on the alcohol tolerance of the yeast strain (the alcohol eventually kills the yeast that produces it), the final product may contain 10 to 14% alcohol. Clearing and development of flavor occur during the aging process. Grape juice contains high levels of organic acids, including malic and tartaric acids. If the levels of these acids are not decreased during the fermentation process, the wine will be too acidic and have poor stability and "mouth feel." Malic acid levels are decreased when fermented by the bacteria *Leuconostoc oenos, L. plantarum, L. hilgardii, L. brevis*, and *L. casei*. These microbes transform malic acid (a four-carbon dicarboxylic acid) to lactic acid (a three-carbon monocarboxylic acid) and carbon dioxide. This malolactic fermentation results in deacidification, improvement of flavor stability, and, in some cases, the possible accumulation of bacteriocins in the wines. ⏮ *Fermentation does not involve an electron transport chain (section 11.8);* Ascomycota *includes yeasts and molds (section 26.5)*

A critical part of wine making involves the choice of whether to produce a dry (no remaining free sugar) or a sweeter (varying amounts of free sugar) wine. This can be controlled by regulating the initial must sugar concentration. With higher levels of sugar, alcohol will accumulate and inhibit the fermentation before the sugar is completely used, producing a sweeter wine. During final fermentation in the aging process, flavoring compounds accumulate and influence the bouquet of the wine.

Microbial growth during the fermentation process produces sediments, which are removed during **racking.** Racking can be carried out at the time the fermented wine is transferred to bottles or casks for aging or after the wine is placed in bottles.

Champagnes and sparkling wines are essentially the same product, but a champagne must be made in the Champagne region of France. They result when the fermentation is continued in bottles to produce carbon dioxide, which forms bubbles. Sediments that remain are collected in the necks of inverted champagne bottles after the bottles have been carefully turned. The necks of the bottles are then frozen and the corks removed to disgorge accumulated sediments. The bottles are refilled with clear champagne from another disgorged bottle, and the product is ready for final packaging and labeling.

Beers and Ales

Beer and ale production uses cereal grains such as barley, wheat, and rice. The first step in beer production, known as **mashing,** involves germination of the barley grains and activation of their enzymes to produce a **malt** (**figure 41.11**). The malt is then mixed with water and the desired grains, and the mixture is transferred to the mash tun or cask where the active barley enzymes hydrolyze starch to usable carbohydrates. Once this process is completed, the **mash** is heated with **hops** (dried flowers of the female vine *Humulus lupulus*), which were originally added to the mash to inhibit spoilage microorganisms. The hops also provide flavor and assist in clarification of the liquid portion called the wort (**figure 41.12**). In this heating step, the hydrolytic enzymes are inactivated and the wort can be **pitched**—inoculated—with the desired yeast.

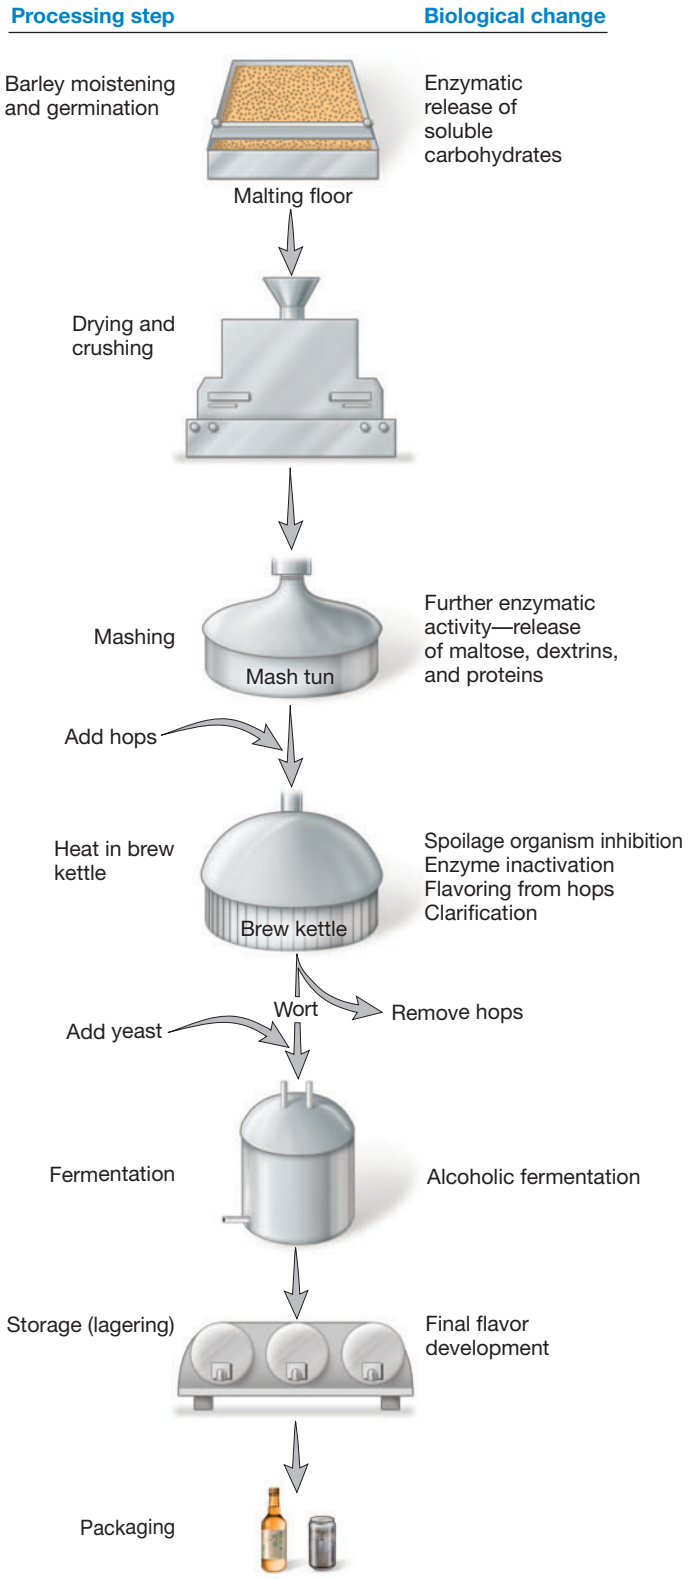

Figure 41.11 Producing Beer. To make beer, the complex carbohydrates in the grain must first be transformed into a fermentable substrate. Beer production thus requires the important steps of malting and the use of hops and boiling for clarification, flavor development, and inactivation of malting enzymes to produce the wort.

Figure 41.12 Brew Kettles Used for Preparation of Wort. In large-scale processes, copper brew kettles can be used for wort preparation, as shown here.

Most beers are fermented with bottom yeasts, related to *Saccharomyces pastorianus,* which settle at the bottom of the fermentation vat. The beer flavor also is influenced by the production of small amounts of glycerol and acetic acid. Bottom yeasts require 7 to 12 days of fermentation to produce beer with a pH of 4.1 to 4.2. With a top yeast, such as *Saccharomyces cerevisiae,* the pH is lowered to 3.8 to produce ales. Freshly fermented (green) beers are aged, and when they are bottled, CO_2 is usually added. Beer can be pasteurized at 40°C or higher or sterilized by passage through membrane filters to minimize flavor changes.

Distilled Spirits

Distilled spirits are produced by an extension of beer production processes. Rather than starting with fresh grain, a **sour mash** is used. This is the liquid fermented grain collected from a previously prepared batch of alcohol. The mash is inoculated with a homolactic (lactic acid is the major fermentation product) bacterium such as *Lactobacillus delbrueckii* subspecies *bulgaricus* (figure 41.8*b*), which can lower the mash pH to around 3.8 in 6 to 10 hours. This limits the development of undesirable organisms. It is boiled, and the volatile components are condensed to yield a product with a higher alcohol content than beer. Rye and bourbon are examples of whiskeys. Rye whiskey must contain at least 51% rye grain, and bourbon must contain at least 51% corn. Scotch whiskey is made primarily of barley. Vodka and grain alcohols are also produced by distillation. Gin is vodka to which resinous flavoring agents—often juniper berries—have been added to provide a unique aroma and flavor.

Production of Breads

Bread is one of the most ancient of human foods. The use of yeasts to leaven bread is carefully depicted in paintings from ancient Egypt, and a bakery at the Giza Pyramid area, from the year 2575 BCE, has been excavated. In bread making, yeast growth is carried out under oxic conditions. This results in increased CO_2 production and minimum alcohol accumulation. The fermentation of bread involves several steps: α- and β-amylases present in the moistened dough release maltose and glucose from starch. Then a baker's strain of the yeast *Saccharomyces cerevisiae,* which produces maltase, invertase, and zymase enzymes, is added. The CO_2 produced by the yeast results in the light texture of many breads, and traces of fermentation products contribute to the final flavor. Usually bakers add sufficient yeast to allow the bread to rise within 2 hours—the longer the rising time, the more additional growth by contaminating bacteria and fungi can occur, making the product less desirable. For instance, bread products can be spoiled by *Bacillus* species that produce ropiness. If the dough is baked after these organisms have grown, stringy and ropy bread results.

Other Fermented Foods

Many other plant products can be fermented, as summarized in **table 41.6**. These include *sufu,* which is produced by the fermentation of tofu, a chemically coagulated soybean milk product. To carry out the fermentation, the tofu curd is cut into small chunks and dipped into a solution of salt and citric acid. After the cubes are heated to pasteurize their surfaces, the fungi *Actinomucor elegans* and some *Mucor* species are added. When a white mycelium develops, the cubes, now called *pehtze,* are aged in salted rice wine. This product has achieved the status of a delicacy in many parts of Asia. Another popular product is tempeh, a soybean mash fermented by *Rhizopus* spp.

Sauerkraut or sour cabbage is produced from shredded cabbage. Usually the mixed microbial community of the cabbage is used. A concentration of 2.2 to 2.8% sodium chloride restricts the growth of Gram-negative bacteria while favoring the development of lactic acid bacteria. The primary microorganisms contributing to this product are *Leuconostoc mesenteroides* and *Lactobacillus plantarum*. A predictable microbial succession occurs in sauerkraut's development. The activities of the lactic acid–producing cocci usually cease when the acid content reaches 0.7 to 1.0%. At this point, *Lactobacillus plantarum* and *Lactobacillus brevis* continue to function. The final acidity is generally about pH 1.7, with lactic acid comprising 1.0 to 1.3% of the total acid in a satisfactory product.

Pickles are produced by placing cucumbers and components such as dill seeds in casks filled with a brine. The sodium chloride concentration begins at 5% and rises to about 16% in 6 to 9 weeks. The salt not only inhibits the growth of undesirable bacteria but also extracts water and water-soluble constituents from the cucumbers. These soluble carbohydrates are fermented to lactic acid. The fermentation, which can require 10 to 12 days, involves the growth of the Gram-positive bacteria *L. mesenteroides, Enterococcus faecalis, Pediococcus acidilactici, Lactobacillus brevis,* and *L. plantarum*. *L. plantarum* plays the dominant role in this fermentation process. Sometimes, to achieve more uniform pickle quality, natural microorganisms are first destroyed and the cucumbers are fermented using pure cultures of *P. acidilactici* and *L. plantarum*.

When grass, chopped corn, and other fresh animal feeds are stored under moist anoxic conditions, they undergo a mixed acid

Table 41.6 Fermented Foods Produced from Fruits, Vegetables, Beans, and Related Substrates

Foods	Raw Ingredients	Fermenting Microorganisms	Location
Bacteria-Fermented Foods			
Coffee	Coffee beans	*Erwinia dissolvens, Saccharomyces* spp.	Brazil, Congo, Hawaii, India
Gari	Cassava	*Corynebacterium manihot, Geotrichum* spp.	West Africa
Kimchi	Cabbage and other vegetables	Lactic acid bacteria	Korea
Ogi	Corn	*Lactobacillus plantarum, Lactococcus lactis, Z. rouxii*	Nigeria
Olives	Green olives	*Leuconostoc mesenteroides, Lactobacillus plantarum*	Worldwide
Pickles	Cucumbers	*Pediococcus cerevisiae, L. plantarum, L. brevis*	Worldwide
Poi	Taro roots	Lactic acid bacteria	Hawaii
Sauerkraut	Cabbage	*L. mesenteroides, L. plantarum, Lactobacillus brevis*	Worldwide
Mold-Fermented Foods			
Kenkey	Corn	*Aspergillus* spp., *Penicillium* spp., lactobacilli, yeasts	Ghana, Nigeria
Miso	Soybeans	*Aspergillus oryzae, Zygosaccharomyces rouxii*	Japan
Ontjom	Peanut presscake	*Neurospora sitophila*	Indonesia
Peujeum	Cassava	Molds	Indonesia
Soy sauce	Soybeans	*A. oryzae* or *A. soyae, Z. rouxii, Lactobacillus delbrueckii*	Japan
Sufu	Soybeans	*Actinimucor elegans, Mucor* spp.	China
Tao-si	Soybeans	*A. oryzae*	Philippines
Tempeh	Soybeans	*Rhizopus oligosporus, R. oryzae*	Indonesia, New Guinea, Surinam

fermentation that produces pleasant-smelling **silage.** Trenches or more traditional vertical steel or concrete silos are used to store silage. The accumulation of organic acids in silage can cause rapid deterioration of silos. Older wooden stave silos, if not properly maintained, allow the outer portions of the silage to become oxic, resulting in spoilage of a large portion of the plant material.

41.6 Probiotics

After reading this section, you should be able to:

- Describe how a food is classified as a probiotic and identify two microorganisms used in probiotic foods

The health benefits of fermented foods such as yogurt, which commonly contain bacteria in the genera *Lactobacillus* and *Bifidobacterium,* have been touted for many years. Recent advances in understanding the human gut microbiome show that specific microbial products, often attributed to these bacteria, have a profound influence on immune system function. For example, lactobacilli and bifidobacteria stimulate immune maturation and minimize inflammation. Other health benefits attributed to the consumption of fermented milks involve minimizing lactose intolerance, lowering serum cholesterol, and possibly protecting against colon cancer. Several lactobacilli have antitumor compounds in their cell walls. With only a few exceptions, our increased understanding of the human microbiome has yet to translate into clinically tested probiotic foods or treatments.

|◀◀ *The human-microbe* ecosystem *(section 32.2)*

The enormous volume of research currently performed on the human microbiome and the media attention it has received have helped fuel explosive growth in the probiotic food and supplement market. However, most consumers are unaware that the term "probiotic" is not regulated. In an effort to standardize the use of the term **probiotic,** the Food and Agricultural Organization of the United Nations–World Health Organization (FAO-WHO) has defined it as "live microorganisms, which, when administered in adequate amounts, confer a health benefit to the host." FAO-WHO guidelines published in 2002 provide specific requirements that should be met for products to meet this standard (**figure 41.13**).

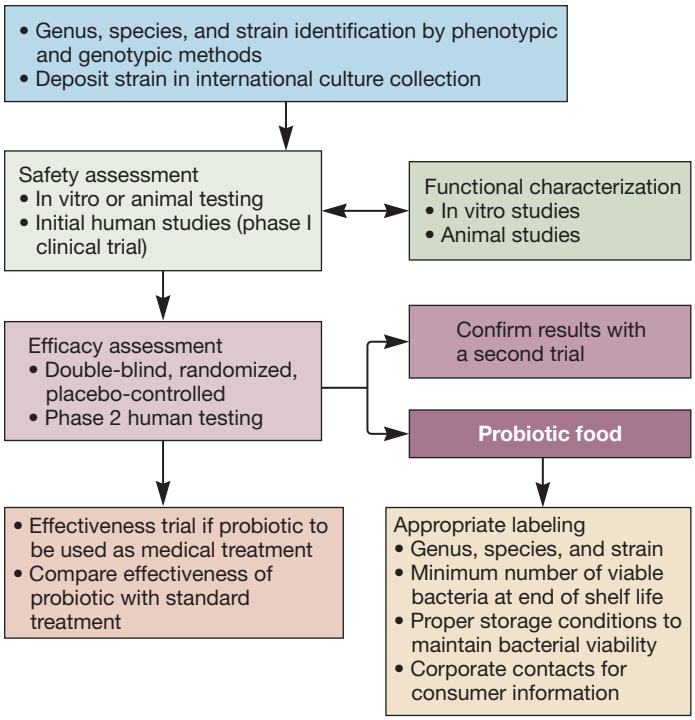

Figure 41.13 The Development of a Probiotic Food.

Probiotic microbes are also used to promote the health of farm animals. Such microbes, primarily *Lactobacillus acidophilus,* are used in beef cattle feed. When the bacteria are sprayed on feed, cattle that eat it appear to have markedly lower (as much as 60%) carriage of the pathogenic *E. coli* strain O157:H7. This can make it easier to produce beef that will meet current standards for microbiological quality at the time of slaughter. Probiotics are also used successfully with poultry. For instance, the USDA has designated a probiotic *Bacillus* strain for use with chickens as GRAS (p. 931). Feeding chickens a strain of *Bacillus subtilis* leads to increased body weight and feed conversion. There is also a reduction in coliforms and *Campylobacter* spp. in the processed carcasses. It has been suggested that this probiotic decreases the need for antibiotics in poultry production and pathogen levels on farms. *Salmonella enterica* can be controlled by spraying a patented blend of 29 bacteria, isolated from the chicken cecum, on day-old chickens. As they preen themselves, the chicks ingest the bacterial mixture, establishing a functional microbial community in the cecum that limits *Salmonella* colonization of the gut in a process called competitive exclusion.

2. How are probiotics used in agriculture?

Key Concepts

41.1 Microbial Growth Can Cause Food Spoilage

- Most foods, especially when raw, provide an excellent environment for microbial growth. This growth can lead to spoilage or preservation, depending on the microorganisms present and environmental conditions.
- The course of microbial development in a food is influenced by the intrinsic characteristics of the food itself—pH, salt content, substrates present, water presence, and availability—and extrinsic factors, including temperature, relative humidity, and atmospheric composition.
- Microorganisms can spoil meat, dairy products, fruits, vegetables, and canned goods in several ways. Spices, with their antimicrobial compounds, sometimes protect foods.

41.2 Various Methods Are Used to Control Food Spoilage

- Foods can be preserved in a variety of physical and chemical ways, including filtration, alteration of temperature (cooling, pasteurization, sterilization), drying, addition of chemicals, radiation, and fermentation.
- Modified atmosphere packaging (MAP) is used to control microbial growth in foods and to extend product shelf life. This process involves decreased oxygen and increased carbon dioxide levels in the space between the food surface and the wrapping material.
- Interest is increasing in using bacteriocins for food preservation. Nisin, a product of *Lactococcus lactis,* is a major substance approved for use in foods.

41.3 Food-Borne Disease Outbreaks

- Foods can be contaminated by pathogens at any point in the food production, storage, or preparation processes. Pathogens such as *Salmonella enterica, Campylobacter jejuni, Listeria monocytogenes,* and *E. coli* can be transmitted to susceptible consumers, where they grow and cause a food-borne infection (**table 41.4**).
- If the pathogen grows in the food before consumption and forms toxins that affect food consumers without further microbial growth, the disease is a food intoxication. Examples are intoxications caused by *Staphylococcus, Clostridium,* and *Bacillus* spp. Fungi that grow in foods, especially cereals and grains, can produce important disease-causing chemicals, including the carcinogens aflatoxins (**figure 41.5**) and fumonisins (**figure 41.6**).

41.4 Detection of Food-Borne Pathogens Requires Government-Industry Cooperation

- Detection of food-borne pathogens is a major part of food microbiology. Many assays rely on culture-based approaches.

- The use of immunological and molecular techniques such as DNA and RNA hybridization, PCR, and pulsed-field gel electrophoresis often makes it possible to link disease occurrences to a common infection source. The PulseNet network is used to coordinate these control efforts (**figure 41.7**).

41.5 Microbiology of Fermented Foods: Beer, Cheese, and Much More

- Dairy products can be fermented to yield a wide variety of cultured milk products. These include mesophilic, therapeutic probiotic, thermophilic, yeast-lactic, and mold-lactic products.
- Growth of lactic acid–forming bacteria, often with the additional use of rennin, can coagulate milk solids. These solids can be processed to yield a wide variety of cheeses, including soft unripened, soft ripened, semisoft, hard, and very hard types (**table 41.5**). Both bacteria and fungi are used in these cheese production processes.
- Wines are produced from pressed grapes and can be dry or sweet, depending on the level of free sugar that remains at the end of the alcoholic fermentation (**figure 41.10**). Champagne is produced when the fermentation, resulting in CO_2 formation, is continued in the bottle.
- Beer and ale are produced from cereals and grains. The starches in these substrates are hydrolyzed, in the processes of malting and mashing, to produce a fermentable wort. *Saccharomyces cerevisiae* and *S. pastorianus* are yeasts commonly used in the production of beer and ale (**figure 41.11**).
- Many plant products can be fermented with bacteria, yeasts, and molds. Important products are breads, soy sauce, *sufu,* and tempeh (**table 41.6**). Sauerkraut and pickles are produced in a fermentation process in which natural populations of lactobacilli play a major role.

41.6 Probiotics

- Foods containing microorganisms that are thought to confer a health benefit have been consumed for hundreds of years. The recent appreciation of human gut microflora has helped engender more interest in these probiotic foods.
- Probiotic foods are a growing industry; probiotics are also used in agriculture.

Compare, Hypothesize, Invent

1. Compare the "sell-by" date of a package of hot dogs with that of a fresh cut of meat. What are the intrinsic and extrinsic factors that contribute to the difference?
2. You are going through a salad line in a cafeteria at the end of the day. Which types of foods would you tend to avoid? Or would you skip the salad altogether? Explain.
3. Why were aflatoxins not discovered before the 1960s? Do you think this was the first time they had grown in a food product to cause disease?
4. What advantage might the Shiga-like toxin give *E. coli* O157:H7? Can we expect to see other "new" pathogens appearing, and what should we do, if anything, to monitor their development?
5. Keep a record of what you eat for a day or two. Determine if the food, beverages, and snacks you ate were produced (at any level) with the aid of microorganisms. Indicate at what levels microorganisms were deliberately used. Be sure to consider ingredients such as citric acid, which is produced at the industrial level by several species of fungi.
6. During cheese production, LAB convert lactose to lactate and casein (milk protein) to amino acids. Lactate and amino acids then become the substrates for further microbial growth, which results in aroma production and deacidification of the cheese. The yeast *Yarrowia lipolytica* grows on the surface of many cheeses; it is capable of both lactate and amino acid catabolism. When grown on a lactate plus amino acid medium, *Y. lipolytica* preferentially consumes amino acids. Amino acid degradation results in the release of ammonia, which increases the pH. Draw a flow chart that shows the LAB fermentation of milk, followed by the growth of *Y. lipolytica*. Indicate which substrates are consumed first and what happens to the pH. Based on this simplified scenario, why do you think most cheeses involve the activity of more than one yeast species?
7. Following recent outbreaks of *E. coli* O157:H7 associated with leafy vegetables, there has been a need to better understand the growth of this pathogen on vegetables. To that end, a study was performed to compare the colonization and growth of *E. coli* O157:H7 on lettuce. In this study, the success of the microbe on intact leaves was compared with regions that had been mechanically damaged by shredding or bruising. Indeed, even within 4 hours after inoculation, there was a marked increase in microbial growth on the injured surfaces of the lettuce.

   Why do you think this was the case? If you were to perform this study (or one similar to it), how would you quantify *E. coli* colonization? If you were able to repeat and extend these findings, what kinds of recommendations might you make to the vegetable producers? To consumers?

Biotechnology and Industrial Microbiology

There is little, if any, financial incentive for large pharmaceutical companies to develop new antibiotics, despite a pressing need for them.

Where Are the New Antibiotics?

Bill's dad takes a statin drug to lower his cholesterol, and his grandmother takes beta-blocker for her heart. His mom has a steroid inhaler to keep her asthma under control. When Bill comes down with strep throat, his physician prescribes a 10-day course of amoxicillin and he gets better.

Bill's relatives are benefiting from drugs that pharmaceutical companies love to develop. They aren't so wild about helping Bill, though. It's not that they don't want to; they believe they can't afford it. Consider this: it costs over 2 billion U.S. dollars and at least a decade to bring a drug from discovery to market. Then the patent lasts for about another 10 years. Once the patent expires, the cost of the drug (and the profit therein) drops precipitously. Whereas Bill's relatives will very likely take their medicines for the rest of their lives, Bill takes his antibiotic for 10 days. When he's done: no more strep throat, no more profit for the drug manufacturer.

But in the meantime, amoxicillin (like almost all antibiotics) is losing its effectiveness as more and more bacteria develop resistance. So when new antibiotics are developed, they cannot be widely prescribed, lest resistance quickly develop.

Despite these disincentives, the need for new antibiotics grows more urgent with each passing year. Recall that two-thirds of antibiotics are natural microbial products. However, because only about 1% of all bacteria and archaea—and even fewer fungi—have been cultured, the environment holds great untapped resources. But history tells us we need a new strategy to access this potential antibiotic reservoir. Between 1935 and 1962, the seven classes of antibiotics* we still use today were developed. Then from 1962 to 2000, no new drug classes were discovered. Instead, while men went to the moon and the Internet was born, existing antibiotics were chemically modified, generating multiple generations of existing drugs. Newly introduced drugs all belong to drug classes already in use, subject to the same mechanisms of resistance. It was not until the first decade of the twenty-first century that three new classes were introduced to clinical practice: oxazolidinones, lipopeptides, and mutilins. Currently, drug discovery is becoming synonymous with microbial discovery: looking in new habitats, such as deep-sea trenches and the symbionts of other animals, or inventing new ways to coax microbes from common environments (like soil) to grow in the lab.

Industrial microbiology harnesses the capacity of microbes to synthesize compounds that have important applications in medicine, agriculture, food preparation, and other industrial processes. These compounds are commonly called **natural products.** In this chapter, we discuss these products and how microorganisms (or their genes) are optimized for industrial manufacturing.

* In chronological order of discovery, the seven drug classes include sulfa drugs, β-lactams, chloramphenicol/tetracyclines, aminoglycosides, macrolides, glycopeptides, quinolones, and streptogramins.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Compare and contrast at least five different classes of antibiotics (section 9.2)
- ✔ Describe the difference between batch and continuous culture techniques (sections 7.7 and 7.9)
- ✔ Recall the principle biochemical pathways involved in central metabolism (chapters 11 and 12)
- ✔ Explain oxidation-reduction (redox) reactions (section 10.3)
- ✔ Describe the means by which DNA mutations can be induced (section 16.1)
- ✔ Explain the mechanisms of horizontal gene transfer (sections 16.4–16.9)
- ✔ Summarize the process and importance of PCR (section 17.2)
- ✔ Define metagenomics and discuss its applications (section 18.3)
- ✔ Discuss the principles by which vaccines confer immunity (section 37.6)

42.1 Microbes Are the Source of Many Products of Industrial Importance

After reading this section, you should be able to:

- Describe at least five compounds of industrial importance made by microbes
- Define biocatalysis and explain its advantages over chemical synthesis

Industrial microbiology has profoundly changed our lives and lifespans. Microbial products include antibiotics and other medicines, food additives, enzymes with industrial applications, and biofuels, just to name a few (**table 42.1**). Here we introduce a few of the more common microbial products that are an integral part of modern life.

Antibiotics

More than 65% of all antibiotics are produced by microorganisms. Currently most antibiotics are produced by members of the genus *Streptomyces* and by filamentous fungi (*see table 24.3*). Antibiotics are secreted by these microbes and either used in the native state or chemically modified to produce semisynthetic derivatives. Such derivatives generally are manufactured to address the problem of antibiotic resistance or the desire for a broader-spectrum drug.

The synthesis of penicillin and its derivatives illustrates how an antibiotic is commercially produced. As with any industrially important natural product, the manufacturer will determine how to maximize product yield. In this case, the growth of the fungus *Penicillium chrysogenum* requires careful adjustment of the medium, so that the slowly hydrolyzed disaccharide lactose is used in combination with a limited supply of nitrogen to stimulate a greater accumulation of penicillin after growth has stopped (**figure 42.1**). If a particular penicillin is needed, the specific precursor is added to the medium. For example, phenylacetic acid is added to maximize production of penicillin G, which has a benzyl side chain (*see figure 9.5*). The pH is maintained around neutrality by the addition of sterile alkali, which ensures maximum stability of the newly synthesized penicillin. After about a week, the broth is separated from the fungal hyphae and processed by absorption, precipitation, and crystallization to yield the final product. This basic product can then be modified by chemical procedures to yield a variety of semisynthetic penicillins. Manufacture of semisynthetic β-lactam antibiotics, such as ampicillin and amoxicillin, begins with natural penicillin. The β-lactam ring is preserved, but the side chain is modified to provide a broader spectrum of activity. ⏮ *Inhibitors of cell wall synthesis (section 9.4)*

Amino Acids

Amino acids such as lysine and glutamic acid are used in the food industry as nutritional supplements in bread products and as flavor-enhancing compounds such as monosodium glutamate (MSG). Amino acid production is typically carried out by regulatory mutants that have a reduced ability to limit synthesis of a specific amino acid or a key intermediate. Wild-type microorganisms avoid overproduction of biochemical intermediates by the careful regulation of cellular metabolism. Production of glutamic acid and several other amino acids is carried out using mutants of *Corynebacterium glutamicum* that lack or have only a limited ability to process the TCA cycle intermediate α-ketoglutarate to succinyl-CoA (*see figure 11.8*). A controlled low biotin level and the addition of fatty acid derivatives increase membrane permeability so that high concentrations of glutamic acid are secreted. The impaired bacteria use the glyoxylate pathway (*see figure 12.22*) to meet their needs for essential biochemical intermediates, especially during the growth phase. By the time nutrients are depleted and growth stops, an

Table 42.1 Major Microbial Products and Processes of Interest in Industrial Microbiology

Substances	Microorganisms
Industrial Products	
Ethanol (from glucose)	*Saccharomyces cerevisiae*
Ethanol (from lactose)	*Kluyveromyces fragilis*
Acetone and butanol	*Clostridium acetobutylicum*
2,3-butanediol	*Enterobacter, Serratia*
Enzymes	*Aspergillus, Bacillus, Mucor, Trichoderma*
Agricultural Products	
Gibberellins	*Gibberella fujikuroi*
Food Additives	
Amino acids (e.g., lysine)	*Corynebacterium glutamicum*
Organic acids (citric acid)	*Aspergillus niger*
Nucleotides	*Corynebacterium glutamicum*
Vitamins	*Ashbya, Eremothecium, Blakeslea*
Polysaccharides	*Xanthomonas*
Medical Products	
Antibiotics	*Penicillium, Streptomyces, Bacillus*
Alkaloids	*Claviceps purpurea*
Steroid transformations	*Rhizopus, Arthrobacter*
Insulin, human growth hormone, somatostatin, interferons	*Escherichia coli, Saccharomyces cerevisiae,* and others (recombinant DNA technology)
Biofuels	
Hydrogen	Photosynthetic microorganisms
Methane	*Methanobacterium*
Ethanol	*Zymomonas, Thermoanaerobacter*

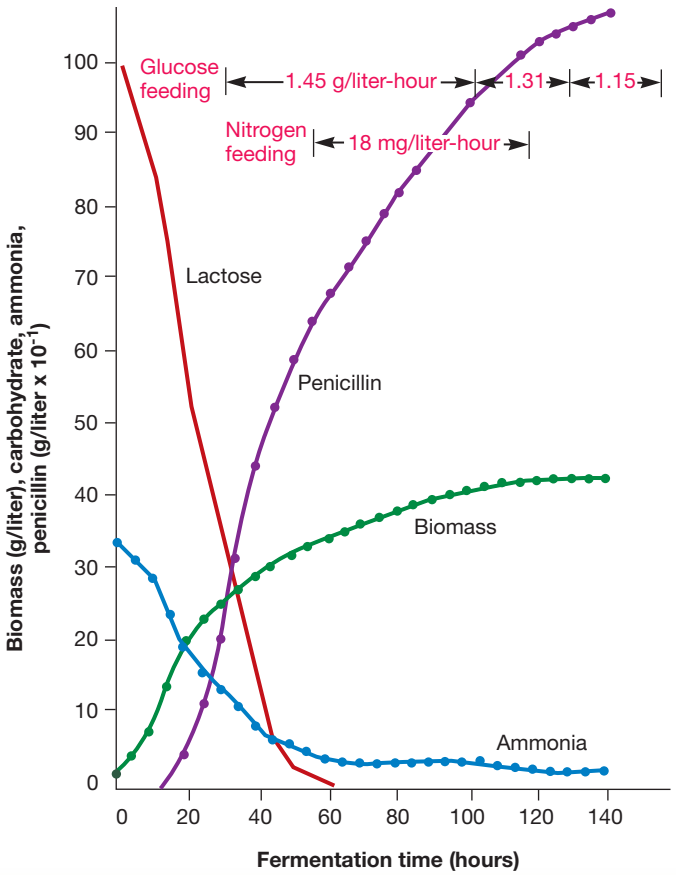

Figure 42.1 Penicillin Fermentation Involves Precise Control of Nutrients. The synthesis of penicillin begins when nitrogen from ammonia becomes limiting. After most of the lactose (a slowly catabolized disaccharide) has been degraded, glucose (a rapidly used monosaccharide) is added along with a low level of nitrogen. This stimulates maximum transformation of the carbon sources to penicillin. The scale factor is presented using the convention recommended by the American Society for Microbiology; that is, a number on the axis should be multiplied by 0.10 to obtain the true value.

MICRO INQUIRY *Why are the cells first fed lactose and then glucose?*

almost complete molar conversion (or 81.7% weight conversion) of isocitrate to glutamate occurs. ⏮ *Synthesis of amino acids consumes many precursor metabolites (section 12.5)*

Organic Acids

Simply reading the ingredient list on most processed foods will illustrate the widespread use of organic acids such as citric, acetic, and lactic acids. These acids are principally used as preservatives. Organic acid production illustrates how the concentration of trace elements can influence product yield.

Citric acid fermentation involves limiting the amounts of trace metals such as manganese and iron to stop *Aspergillus niger* growth at a specific point. The medium often is treated with ion exchange resins to ensure low and controlled concentrations of available metals. Generally, high sugar concentrations (15 to 18%) are used, and copper has been found to counteract the inhibition of citric acid production by iron. This reflects the regulation of glycolysis and the tricarboxylic acid cycle (recall that citric acid is a constituent of the TCA cycle). After the active growth phase, when the substrate level is high, citrate synthase activity increases and the activities of aconitase and isocitrate dehydrogenase decrease. This results in citric acid accumulation and excretion by the stressed microorganism.

Biopolymers

Biopolymers are microbially produced polymers, primarily polysaccharides, used to modify the flow characteristics of liquids and to serve as gelling agents. These are employed in many areas of the pharmaceutical and food industries.

Biopolymers include (1) dextrans, which are used as blood expanders and absorbents; (2) *Erwinia* polysaccharides used in paints; (3) polyesters, derived from *Pseudomonas oleovorans,* which are used for specialty plastics; (4) cellulose microfibrils, produced by an *Acetobacter* strain, that serve as a food thickener; (5) polysaccharides such as scleroglucan used by the oil industry as drilling mud additives; and (6) xanthan polymers, which have a variety of applications as food additives as well to enhance oil recovery by thickening drilling mud. This use of xanthan gum, produced by *Xanthomonas campestris,* represents a large market for this microbial product.

Biosurfactants

Biosurfactants are amphiphilic molecules; that is, they possess both hydrophobic and hydrophilic regions. Thus they partition at the interface between fluids that differ in polarity, such as oil and water. For this reason, they are used for emulsification, increasing detergency, wetting, and phase dispersion, as well as solubilization. These properties are especially important in bioremediation, oil spill dispersion, and enhanced oil recovery. The most widely used microbially produced biosurfactants are glycolipids. These are carbohydrates that bear long-chain fatty acids. They can be isolated as extracellular products from a variety of microorganisms, including pseudomonads and yeasts.

Biocatalysts

Biocatalysts are enzymes used in the industrial production of chemicals and pharmaceuticals. The vast majority of such enzymes are of microbial origin and include dehydrogenases, oxygenases, hydrolases, transferases, and lyases. These enzymes may introduce minor changes in molecules, such as the insertion of a hydroxyl or keto function, or the saturation or desaturation of a complex cyclic structure. A typical bioconversion is the hydroxylation of a steroid as shown in **figure 42.2**. In this example, the water-insoluble steroid is dissolved in acetone and then added to the reaction system. The course of the modification is monitored, and the final, soluble product is extracted and purified.

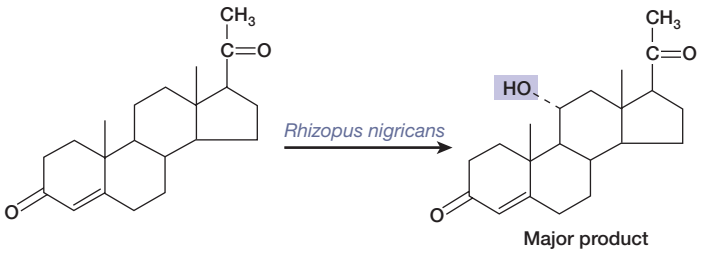

Figure 42.2 Biotransformation to Modify a Steroid. Hydroxylation of progesterone in the 11α position by *Rhizopus nigricans*. The steroid is dissolved in acetone before addition to the pregrown fungal culture.

Biocatalysis generally has the advantage over chemical synthesis in that natural enzymes have stereospecificity so that the product is not a mixture of isomers and is biologically active. Further, microbial enzymes catalyze reactions under mild conditions; some of these reactions would require harsh conditions (e.g., extreme pH, temperature) if performed by chemical synthesis.

Vaccines

Vaccines are the single most important public health weapon. The most common vaccines are live attenuated viruses (e.g., measles vaccine) or killed pathogens (influenza vaccine). However, these traditional forms of vaccines cannot be used for certain pathogens. For instance, if the pathogen cannot be grown in vitro (e.g., hepatitis B and C viruses), neither attenuation or killing the purified microbe is possible. Likewise, different vaccine strategies must be used if the pathogen produces molecules that are too similar to host molecules, as this can trigger autoimmunity, or if there is too much genetic diversity among pathogenic strains. This is the case for group B *Streptococcus,* also called GBS, which causes serious infections in infants, so a vaccine is highly desired. In these cases, **reverse vaccinology** may be a fruitful approach. Reverse vaccinology mines the genomic sequence of the pathogen to assemble a list of antigens that may be good vaccine targets. ◀◀ *Vaccines immunize susceptible populations (section 37.6)*

Recall that an antigen is a foreign molecule targeted by the host immune system. Purified antigens, rather than whole organisms, can be used in vaccines. Such antigens must (1) be expressed by the pathogen during infection; (2) be secreted or found on the surface of the pathogen; (3) be found in all strains of the pathogen; (4) elicit a host immune response; and (5) be essential for the survival of the pathogen, at least while it is in the host.

Considering the thousands of genes that are revealed in each annotated genome, finding genes whose products meet all of these criteria might seem next to impossible. But there are two approaches to generating a list of antigen candidates: Either the genome of a single species is examined for vaccine targets, or a pan-genomic approach is taken so that the genomes of a number of strains are compared. The first approach was used to develop a *Neisseria meningitidis* serogroup B (MenB) vaccine. For many years there were two vaccines made of capsular polysaccharides (CPS) to protect against serogroups A, C, Y, and W-135. Because the CPS of MenB is identical to a human polysaccharide, it could not be included in these vaccines. By using the complete genome sequence of serogroup B *N. meningitidis*, 600 surface proteins were identified and about 300 were tested in mice. Of these about 25 were worthy of further study, and in 2014 the first MenB vaccine was approved for use in the United States.

By contrast, a pan-genomic approach was used to develop a GBS vaccine because there are many genetically variable pathogenic strains. Thus the genomes of eight GBS isolates were compared and 312 surface proteins were identified as potential targets. When tested for their ability to protect mice from infection, four were found to be effective. These were combined into a single vaccine capable of protecting animals against infection by all known clinical strains. This vaccine and others are in clinical trials. Reverse vaccinology is currently being applied in the development of vaccines to protect against a variety of other pathogens, including *Staphylococcus aureus, Chlamydophila pneumoniae,* and *Bacillus anthracis.*

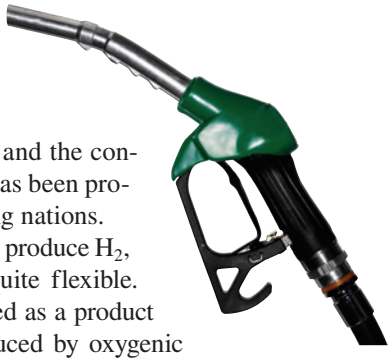
1. What critical limiting factors are used in the production of penicillin? Why do you think the microbe must be stressed to produce high levels of drug?
2. Why are regulatory mutants used to increase the production of glutamic acid by *Corynebacterium glutamicum*?
3. Discuss the major uses for biopolymers and biosurfactants.
4. What kinds of molecular changes result from biocatalysis?
5. Why is serogroup B not included in the meningitis vaccine? How was the MenB vaccine developed?

42.2 Biofuel Production Is a Dynamic Field

After reading this section, you should be able to:

- Compare the value of biofuel use with the challenges presented in its manufacture and transport
- Discuss at least two types of biofuels

Global energy consumption is predicted to increase by roughly 40% between 2014 and 2040. Currently the world relies on petroleum to fuel almost all its transportation, while coal and natural gas (methane) are used in abundance to generate power and heat buildings. These fossil fuels need to be phased out of use, not only because they are finite resources but also because they are the major contributors of greenhouse gases and global climate change. Many agree that renewable energy sources based on microbial transformation of organic material are the most viable approach to solve our global energy and climate crises. **Microbial energy conversion** includes the microbial transformation of organic materials into **biofuels,** such as ethanol and hydrogen, that can be burned to fuel cars or other machines. In this section, we discuss the microbial production of the biofuels ethanol (and other alcohols) and hydrogen. ◀◀ *Global climate change (section 28.2)*



The U.S. Department of Energy has set a goal of substituting 30% of gasoline with biofuels by 2030. Currently ethanol is used as an additive to gasoline because it is easy to store and can be burned in cars designed to use pure gasoline. This is why gasoline sold in the United States contains at least 10% ethanol. Corn is currently the substrate most commonly used for generating ethanol in the United States. Its fermentation into ethanol involves the microbial degradation of plant starch using amylases and amyloglucosidases. The resulting sugars are then fermented to ethanol. However, the use of corn to make bioethanol has had unintended consequences, chiefly in the form of higher worldwide food prices. Therefore much research is now devoted to finding other substrates for the production of alcohol biofuels. In addition to the use of cyanobacteria and algae (*see p. 509*), crop residues could significantly boost biofuel yields and ease the cost of corn and corn-based foods. Crop residues are the plant material left in the field after harvest. This material consists of cellulose and hemicellulose—polymers of five different hexoses and pentoses: glucose, xylose, mannose, galactose, and arabinose. Degradation of cellulose and hemicellulose to release these monomers is commonly done by heating the plant material and treating it with acid, which is energy-intensive and corrosive. This is an expensive and potentially hazardous process. Nonetheless, 2014 marked the opening of the first large-scale plant to produce cellulosic ethanol—that is, ethanol made from crop residues. Research continues to eliminate the need for chemical pretreatment. This has led to the development of an *E. coli* strain engineered to express yeast enzymes as well as to the isolation of hyperthermophilic archaea that can degrade cellulose at temperatures in excess of 100°C. These are excellent examples of biocatalysis.

Even if cheaper plant material were found for ethanol production, ethanol as a biofuel has several disadvantages. One is that it absorbs water and cannot be shipped through existing pipelines because they almost always contain some water. So ethanol must be distilled twice to remove the water: once when it is generated and then again after shipping. Furthermore, ethanol contains far less energy than other fuels, including gasoline and higher molecular weight alcohols such as butanol, which are easier to generate. In fact, the entire ethanol manufacturing process consumes more energy than it yields; that is, ethanol is not a carbon-neutral fuel. This has motivated a number of small biotechnology companies to engineer microbes to produce other alcohols and even hydrocarbons. Currently, synthetic biologists have built strains of *E. coli* that produce both short-chain alkanes and alkenes. These products more closely resemble gasoline (petrol), which is a mixture of C4-C12 short-chain hydrocarbons.

In many ways, hydrogen (H_2) as a biofuel compares very favorably to ethanol and other fuels. In fact, H_2 has about three times more potential energy per unit weight than gasoline; it is thus the highest energy-content fuel available. However, until a liquid fuel with a high hydrogen content is developed, the storage and distribution of hydrogen will remain a problem. Also, unlike ethanol, hydrogen cannot simply be mixed with gasoline and used in today's vehicles. Nonetheless, because of its high energy yield, among other factors, there is great interest in developing H_2 as a fuel source, and the concept of a "hydrogen economy" has been promoted, particularly in developing nations.

A diverse group of microbes produce H_2, thus making its manufacture quite flexible. Like ethanol, H_2 can be produced as a product of fermentation. It is also produced by oxygenic photosynthetic microbes (cyanobacteria and algae) and anoxygenic photoheterotrophs. Two different enzymes (thus processes) generate H_2: hydrogenase and nitrogenase. Both are keenly sensitive to oxygen, so H_2 production is an anaerobic process.

Oxygenic photosynthetic microbes produce H_2 at night, when they oxidize cellular storage products such as poly-β-hydroxybutyrate. The use of aquatic phototrophs to generate H_2 holds promise because there is plenty of substrate (light and CO_2). However, hydrogenase is strongly inhibited by its product, so H_2 must be removed from the system as soon as it is created. By contrast, H_2 production by anoxygenic photoheterotrophic bacteria can occur via cellular hydrogenases or nitrogenases. It is the latter that has sparked interest among industrial microbiologists. This is because in an atmosphere that has been artificially purged of all N_2, nitrogenase will form only H_2. This process requires a tremendous amount of ATP and reductant, but unlike hydrogenase, nitrogenase is not inhibited by the accumulation of H_2, and electron conversion to H_2 reaches efficiencies near 100%.

Although we have painted an uncertain picture of which biofuel will eventually dominate, several things are clear. With the global population predicted to expand to 9.6 billion people by 2050, the desire for energy will eventually make fossil fuels rare and prohibitively expensive. At the same time, the need to increase food production will make it untenable to grow feedstocks for biofuel production on scarce arable land. It may be that synthetic biology (p. 956) will save the day, and instead of drilling for oil, we will be harvesting it from bioreactors. Or it may turn out that H_2 will become an important resource, especially in countries that have not yet built an extensive infrastructure to support a hydrocarbon-based lifestyle. But no matter what eventually transpires, these are exciting times for the microbial energy conversion field.

2. What types of microbes are good candidates for the industrial production of H_2?

42.3 Growing Microbes in Industrial Settings Presents Challenges

After reading this section, you should be able to:

- Explain the use of the term fermenter as it is used in an industrial setting
- Describe two types of fermenters

As our review of natural products and processes points out, the development of appropriate culture media and conditions is critical to the manufacture of the desired product. Culturing microbes in industrial settings is much different than their growth in either nature or the laboratory. However, before describing microbial growth on an industrial scale, we must clarify terminology. The term **fermentation,** used in a physiological sense, is employed differently in the context of industrial microbiology and biotechnology. To industrial microbiologists, fermentation means the mass culture of microorganisms, and plant and animal cells. Industrial fermentations require the development of appropriate culture media and the transfer of small-scale technologies to a much larger scale. In fact, the success of an industrially important microbial product rests on the process of **scale-up.** This is when a procedure developed in a small flask is modified for use in a large fermenter. The microenvironment of the small culture must be maintained despite increases in culture volume. Although the process of transitioning a culture originally developed in a 250-milliliter Erlenmeyer flask to a 100,000-liter reactor seems like it should be relatively straightforward, it is often very difficult to obtain the same yield of the desired product, and a series of troubleshooting experiments must be devised.

Microorganisms are often grown in stirred fermenters or other mass culture systems. Stirred **fermenters** can range in size from 3 liters to over 100,000 liters, depending on production requirements. A typical industrial stirred fermentation unit is illustrated in **figure 42.3**. Upon inoculation of the microbe into sterile growth medium, aeration, pH and temperature adjustments, and sampling are carried out under rigorously controlled conditions. When required, foam control agents are added, especially with high-protein media. Computers are used to monitor outputs from probes that determine microbial biomass, levels of critical metabolic products, pH, input and exhaust gas composition, and other parameters. Environmental conditions can be changed or held constant over time, depending on the requirements of the particular process.

Frequently a critical component in the medium, often the carbon source, is added continuously—a process called **continuous feed**—so that the microorganisms will not have excess substrate available at any given time. This is particularly important with glucose and other carbohydrates. If excess glucose is present at the beginning of a fermentation, it can be catabolized and lost as volatile end products, reducing the final yield of the desired product.

Other culturing approaches exist, among them continuous culture techniques using chemostats. These can sometimes markedly improve rates of substrate use and product yield because microorganisms can be maintained in logarithmic phase. However, for some industrial processes continuous active growth is undesirable, because the product of interest is not made during exponential growth. Microbial products can be classified as primary and secondary metabolites. **Primary metabolites** consist of compounds related to the synthesis of microbial cells during exponential growth. They include amino acids, nucleotides, and fermentation end products such as ethanol and organic acids. In addition, industrially useful enzymes, either associated with the microbial cells or exoenzymes, often are synthesized by microorganisms during log phase growth. **Secondary metabolites** usually accumulate when nutrients become limited or waste products accumulate following the active growth phase. These compounds are sometimes considered part of a stress response as nutrients become scarce. Most antibiotics fall into this category.

◀◀ *Growth curves consist of five phases (section 7.7); Chemostats (section 7.9)*

Retrieve, Infer, Apply

1. What is the objective of the scale-up process and why is it so critical?
2. What parameters can be monitored in a modern, large-scale industrial fermentation?
3. Which of the following are secondary metabolites: pyruvate, a secreted amylase, an antibiotic, leucine? What kind of system (fermenter vs. chemostat) would most likely be used for the production of the streptomycete antibiotic streptomycin? Explain your answer.

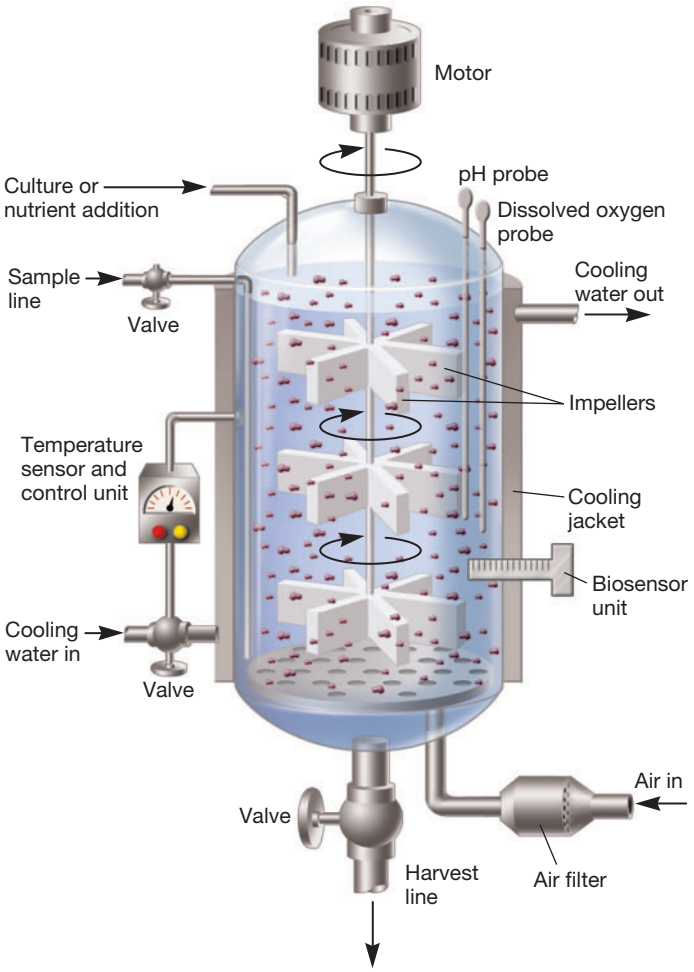

Figure 42.3 An Industrial Fermenter. This unit can be run under oxic or anoxic conditions, and nutrient additions, sampling, and fermentation monitoring can be carried out under aseptic conditions. Biosensors and infrared monitoring can provide real-time information on the course of the fermentation. Specific substrates, metabolic intermediates, and final products can be detected.

42.4 Production Strains Are Developed to Maximize Output of Industrially Important Compounds

After reading this section, you should be able to:

- List three techniques used to optimize microbial output of industrial products
- Compare and contrast three directed evolution technologies
- Describe how metagenomics increases the pool of microbial products available for screening

Most microbes used in industrial processes originate from natural materials (e.g., soil) and are difficult to grow under standard laboratory conditions. Furthermore, even after appropriate growth conditions are determined, the original strains often produce very low amounts of the desired product. Starting with these microbes, microbiologists expend considerable effort to create strains, called **production strains,** that are optimized for industrial purposes. Here we describe some of the approaches they use.

Mutagenesis

Once a microbe is found to produce a promising compound, a variety of mutagenic techniques can be used to increase product yield. For many years, biotechnologists were limited to chemical, ultraviolet (UV) light, and X-ray mutagenesis. For example, the first cultures of *Penicillium notatum* had to be grown in stationary vessels and produced low concentrations of penicillin. In 1943 strain NRRL 1951 of *Penicillium chrysogenum* was isolated and further improved using these methodologies (**figure 42.4**). Today most penicillin is produced with *Penicillium chrysogenum* grown in aerobic, stirred fermenters, yielding 55 times more penicillin than the original static cultures. ⏮ *Mutations (section 16.1)*

Protoplast Fusion

Protoplast fusion is another technique that can be used to promote genetic variability in microorganisms and plant cells. In this method, protoplasts—cells lacking a cell wall—are prepared by growing microbes in an isotonic solution in the presence of enzymes that degrade the cell wall (e.g., lysozyme for bacteria, chitinase for yeasts). The protoplasts of cells of the same or even different species physically fuse during coincubation. The cell wall is then regenerated during growth on osmotic stabilizers such as sucrose. Protoplast fusion is also inherently mutagenic and is especially useful for prompting recombination. For example, when protoplasts of *Penicillium roqueforti* were fused with those of *P. chrysogenum,* new industrially useful *Penicillium* strains were created.

Genetic Transfer Between Different Organisms

The transfer and expression of genes between different organisms can give rise to novel products, may change the way in which

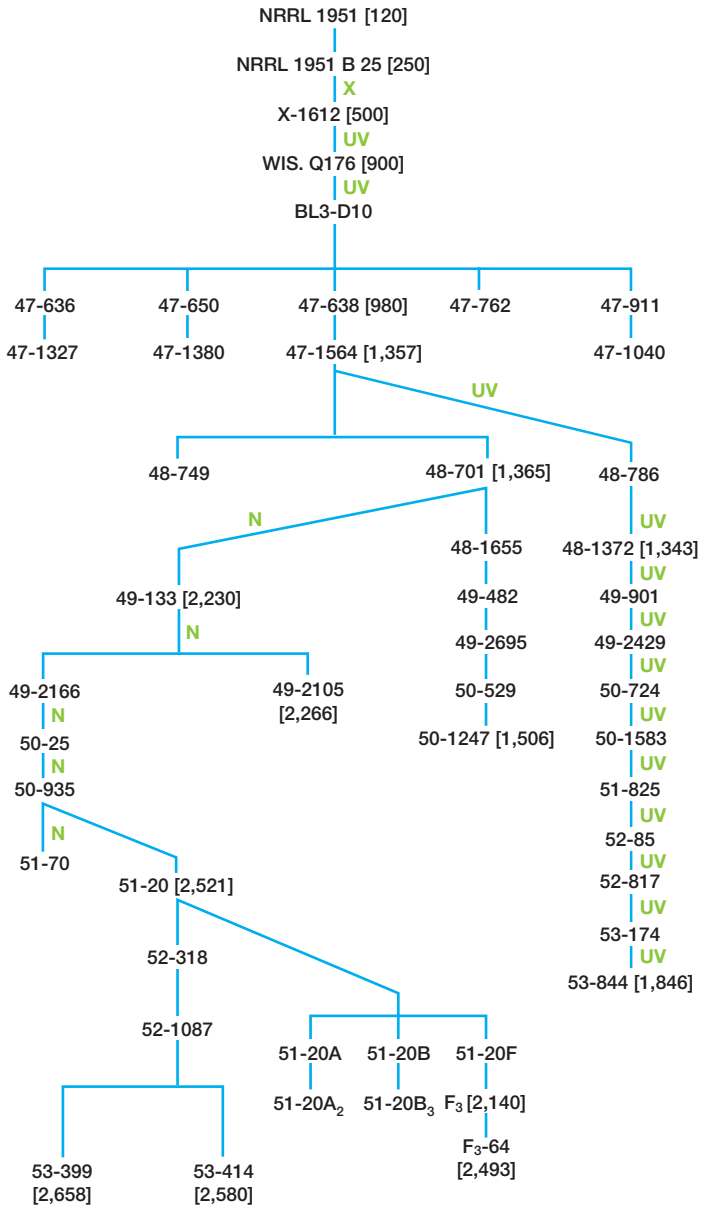

Figure 42.4 Mutation Makes It Possible to Increase Fermentation Yields. The genealogy of the mutational processes used to increase penicillin yields with *Penicillium chrysogenum.* These included X-ray treatment (X), UV treatment (UV), and mustard gas (N). By using these mutational processes, the yield was increased 20-fold. Unmarked transfers were used for mutant growth and isolation. Yields in International Units/mL in brackets.

genes of interest are regulated, or may even change the posttranslational modification of the protein product. Whereas protoplast fusion results in the in vivo recombination between microbial genomes, in vitro genetic transfer of specific genes enables a more targeted approach to strain construction. When genes from one organism are cloned into another and then transcribed and translated into protein, it is called **heterologous gene expression.** An important and early example of heterologous gene expression is the cloning and expression of the human insulin genes in

E. coli. Heterologous gene expression enables the production of specific proteins and peptides without contamination by other products that might be synthesized in the original organism. This approach can decrease the time and cost of recovering and purifying a product. Another major advantage of engineered protein production is that only biologically active stereoisomers are produced. This specificity is required to avoid the possible harmful side effects of inactive stereoisomers.

Modification of Gene Expression

In addition to inserting new genes in organisms, it also is possible to increase product yield by modifying regulatory molecules or the DNA sites to which they bind. For instance, the tight regulation of secondary metabolites such as antibiotics can be diminished by promoter mutations. The goal is to prompt microbes to begin antibiotic synthesis earlier and at a higher level than the parental strain. These approaches make it possible to overproduce a wide variety of products, such as antibiotics, amino acids, and enzymes of industrial importance.

Directed Evolution

As demonstrated in figure 42.4, mutants that overproduce a product or had some other desirable trait were traditionally obtained by "brute force" mutation. That is, mutations that conferred the trait were allowed to accumulate in a microbial strain after repeated rounds of mutagenesis and transfer from culture to culture. Production strains created in this way have a genotype quite different from the parental strain. Indeed, until the advent of genomic sequencing, the number and sites of most mutations remained a mystery. **Directed evolution** takes a more rational approach to the construction of production strains because only genes of interest are targeted for mutagenesis. In most cases, this requires that the gene sequences be altered in vitro, then replaced in the original strain or a heterologous host that may be better suited to produce the compound at high levels.

Several technical advancements were key to the development of direct evolution methodologies. The first is **site-directed mutagenesis.** In this technique, the nucleotide sequence of a specific gene is altered. The steps required are outlined in **figure 42.5**. Biotechnologists have discovered that making even minor amino acid substitutions can lead to unexpected changes in protein function and stability, resulting in higher yields of existing products or new products such as more environmentally resistant enzymes.

Site-directed mutagenesis changes only a few nucleotides at a time. A variety of other directed evolution techniques have been developed that can make larger changes to the gene of interest; some of these are listed in **table 42.2**. Careful inspection of table 42.2 reveals that many natural products are not proteins and therefore cannot be modified by simply mutating a single, structural gene. Instead, altering these nonprotein products requires an understanding of the biosynthetic

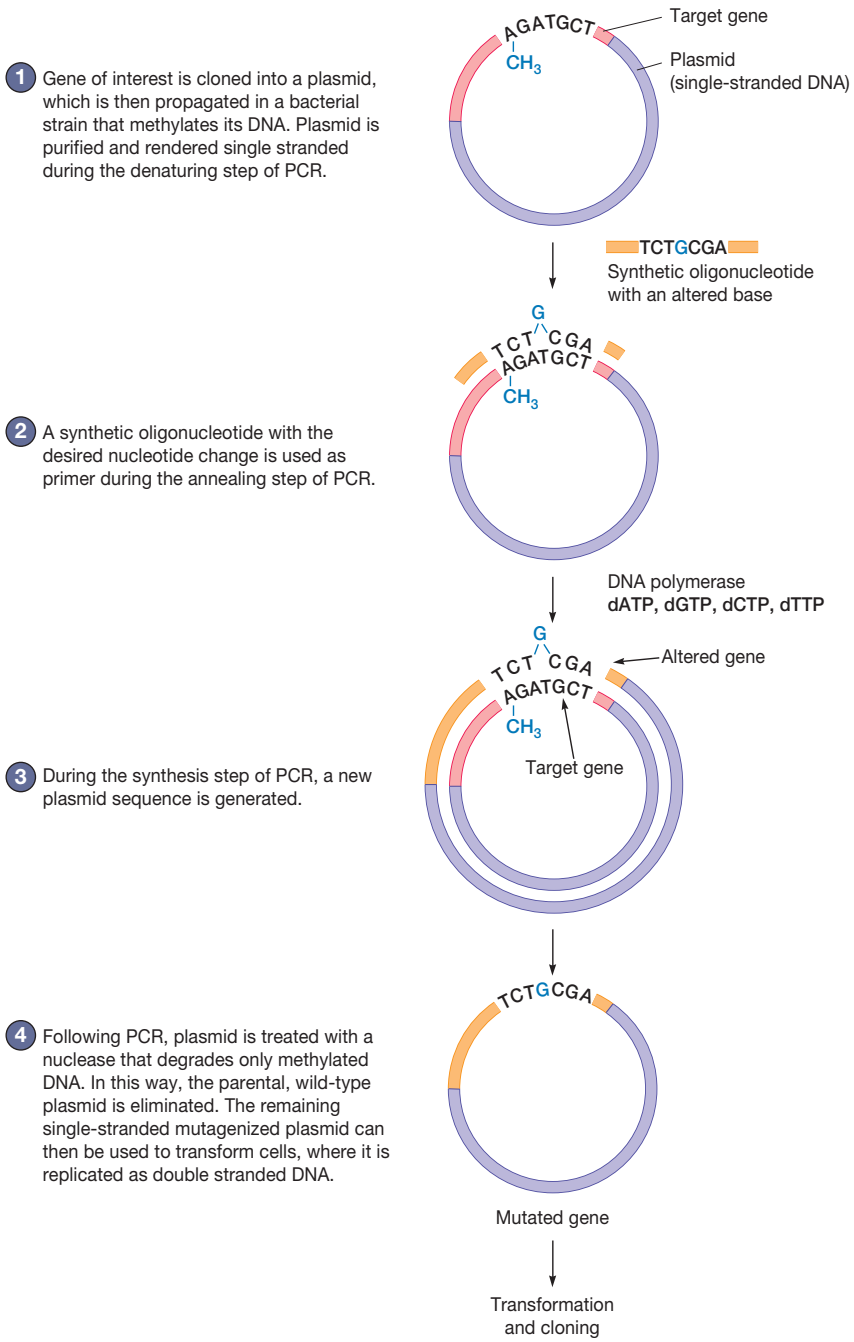

Figure 42.5 Site-Directed Mutagenesis. A synthetic oligonucleotide is used to add a specific mutation to a gene.

Table 42.2 Some Directed Evolution Technologies

Technology	Overview of Approach	Examples of Products Generated
Genome-based strain reconstruction	A new strain is constructed based on the genotype of a production strain previously generated by "brute force." The new strain possesses only the mutations that are required for overproduction of the product.	Lysine
Metabolic pathway engineering	Rational approach to product improvement by either modification of specific biochemical reactions in a pathway, such as by site-directed mutagenesis of biosynthetic enzyme genes or the use of recombinant DNA technology to introduce new genes into the production strain. The goal is to optimize the flux of metabolites so the pathway operates most efficiently and the highest product yields possible are obtained.	Antibiotics: cephamycin C, neomycin, spiramycin, erythromycin L-lysine, aromatic amino acids, ethanol, vitamins
Assembly of designed oligonucleotides (ADO)	If the gene of interest contains a conserved sequence flanking the region to be mutated, oligonucleotides can be designed that include the conserved region and a mixture of point mutations in the region to be mutated. This combination of different (called degenerate) oligonucleotides is used to create variants by in vitro homologous recombination.	Lipases
Error-prone PCR	Variants of a gene are produced by using a DNA polymerase that is particularly error-prone during PCR.	Lycopene
DNA shuffling	Similar genes from different species are randomly fragmented and pooled, and new DNA fragments are generated by in vitro homologous recombination. Progeny sequences encoding desirable traits are identified; these new genes are then shuffled (bred) over and over again, creating new progeny that contain multiple desirable mutations.	Cephalosporinase
Whole genome shuffling	Similar to DNA shuffling described above, except entire genomes are recombined. Protoplast fusion may be used to obtain a single cell with the genomes of two microbial species so that recombination can occur.	Lactic acid

Modified from Adrio, J. L., and Demain, A. L. 2006; Genetic improvement of processes yielding microbial products. FEMS Microbiol. Rev. *30:187–214.*

pathway by which they are catalytically assembled. The genetic manipulation of enzymes with the goal of changing an industrially important product is sometimes called **metabolic engineering.** Metabolic engineering can be used to develop novel biochemical pathways that either improve product yield or generate new products.

The biosynthesis of certain types of natural products makes them particularly amenable to bioengineering. For instance, polyketide and certain peptide antibiotics have become models of bioengineering because the biosynthetic enzymes are grouped into large modular complexes, which function in an assembly-line fashion (**figure 42.6**). Each module within the complex catalyzes a specific type of reaction. For instance, the anticancer agents epothilones C and D are synthesized by a combination of polyketide synthase (PKS) and nonribosomal peptide synthetase (NRPS) enzymes. The first module is responsible for binding a starter unit and transferring it to the first extension module. Each extension module modifies the intermediate and hands it off to the next module in line until it reaches the last module and is released. The mixing and matching of domains encoding extension modules from hundreds of such modular multienzyme complexes can be used to generate new products. Many soil bacteria, such as members of the genera *Streptomyces* and *Bacillus*, possess PKS and NRPS genes. Biotechnologists are mining other microbes and metagenomes for novel PKS and NRPS genes.

The recognition that RNA is a versatile molecule that can have catalytic activity and control gene expression has given rise to a new class of therapeutic agents. Noting that RNA can fold into seemingly an infinite number of complex three-dimensional structures, molecular biologists use in vitro evolution to generate a library of up to 10^{15} different RNA molecules of interest. This procedure is called "systematic evolution of ligands by exponential enrichment" (SELEX) and is outlined in **figure 42.7**. Recall that a molecule that binds to a specific target or receptor is called a ligand, so in this case, the goal is to design an RNA ligand that has biological activity because it fits very tightly into a cleft or groove in a specific target molecule. This class of engineered RNAs have been given the name **aptamers** (Latin *aptus*, means "fitting"). In 2005 the first aptamer-based therapy, for the progressive vision disease macular degeneration, began clinical use.

◀◀ *Ribozymes (section 10.6)*

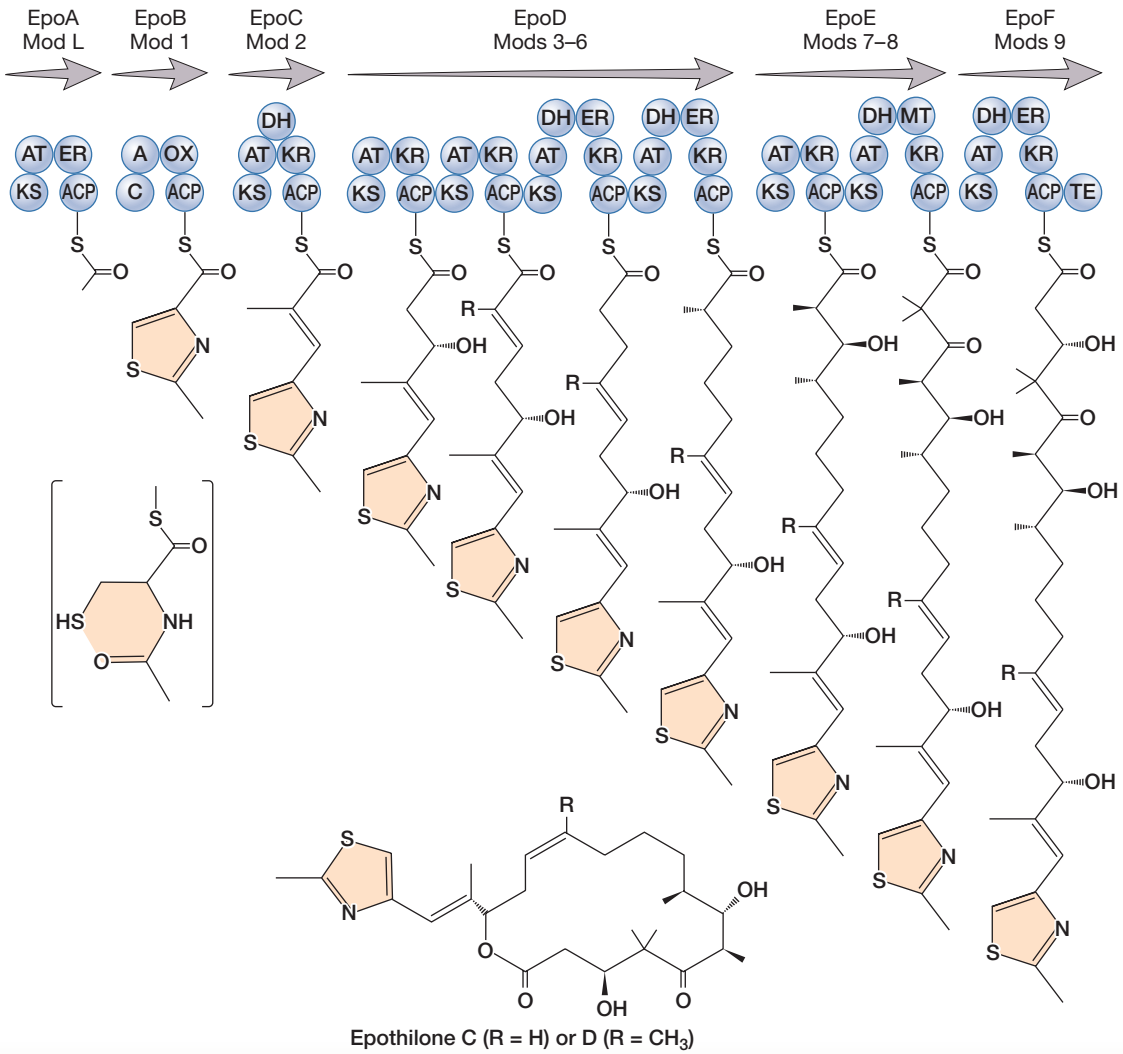

Figure 42.6 **Modular Assembly of the Anticancer Agents Epothilone C and D.** The genes encoding the enzymes that assemble this polyketide are found on the genome of the myxobacterium *Sorangium cellulosum*. They are arranged on the genome in the order of synthesis. The catalytic domains in the corresponding enzyme are shown as circles. These domains include keto-acyl synthase (KS), acyltransferase (AT), enoyl reductase (ER), acyl carrier protein (ACP), adenylation (A), condensation (C), oxidation (O), dehydratase (DH), ketoreductase (KR), and thioesterase (TE). The progression of synthesis of the molecule is shown, as is the mature structure.

MICRO INQUIRY *Why are modular genes particularly suitable as platforms for the development of new natural products of industrial interest?*

All directed evolution methodologies are designed to produce new genes, proteins, or RNAs that will create hundreds, if not thousands, of variants. Sorting through so many new candidate molecules requires a specific assay that assesses the desired trait, such as stability under reducing conditions or increased ability to bind a specific molecule. Selecting the best variant could represent a tremendous workflow bottleneck; however, the development of **high-throughput screening** (**HTS**) enables the rapid selection of a subset of desirable molecules from tens of thousands of candidates. HTS employs a combination of robotics and computer analysis to screen samples (proteins, natural compounds, and whole cells) for a specific trait, usually in 96-well microtiter plates. The combination of directed evolution approaches and HTS has propelled industrial microbiology to a new level of exploration and efficiency not previously envisioned.

Synthetic Biology

So far we have discussed the modification of existing regulatory genetic networks and biochemical pathways. **Synthetic biology** looks beyond the constraints of what is already present in an organism and constructs or repurposes entirely new capabilities. Simply put, the new field of synthetic biology involves the engineering of biological systems (plants, microbes) to perform

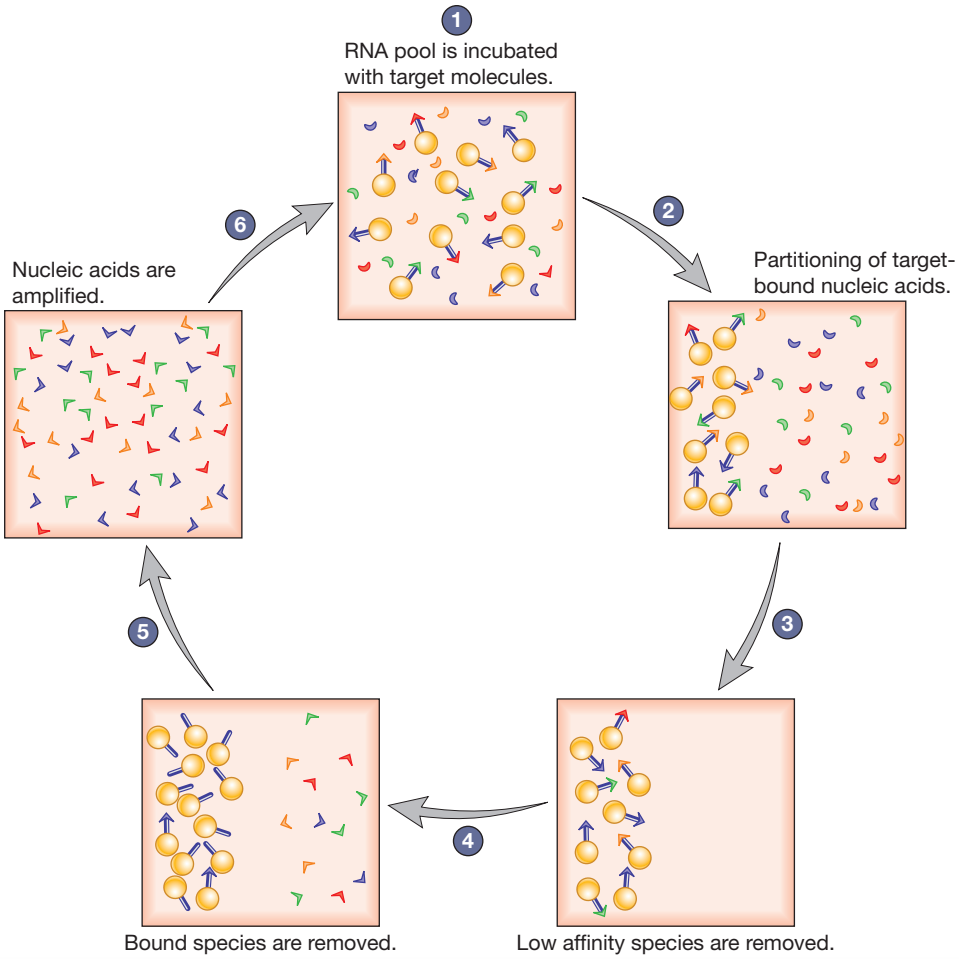

Figure 42.7 Directed Evolution of RNA Molecules. Systematic evolution of ligands by exponential enrichment (SELEX) starts with (1) an assortment of RNA molecules incubated with target molecule. (2) RNAs that have bound the target are separated from those that have not. (3) RNAs that have not bound tightly to the target molecule are removed. (4) RNAs that have bound tightly to the target are removed from the target so that (5) they can be amplified. (6) This pool of tight-binding RNAs is now subject to repeated rounds of SELEX so that a molecule with the highest binding affinity can evolve.

MICRO INQUIRY *Why is SELEX considered an "enrichment" technique?*

completely novel functions. Examples include the design of microorganisms that seek out and kill cancerous tumor cells and the redesign of photosynthesis to produce excess energy that can be fed into existing electrical grids.

There is no set of instructions for something so complex as designing a microbe to perform a completely novel function. Each project requires careful planning followed by the iterative process of design, build, test, redesign, rebuild, retest, and so on. For instance, if one wanted to engineer a bacterium to produce a biofuel, the first step would be to review literature to determine what genes are needed (planning). The next step would be to figure out how these genes are going to be cloned and what bacterial species should host them (design). Once the genes are inserted into the host (build), the amount of biofuel made would be quantified (test). It is safe to say that perfection is never attained with the first try. However, the results inform the synthetic biologist of what steps need redesign (or if the entire design should be scrapped and fresh approach taken). Synthetic biology has the potential to generate a vast diversity of products, and researchers at the J. Craig Venter Institute have prepared for such versatility by constructing and expressing a completely synthetic genome in mycoplasma cells (*see p. 412*). This genome serves as the platform into which new genes can be added for the production of novel compounds.

Metagenomics

As we have learned, techniques for growing most microbes found in nature have not yet been developed. While having a pure culture of the microorganism that produces an interesting

compound is always the best approach, industrial microbiologists would be at a great disadvantage if they limited their search for products to only those found in microbes that can be grown in the laboratory. Indeed, this would exclude over 90% of microbial gene products. The example of antibiotics made by actinobacteria is instructive. Worldwide, the top 10 centimeters of many soils are estimated to contain so many actinobacteria that have never been screened for antibiotic production that at the current rate, it would take another 128 years to screen them all, assuming they can be easily cultured. Industrial microbiologists have therefore turned to metagenomics to sample the genetic diversity from a number of environments. Certain areas of the globe have been dubbed "biodiversity hot spots," and these are of particular interest when exploring genetic diversity. The process of exploring nature for new and potentially useful organisms and their products is called **bioprospecting.** ⏮ *Metagenomics provides access to uncultured microbes (section 18.3)*

Metagenomic libraries from natural samples are generally screened in two ways. First, all the cloned DNA from the environment can be sequenced and compared to genes that have already been characterized *(see figure 18.8)*. In this way, new versions of known genes can be identified based upon similarity to genes that are already known. This means that genes for which no function can be deduced will be ignored. But what if one of these novel genes encodes a previously undiscovered protein with a highly desirable activity? A functional screen of the metagenomic library can be used to explore this possibility (**figure 42.8**). In a functional screen, the genes are cloned into vectors and expressed in microbes such as *E. coli* or *Bacillus subtilis*, which are then screened for the acquisition of a new, specific function. Of course, these two lines of inquiry are not mutually exclusive. Keep in mind that once interesting genes are identified, they can undergo directed evolution techniques to optimize products for industrial use. ⏮ *Genomic libraries (section 17.5)*

Retrieve, Infer, Apply

1. Why was it important to reconstruct production strains with induced mutations with strains bearing defined mutations?
2. Define protoplast fusion and list types of microorganisms used in this process.
3. What is metabolic engineering? Besides antibiotics, what other types of biologically active molecules do you think might be created using combinatorial biology?
4. What is high-throughput screening and why has it become so important?
5. Compare and contrast genetic and functional screening of metagenomic libraries.

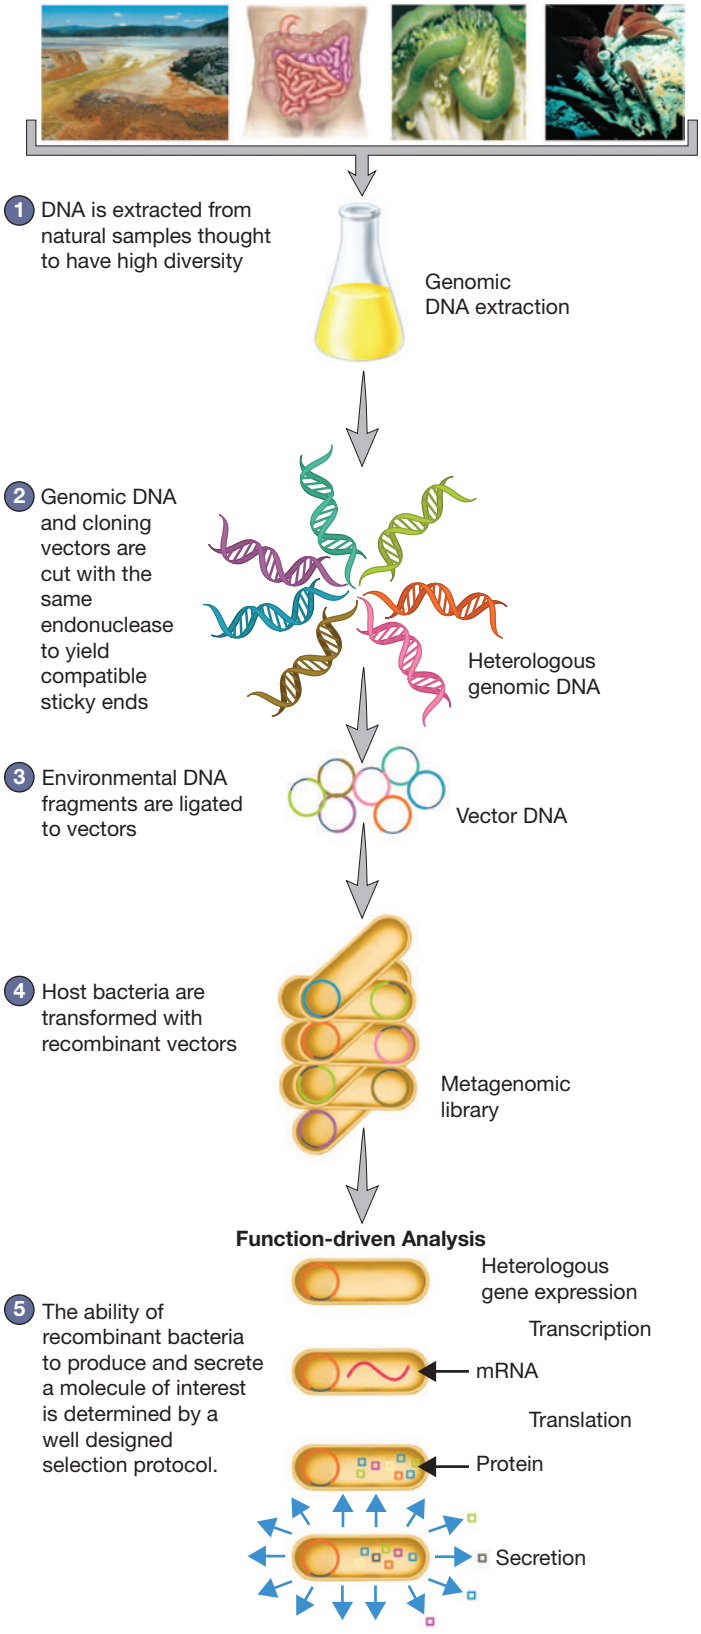

Figure 42.8 Bioprospecting by Functional Screening of Metagenomic Libraries. Rather than trying to culture every organism in a natural sample to look for the production of an important, novel compound, a metagenomic library can be constructed and expressed in host bacteria, which are screened for the desired protein function. This is usually performed in a high-throughput fashion.

42.5 Agricultural Biotechnology Relies on a Plant Pathogen

After reading this section, you should be able to:

- Explain how the natural infection process used by *Agrobacterium tumefaciens* has been leveraged for the genetic modification of plants
- Defend the use of Bt as a pesticide

A plasmid from the plant pathogenic bacterium *Agrobacterium tumefaciens* is chiefly responsible for the successful genetic engineering of plants. In nature, infection of dicotyledonous (dicot) plant cells by this bacterium transforms the cells into tumor cells, and crown gall disease develops. Only strains of *A. tumefaciens* possessing a large conjugative plasmid called the Ti (*t*umor *i*nducing) plasmid are pathogenic (*see figures 31.12 and 31.13*). This is because the Ti plasmid transfers a region known as T-DNA to the plant's chromosomes at sites where it is stably maintained. ⏮ *Transposable elements move genes within and between DNA molecules (section 16.5)*

When the molecular nature of crown gall disease was recognized, it became clear that the Ti plasmid and its T-DNA had great potential as a vector for the insertion of recombinant "good" DNA into plant chromosomes. The Ti plasmid has been genetically engineered to improve its utility as a cloning vector. The tumor-inducing genes have been deleted, while elements found in other vectors (e.g., selectable marker and multicloning site; *see figure 17.10*) have been added. Genes required for infection of plant cells by the plasmid are retained. The gene or genes to be expressed by the plant are inserted into the T-DNA region between the direct repeats needed for integration into the plant genome (**figure 42.9**). Then the plasmid is returned to *A. tumefaciens,* plant cells are infected with the bacterium, and transformants are selected by screening for antibiotic resistance (or another trait encoded by T-DNA). Finally, whole plants are regenerated from the transformed cells.

While it is relatively easy to use the *A. tumefaciens* Ti plasmid to modify dicots such as potato, tomato, celery, lettuce, and alfalfa, its use in monocots has only recently been optimized. The creation of new procedures for inserting DNA into monocot plant cells may lead to the use of recombinant DNA techniques with many important crop plants such as corn, wheat, and other grains *(see p. 680).*

Another microbial application to agriculture involves the use of bacteria, fungi, and viruses as **bioinsecticides** and **biopesticides.** These are defined as biological agents; that is, microbes or their components that kill susceptible insects. Bacterial agents include a variety of *Bacillus* species; however, *B. thuringiensis* is most widely used. This bacterium is only weakly toxic to insects as a vegetative cell, but during sporulation, it produces an intracellular protein toxin crystal, the parasporal body, that kills insect groups (*see figure 23.10*). The parasporal crystal, after exposure to alkaline conditions in the insect hindgut, breaks apart to release protoxin. After protoxin reacts with a protease enzyme in the target insect's gut, active toxin is generated. Six of the active toxin units integrate into the plasma membrane to form a hexagonal-shaped pore through the midgut cell, as shown in **figure 42.10**. This leads to the loss of osmotic balance and ATP, and finally to cell lysis. ⏮ *Order* Bacillales *(section 23.3)*

B. thuringiensis has become an important industrial microbe. The toxin is widely marketed as the insecticide **Bt,** and the toxin genes can be used to genetically modify plants. The manufacture of Bt begins by growing *B. thuringiensis* in fermenters. The spores and crystals are released into the medium when cells lyse. The medium is then centrifuged and converted to a dust or wettable powder for application to plants. This insecticide has been used on a worldwide basis for over 40 years. Unlike chemical insecticides, Bt does not accumulate in the soil or in nontarget animals. Rather, it is readily lost from the environment by microbial and abiotic degradation.

Unlike many other genetically modified organisms, transgenic plants expressing the *B. thuringiensis* toxin gene, *cry* (for *cry*stal), have generally been well accepted. The widespread acceptance of these plants reflects the history of safe application of Bt as an insecticide without adverse environmental or health impacts. In addition, it is well understood that the Cry protein can only be activated in target insects. Long-term studies have shown that Bt is nontoxic to mammals and is not an allergen in humans. One potential problem, the horizontal gene flow of the *cry* gene to weeds and other plants, has not been reliably demonstrated. On the contrary, the decreased need for insecticides when cultivating Bt-modified crops has resulted in the recovery of nontarget insects that were also eliminated by insecticide application. Many of these insects eliminate undesirable pest insects, resulting in enhanced levels of biocontrol where Bt crops have been sown.

Retrieve, Infer, Apply

1. What is the Ti plasmid and how is it modified for the genetic modification of plants?
2. How is Bt toxin produced and why is it so widely accepted?
3. Can you think of other traits that might be useful, either to the farmer or the consumer, that could be introduced into plants?

42.6 Some Microbes Are Products

After reading this section, you should be able to:

- Describe the use of microbes in nanotechnology
- Explain the utility of biosensors

So far, we have discussed the use of microbial products to meet defined goals. However, microbial cells can be marketed as valuable products. Perhaps the most common example is the inoculation of legume seeds with rhizobia to ensure efficient nodulation and nitrogen fixation. Here we introduce several other microbes and microbial structures that are of industrial or agricultural

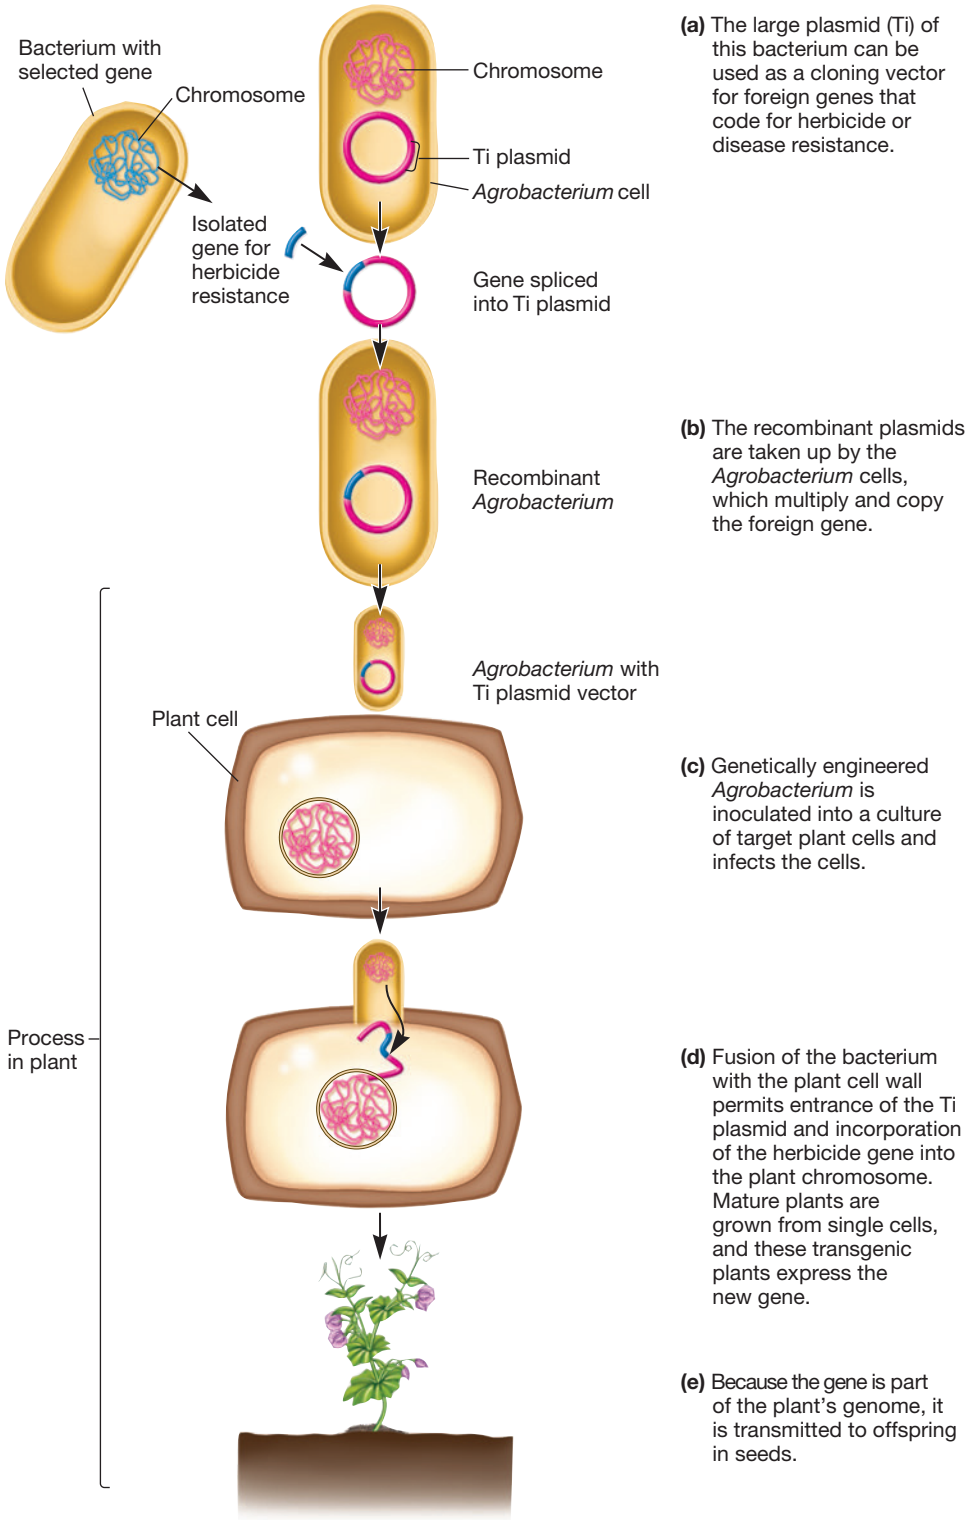

Figure 42.9 Bioengineering of Plants. Most techniques employ a genetically modified strain of the natural tumor-producing bacterium called *Agrobacterium tumefaciens*.

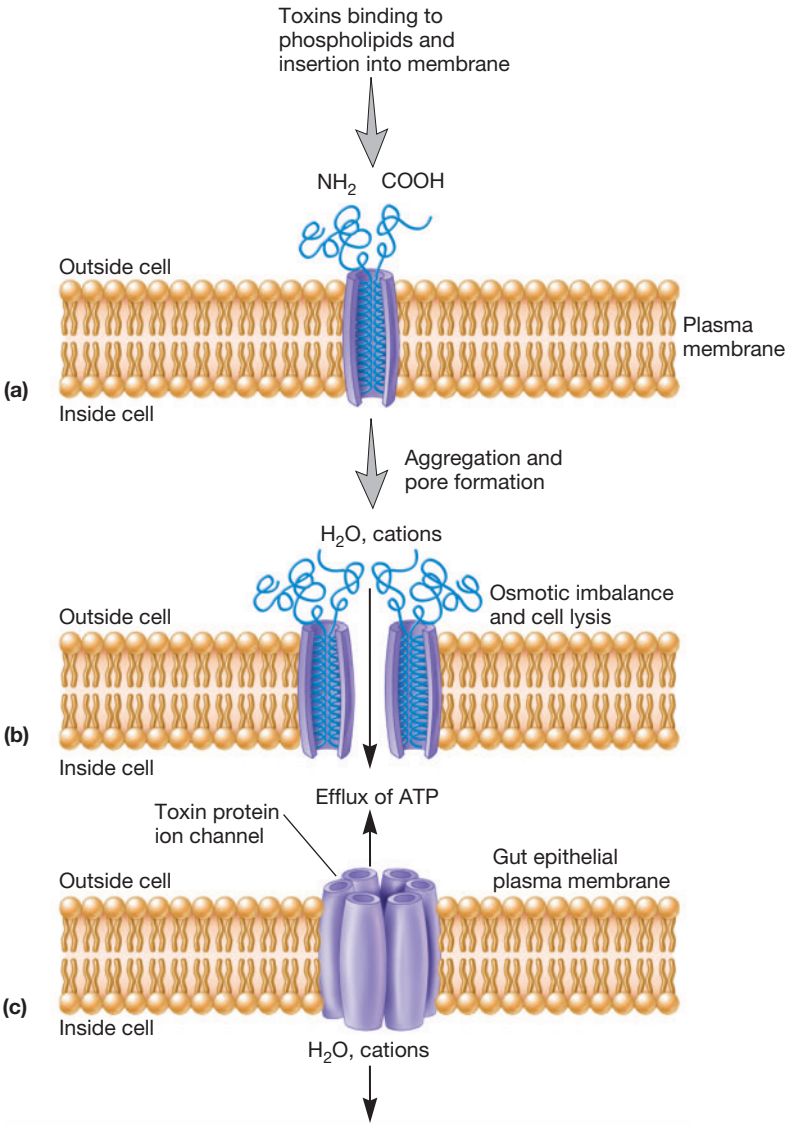

Figure 42.10 The Mode of Action of the *Bacillus thuringiensis* Toxin. (a) Insertion of the 68 kDa active toxin molecules into the membrane. (b) Aggregation and pore formation, showing a cross section of the pore. (c) Final hexagonal pore, which causes an influx of water and cations as well as a loss of ATP, resulting in cell imbalance and lysis.

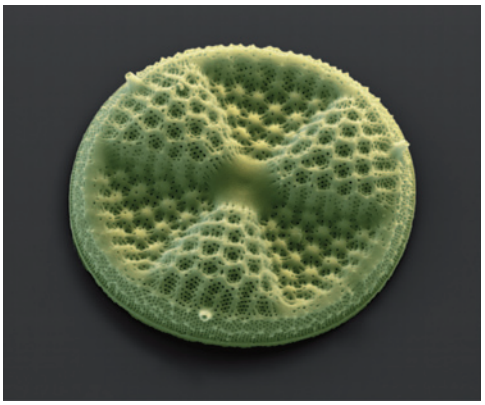
MICRO INQUIRY *Why is it advantageous to have the Bt toxin inactive until it reaches the insect gut?*

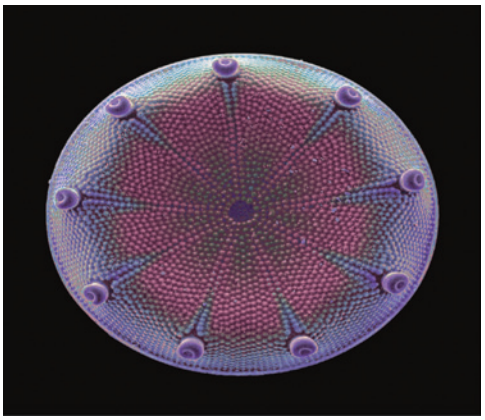
relevance. ◀◀ *Nitrogen-fixing bacteria are vital to agriculture (section 31.3)*

Diatoms have aroused the interest of nanotechnologists. These photosynthetic protists produce intricate silica shells that differ according to species (**figure 42.11**). Nanotechnologists are interested in diatoms because they create precise structures at the micrometer scale that can be used for making optical, catalytic, or electrical materials. Three-dimensional structures in nanotechnology are currently built plane by plane, and meticulous care must be taken to etch each individual structure to its final, exact shape. Diatoms, on the other hand, build directly in three dimensions and do so while growing exponentially. The silica in these shells can be chemically converted to silicon to generate nanoelectronics. Another application involves the use of diatom shells to coat solar energy cells. This is attractive because diatom shells capture three times more electrons than the standard coatings. ◀◀ Stramenopila *(section 25.4)*

Magnetotactic bacteria are also of interest to nanotechnologists. Magnetosomes are formed by certain bacteria that convert iron to magnetite. The sizes and shapes of the magnetosomes differ among species, but like diatom shells, they are perfectly formed despite the fact that they are only tens of nanometers in diameter. Although tiny, magnetic beads can be chemically synthesized, they are not as precisely formed and lack the membrane that surrounds magnetosomes. This membrane enables the attachment of useful biological molecules such as enzymes and antibodies. Potential applications for magnetosomes



(a)



(b)

Figure 42.11 Marine Diatom Surface Features Are Attractive Platforms for Nanotechnology. currently under investigation include their use as a contrast medium to improve magnetic resonance tomography (MRI) and as biological probes to detect cancer at early stages. ⏮ *Inclusions (section 3.6)*

Another rapidly developing area of biotechnology is that of **biosensor** production. In this field of bioelectronics, living microorganisms (or their enzymes or organelles, and most recently diatom frustules) are linked with electrodes, and biological reactions are converted into electrical currents. Biosensors are used to measure specific components in beer, monitor pollutants, detect flavor compounds in food, and study environmental processes such as changes in biofilm concentration gradients. Using biosensors, it is possible to measure the concentration of substances from many different environments. Biosensors have been developed using immunochemical-based detection systems. These biosensors detect pathogens, herbicides, toxins, proteins, and DNA. Many of these biosensors are based on the use of a streptavidin-biotin recognition system (*see Techniques & Applications 17.1*).

Retrieve, Infer, Apply

1. Why are diatoms and magnetotactic bacteria of interest to nanotechnologists? What do you think might be special challenges when growing these microbes for industrial applications?
2. In what areas are biosensors being used to assist in chemical and biological monitoring efforts?

Key Concepts

42.1 Microbes Are the Source of Many Products of Industrial Importance

- A wide variety of compounds are produced in industrial microbiology that impact our lives in many ways. These include antibiotics, amino acids, organic acids, biopolymers, and biosurfactants.
- Microorganisms also can be used as biocatalysts to carry out specific chemical reactions.
- Vaccine development continues to challenge biotechnologists; reverse vaccinology identifies potential targets and uses their structure and function to inform vaccine production.

42.2 Biofuel Production Is a Dynamic Field

- The field of microbial energy conversion has become extremely relevant. This includes the production of biofuels and the development of microbial sources of H_2.
- Although corn is currently the most common substrate used for the microbial production of ethanol, the use of both corn as substrate and ethanol as product is being challenged.

42.3 Growing Microbes in Industrial Settings Presents Challenges

- Microorganisms can be grown in controlled environments of various types using fermenters and other culture systems (**figure 42.3**).
- If defined constituents are used, growth parameters can be chosen and varied in the course of growing a microorganism. This approach is used particularly for the production of amino acids, organic acids, and antibiotics.

42.4 Production Strains Are Developed to Maximize Output of Industrially Important Compounds

- Historically, microorganisms used in industry were isolated from nature and modified by the use of classic mutational techniques. Biotechnology involves the use of molecular techniques to modify and improve microorganisms.
- Finding new microorganisms in nature for use in biotechnology is a continuing challenge. Only about 1% of the observable microbial community has been grown, but major advances in growing uncultured microbes are being made.
- Selection and mutation continue to be important approaches for identifying new microorganisms.
- Site-directed mutagenesis and protein engineering are used to modify genes and their expression. These approaches are leading to new and often different products with novel properties (**figures 42.5** and **42.6**).
- Directed evolution includes a suite of techniques designed to target specific molecules for change with the goal of optimizing their function in a particularly useful way (**table 42.2** and **figure 42.7**).
- Metagenomics has become increasingly important in the search for new products, which are detected in a metagenomic functional screen (**figure 42.8**).

42.5 Agricultural Biotechnology Relies on a Plant Pathogen

- Many plants are genetically modified through the use of the Ti plasmid of *Agrobacterium tumefaciens*. The plasmid can be engineered to introduce genes whose products confer new traits to plants (**figure 42.9**).
- *Bacillus thuringiensis* is an important biopesticide, and the Bt gene has been incorporated into several important crop plants (**figure 42.10**).

42.6 Some Microbes Are Products

- Microorganisms are being used in a wide range of biotechnological applications such as nanotechnology and biosensors (**figures 42.11**).

Compare, Hypothesize, Invent

1. You have discovered a secondary metabolite made by an unusual fungus that has great industrial potential. Unfortunately, the fungus makes very little of this product, so you must develop a scheme to increase the yield. Discuss the pros and cons of each of the following strategies: (a) mutagenesis of the fungus followed by repeated passaging until a high-producing strain evolves, (b) heterologous expression of the genes and regulators responsible for producing this product in a bacterial host, (c) heterologous expression of the genes responsible for producing this product in a bacterial host but using a bacterial promoter that will drive constitutive expression of the product.
2. Brewer's yeast, *Saccharomyces cerevisiae,* does not metabolize lactose, but an engineered strain of *S. cerevisiae* able to consume lactose is of industrial interest. This is because such a strain can convert whey (an unusable by-product of cheese production) to ethanol. Such a strain has been engineered by cloning the genes that encode β-galactosidase and lactose permease from another yeast, *Kluyveromyces lactis,* into *S. cerevisiae.* However, the recombinant *S. cerevisiae* expresses the *K. lactis* genes only at a low level, so very little lactose is consumed. In an effort to increase the expression of these heterologous genes, a directed evolution approach was applied.

   Suggest one directed evolution technique that could be applied in vivo (on the entire organism) and one that could be used in vitro; that is, on the two genes from *K. lactis.* Which do you think would be easier to carry out? Which do you think would be more effective?

   Read the original paper: Guimaraes, P. M. R., et al. 2008. Adaptive evolution of a lactose-consuming *Saccharomyces cerevisiae* recombinant. *Appl. Environ. Microbiol.* 74:1748.
3. The detection of unexploded land mines is a horrific problem. Unexploded ordinances emit a small amount of nitroaromatic compounds, affording the opportunity to develop a biosensor. A *Pseudomonas putida* strain has been constructed with a mutated toluene responsive regulator. When activated by bi- and trinitro-substituted toluenes, the regulator triggers the expression of genes transcriptionally fused to GFP (*see figure 17.15*). When spread on soil spotted with nitrotoluenes, there is sufficient activation of GFP-generated light that the location of the chemicals is evident.

   Draw a flow chart of how the signal is emitted, received, and transduced into a light signal that would enable you to explain this biosensor to military personnel.

   Read the original paper: Garmendia, J., et al. 2008. Tracing explosives in soil with transcriptional regulators for *Pseudomonas putida* evolved for responding to nitrotoluenes. *Microbial Biotechnol.* 1:236.

Applied Environmental Microbiology

The explosion of the Deepwater Horizon offshore oil rig resulted in one of the worst environmental disasters in U.S. history. This photograph was taken while the rig was still burning; it eventually sank.

Deepwater Horizon Oil Consumed by Microbes

One of the planet's largest oil disasters occurred on April 20, 2010, when an explosion aboard BP's Deepwater Horizon oil rig resulted in the death of 11 people and the release of nearly 5 million barrels of oil over 83 days into the Gulf of Mexico. Many may recall the dramatic images of oil spewing from the uncapped well and the resulting oil slicks with booms skimming the oil from the water's surface. But about the fate of the oil between the seafloor and the surface? The release of petroleum at such depth resulted in the dissolution of methane and, to a lesser extent, ethane, propane, and butane. These dissolved gases formed lateral plumes trapped 800 to 1,200 meters below the lighter gas-free seawater.

Mass balance calculations revealed that several years later, 22% of the spilled oil could not be accounted for. Could microbes be responsible for some (or all) of this "missing" oil? Could they have mineralized the oil to CO_2 or immobilized it as biomass? Arriving at a satisfactory answer to this question required a combination of methods, including sequencing 16S rRNA genes, metagenomic and single-cell genome sequencing, measuring the flux of ^{14}C-labeled test hydrocarbons, just to name a few. In the end, the scientific community agreed that microbes present in the sediments degraded a large (but unknown) fraction of the oil. Interestingly, the microbial community changed as the oil was degraded. Early in the spill recovery when concentrations of saturated hydrocarbons were high, single-cell genome sequencing revealed genes for alkane degradation, chemotaxis, and motility. However, as alkane hydrocarbons declined, so did evidence of genes whose products degrade them. The loss of alkanes meant that polyaromatic hydrocarbons (PAHs) were enriched, meaning they represented a larger fraction of the undegraded oil. These large PAHs persist because they have proved to be resistant to microbial attack. These compounds are known to be toxic to eukaryotes, so even though microbial oxidation of many of the contaminants has been a helpful outcome, the persistence of PAHs in the environment could negatively impact ongoing Gulf Coast recovery efforts, and have implications for future bioremediation efforts elsewhere.

The Deepwater Horizon experience vividly illustrates that the natural decontamination of soils, waters, and wastewaters is largely a microbial process. Water cleanliness—whether to decontaminate or to prepare it for drinking—is a multidisciplinary endeavor, involving geology, biochemistry, and physics, among other fields. In this chapter, we address water and how to assess the purity of drinking water and as well as how to treat wastewater before returning it to the environment. We also discuss the means by which microbes can contribute to meeting the world's insatiable demand for energy and their role in degrading environmental contaminants—bioremediation.

Readiness Check:

Based on what you have learned previously, you should be able to:

- ✔ Identify several waterborne diseases (sections 38.4, 39.4, and 40.5)
- ✔ List environmental factors that influence microbial growth (section 7.4)
- ✔ Explain how the term redox potential is used to describe microbial habitats and how this influences the elements found in these habitats (section 28.1)
- ✔ Distinguish between mineralization and immobilization of an element (section 28.1)
- ✔ Compare and contrast carbon substrates that are readily degraded with those that are not (section 28.1)
- ✔ Sketch generalized carbon and nitrogen iron cycles (section 28.1)

43.1 Purification and Sanitary Analysis Ensure Safe Drinking Water

After reading this section, you should be able to:

- Trace the water purification steps that are often used from source to tap
- Describe how the U.S. Environmental Protection Agency regulates water purity
- Discuss the use of indicator organisms and how they are enumerated

Access to clean, drinkable water is a fundamental human right, yet over a billion people worldwide do not enjoy a reliable source of potable water. Water that is not adequately monitored for purity can contain pathogens introduced from human and animal waste. The U.S. Environmental Protection Agency (EPA) has designated certain bacterial, viral, and protozoan pathogens that can survive (or thrive) in water as "microbial containment candidates" because they represent particularly severe health risks (**table 43.1**). When waters are used for recreation or are the source of fish and other food, the possibility for disease transmission exists. In many cases, such waters also are a source of drinking water.

Water purification is therefore a critical link in controlling disease transmission. The choice of purification method depends on the volume, source, and initial quality of the water. Many municipalities draw their water from surface sources, such as reservoirs. Surface water is usually purified by a process that consists of at least three steps (**figure 43.1**). First, the water may be held for a specified duration to allow larger particles to settle out in a **sedimentation basin.** Sometimes coagulants are also added in a procedure called **coagulation** or flocculation, which removes some microorganisms, organic matter, toxic contaminants, and suspended fine particles. The coagulated particles are called flocs. The partially clarified water is then moved to a **settling basin** and mixed with chemicals such as alum (aluminum sulfate) and lime to facilitate further precipitation. The water is further purified by passing it through **rapid sand filters.** Here sand of roughly 1 mm in diameter physically traps fine particles and flocs and removes up to 99% of the bacteria. After filtration, the water is disinfected. This step usually involves chlorination or ozonation.

When chlorination is employed, the chlorine dose must be large enough to leave residual free chlorine at a concentration of 0.2 to 2.0 milligrams per liter. The creation of **disinfection by-products** (**DBPs**) such as trihalomethanes (THMs), formed when chlorine reacts with organic matter, must be monitored because some DBPs are carcinogenic.

These purification processes remove or inactivate disease-causing bacteria and indicator organisms (coliforms). Unfortunately, the use of coagulants, rapid filtration, and chemical disinfection often does not remove *Giardia cysts, Cryptosporidium* oocysts, *Cyclospora* spp., and viruses. *Giardia intestinalis,* a cause of human diarrhea, is now recognized as the most commonly identified water borne pathogen in the United States (*see figure 25.4*). *Cryptosporidium* spp. are also a significant problem. These protists are smaller than *G. intestinalis* and even more difficult to remove from water, in part because they are resistant to chlorine and other disinfectants. A major source of *G. intestinalis* and *Cryptosporidium* spp. contamination is the Canada goose, a migratory bird with an ever-expanding population. Water supplies that receive terrestrial runoff are therefore at particular risk of contamination by these protists. ⏮ *Food and water are vehicles of fungal and protozoal diseases (section 40.5)*

In the United States, the EPA has developed regulations called the Long Term 2 Enhanced Surface Water Treatment (LT2) Rule as a means of ensuring protection against pathogens. The LT2 rule applies to all public water systems that draw from surface waters or groundwater fed by surface waters. It sets a **maximum containment level goal** (**MCLG**) for specific pathogens. The EPA defines MCLGs as "health goals set at a level at which no known or anticipated adverse effects on health

Table 43.1 Microbial Water Contaminant Candidates Listed by the EPA

Organism	Concern
Caliciviruses	Viruses that cause relatively mild, self-limiting nausea, vomiting, diarrhea; includes norovirus
Campylobacter jejuni	Causes nausea, vomiting, and diarrhea; usually self-limiting
Entamoeba histolytica	Protozoan that causes short-term as well as long-lasting gastrointestinal (GI) illness
E. coli O157:H7	Enterohemorrhagic *E. coli* that causes severe GI illness; can also cause kidney failure
Helicobacter pylori	Bacterium that causes gastric ulcers and cancer
Hepatitis A virus	Causes liver disease leading to jaundice
Legionella pneumophila	Found in hot water systems; causes bacterial pneumonia when inhaled. Usually limited to elderly patients.
Naegleria fowleri	Protozoan found in warm surface and groundwater; causes primary amoebic meningoencephalitis
Salmonella enterica	Causes GI illness; severity depends on subspecies
Shigella sonnei	Causes GI illness, including bloody diarrhea
Vibrio cholerae	Causes cholera

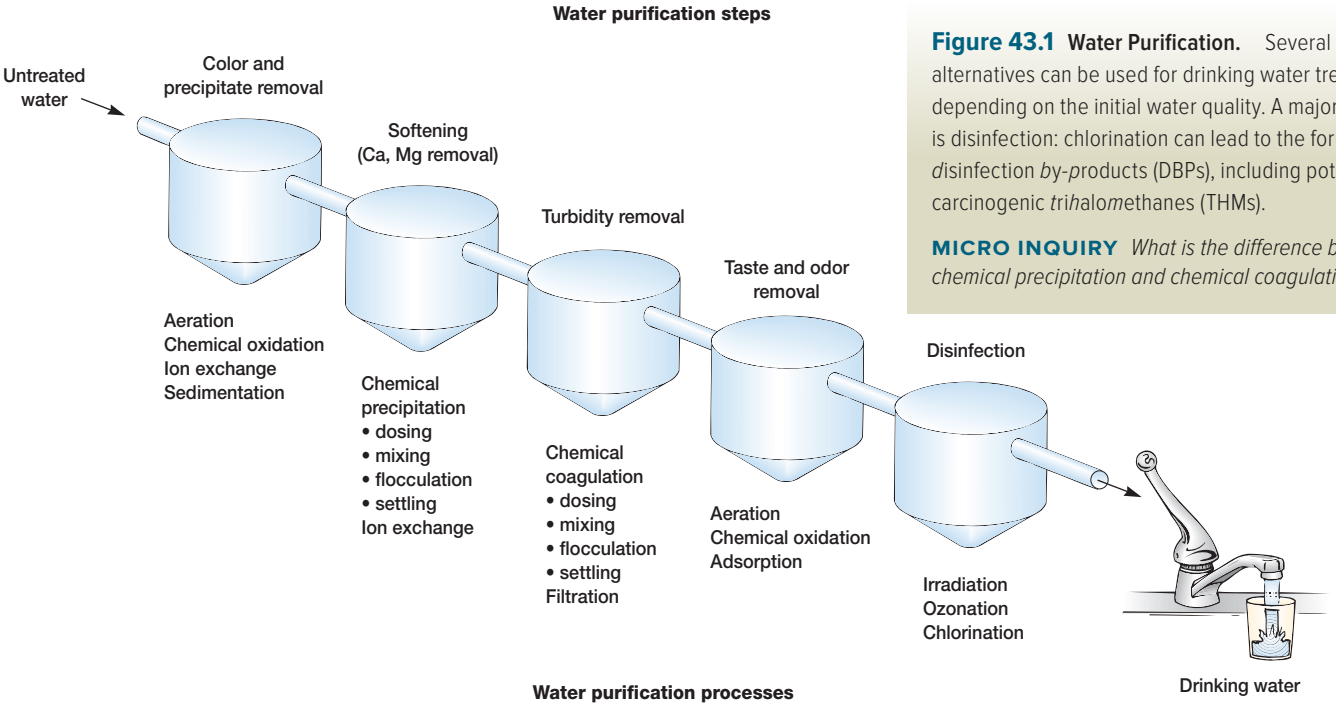

Figure 43.1 Water Purification. Several alternatives can be used for drinking water treatment, depending on the initial water quality. A major concern is disinfection: chlorination can lead to the formation of *d*isinfection *by*-products (DBPs), including potentially carcinogenic *trihalom*ethanes (THMs).

MICRO INQUIRY *What is the difference between chemical precipitation and chemical coagulation?*

of persons occur and which allows an adequate margin of safety." MCLGs are set at zero for *Giardia, Cryptosporidium,* and *Legionella* spp., and certain viruses. In addition, the Total Coliform Rule, which applies to all public water systems regardless of supply source, sets an MCLG of zero for total and fecal coliform bacteria. To meet these MCLGs, water systems found to be contaminated must develop additional water treatment strategies to provide 99.9% inactivation of the microbes. The treatment approach depends on the level of contamination but generally involves filtration techniques such as **slow sand filters.** This treatment involves the slow passage of water through a bed of sand in which a microbial layer (biofilm) covers the surface of each sand grain. Waterborne microorganisms are removed by adhesion to the gelatinous surface microbial layer. Coagulation and filtration reduce virus levels about 90 to 99%. Further inactivation of viruses can be achieved by chemical oxidants, high pH, and photooxidation. ⏮ *Biofilms are common in nature (section 7.5)*

Sanitary Analysis of Waters

Once water has been purified, it must be deemed potable. Although a wide range of viral, bacterial, and protozoan diseases result from the contamination of water with human and other animal fecal wastes (table 43.1), the detection of **indicator organisms** as an index of possible water contamination by human pathogens has long been the standard approach to monitoring drinking water safety. Researchers are still searching for the "ideal" indicator organism to use in sanitary microbiology. Among the suggested criteria for such an indicator microbe are:

1. The indicator bacterium should be suitable for analysis of all types of water: tap, river, ground, impounded, recreational, estuary, sea, and waste.
2. It should be present whenever enteric pathogens are present.
3. It should survive longer than the hardiest enteric pathogen.
4. It should not reproduce in the contaminated water, as this would produce an inflated value.
5. It should be harmless to humans.
6. Its level in contaminated water should have some direct relationship to the degree of fecal pollution.
7. The assay procedure for the indicator should have great specificity; in other words, other bacteria should not give positive results. In addition, the procedure should have high sensitivity and detect low levels of the indicator.
8. The testing method should be easy to perform.

Coliforms, including *Escherichia coli,* are members of the family *Enterobacteriaceae (see p. 527).* These bacteria are commonly found in the intestines of humans and other animals, and are used widely as indicator organisms. They lose viability in freshwater at slower rates than most of the major intestinal bacterial pathogens. When such "foreign" enteric indicator bacteria are not detectable in a specific volume (generally 100 milliliters) of water, the water is considered potable (Latin *potabilis,* fit to drink). ⏮ *Order* Enterobacteriales *includes pathogens and mutualists (section 22.3)*

The original test for coliforms involved the presumptive, confirmed, and completed tests, as shown in **figure 43.2**. The presumptive step is carried out by means of tubes inoculated with three different sample volumes to give an estimate of the ***m*ost *p*robable *n*umber** (**MPN**) of coliforms in the water (*see figure 29.3*). The complete process, including the confirmed and completed tests, requires at least 4 days of incubations and transfers.

The coliforms include a wide range of bacteria whose primary source may not be the intestinal tract. To address this, tests have been developed that assay for the presence of **fecal coliforms.** These are coliforms from the intestines of warm-blooded animals, which grow at the more restrictive temperature of 44.5°C. Other indicator

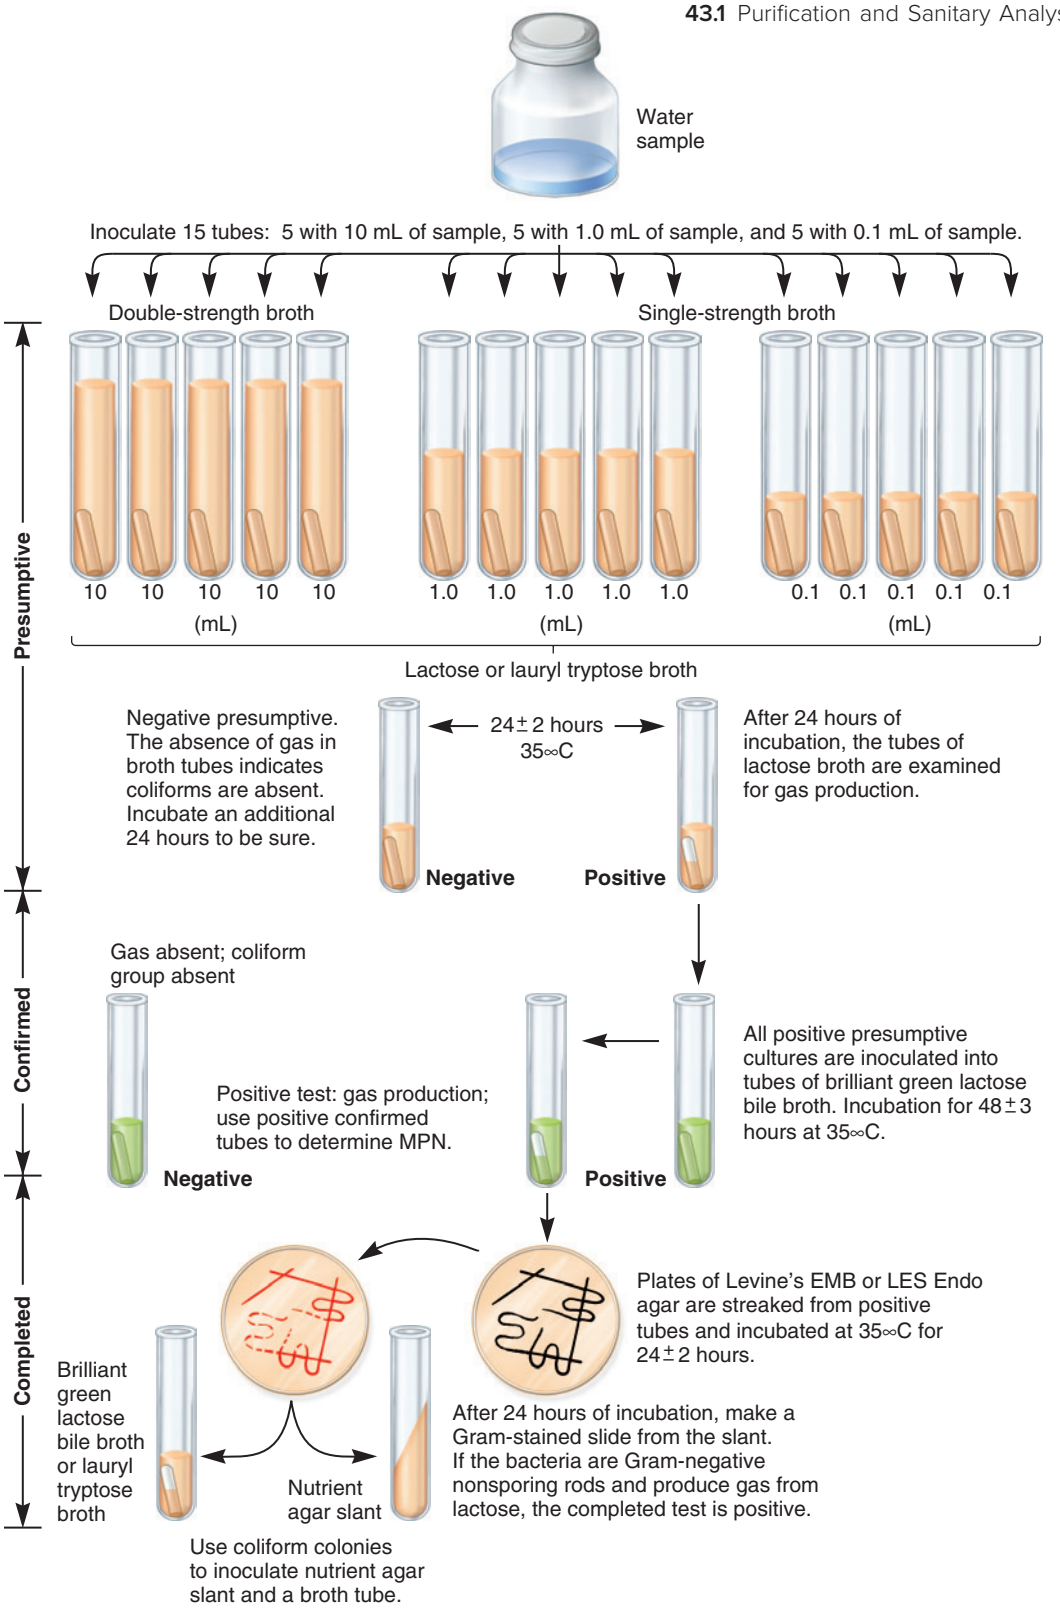

Figure 43.2 The Multiple-Tube Fermentation Test. The multiple-tube fermentation technique has been used for many years for the sanitary analysis of water. Lactose broth tubes are inoculated with different water volumes in the presumptive test. Tubes that are positive for gas production are inoculated into brilliant green lactose bile broth in the confirmed test, and positive tubes are used to calculate the most probable number (MPN) value. The completed test is used to establish that coliform bacteria are present.

microorganisms include **fecal enterococci.** These microbes are increasingly being used as an indicator of fecal contamination in brackish and marine water. In saltwater, these bacteria die more slowly than fecal coliforms, providing a more reliable indicator of possible recent pollution. ⏮ *Order* Lactobacillales *(section 23.3)*

The **membrane filter technique** is a common and preferred method of evaluating the microbiological characteristics of water. The water sample is passed through a membrane filter. The filter with its trapped bacteria is transferred to the surface of a solid medium or to an absorptive pad containing the desired liquid medium. Specific media enable the rapid detection of total coliforms, fecal coliforms, or fecal enterococci by the presence of their characteristic colonies. Samples may first be placed on a less selective resuscitation medium or incubated at a less stressful temperature prior to growth under the final set of selective conditions. An example of such a resuscitation step is the use of

a 2-hour incubation on a pad soaked with lauryl sulfate broth, as is carried out in the LES Endo procedure. A resuscitation step often is needed with chlorinated samples, where the microorganisms are especially stressed. Membrane filters have been widely used with water that does not contain high levels of background organisms, sediment, or heavy metals. ⏮ *Mechanical removal methods rely on barriers (section 8.3)*

More simplified tests for detecting coliforms and fecal coliforms are now available. The ***presence-absence* (P-A) test** can be used for coliforms. This is a modification of the most probable number procedure in which a larger water sample (100 milliliters) is incubated in a single culture bottle with a triple-strength broth containing lactose broth, lauryl tryptose broth, and bromocresol purple indicator. The P-A test is based on the assumption that no coliforms should be present in 100 milliliters of drinking water. A positive test results in the production of acid (a yellow color), which requires confirmation.

To test for both coliforms and *E. coli*, the related **Colilert defined substrate test** can be used. A water sample of 100 milliliters is added to a specialized medium containing *o*-nitrophenyl-β-D-galactopyranoside (ONPG) and 4-methylumbelliferyl-β-D-glucuronide (MUG) as the only nutrients. If coliforms are present, the medium will turn yellow within 24 hours at 35°C due to the hydrolysis of ONPG, which releases *o*-nitrophenol (**figure 43.3**). To check for *E. coli,* the medium is observed under long-wavelength ultraviolet (UV) light for fluorescence. When *E. coli* is present, MUG is modified to yield a fluorescent product. If the test is negative for the presence of coliforms, the water is considered acceptable for human consumption. Current standards dictate that water be free of coliforms and fecal coliforms. If coliforms are present, tests for fecal coliforms or *E. coli* must be performed.

The use of indicator organisms as a means of detecting all pathogenic microbes is limited. Some pathogens simply do not co-occur with indicator organisms. Another problem is that indicator organisms can be more sensitive to disinfectants; thus when drinking water is tested after such treatment, indicator-based assays may be misleading. In addition, these culture-based methods generally require at least 18 hours to complete, and some assays require almost a week. The consequences of these shortcomings were evident in 1993, when about 400,000 Milwaukee, Wisconsin, residents became ill from drinking water contaminated with *Cryptosporidium parvum.* Currently the Centers for Disease Control and Prevention estimates that in the United States, a million people per year are sickened from drinking impure water and another 1,000 die annually.

It is clear that effective, reliable, rapid, and quantitative methods for determining the presence or absence of specific pathogens are needed. Molecular approaches can be all these things—with the ability to quickly detect multiple, specific pathogens in a single water sample. Some of the methodologies that have been developed include the flow cytometry (*sections 29.2 and 36.3*), fluorescent in situ hybridization (*FISH; section 29.2*), quantitative PCR (*section 17.2*), and microarrays (*sections 18.5 and 29.3*). One example is *Legionella pneumophila* contamination, which is routinely detected by PCR amplification. Results are reported in genome units per liter, but the equivalence of these units to colony forming units is unclear. Many communities routinely use 16S rRNA amplification to detect coliforms in waters and other environments, including foods. Following a short enrichment step, this approach can detect 1 colony forming unit (CFU) of *E. coli* per 100 milliliters of water. This technique can also be used to differentiate between nonpathogenic and enterotoxigenic strains, including the Shiga-like toxin–producing *E. coli* O157:H7.

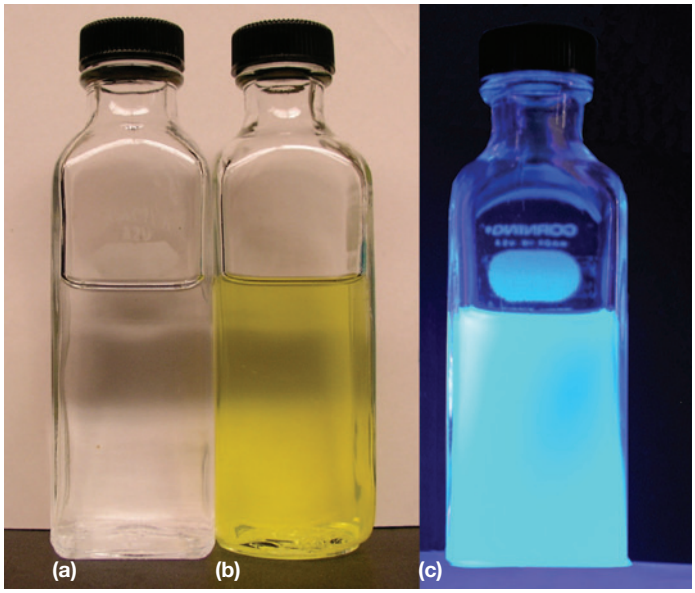

Figure 43.3 The Defined Substrate Test. This test is used to detect coliforms and fecal coliforms in single 100-milliliter water samples. The medium uses ONPG and MUG as defined substrates. (a) Sterile control. (b) Yellow color due to the presence of coliforms. (c) Fluorescence resulting from the presence of fecal coliforms.

1. What steps are usually taken to purify drinking water?
2. Why is chlorination, although beneficial in terms of bacterial pathogen control, of environmental concern?
3. How can *Giardia* and *Cryptosporidium* cysts be removed from a water supply?
4. Why is it important that an indicator microorganism survive but not grow in the water to be tested?
5. Why do you think workers who perform these tests must practice excellent personal hygiene and be specifically trained in the implementation of these techniques?

43.2 Wastewater Treatment Maintains Human and Environmental Health

After reading this section, you should be able to:

- Compare and contrast the processes that occur during primary, secondary, and tertiary wastewater treatment
- Explain how, in general, septic systems operate
- Identify at least two challenges for the future of wastewater treatment

Table 43.2 Common Contaminants of Wastewater

Contaminant	Problems Caused by Contaminant
Suspended solids	Can cause deposition of sludge leading to anoxic conditions when discharged into aquatic environments
Biodegradable organic compounds	Includes proteins, fats, and carbohydrates that when discharged into streams and rivers cause increased heterotrophic growth leading to anoxic conditions
Pathogenic microorganisms	Cause infectious disease
Priority pollutants	Include organic and inorganic compounds that may be toxic, carcinogenic, mutagenic, or teratogenic
Refractory organic compounds	Organic compounds such as phenols, surfactants, agricultural pesticides, and other toxic compounds that resist conventional wastewater treatment
Heavy metals	Usually discharged by industry; discharge into rivers and streams is toxic to all trophic levels
Dissolved inorganic constituents	Include calcium, sodium, and sulfate that may be added to domestic water supplies and may have to be removed prior to wastewater reuse

Source: Modified from Metcalf and Eddy, Inc. Wastewater Engineering, *4th ed. McGraw-Hill, 2002.*

The flip side of ensuring safe drinking water is wastewater management. In fact, the combination of wastewater management, safe drinking water, vaccines, and antibiotics accounts for most of the gain in longevity accomplished in the last century. Citizens of Western nations take this for granted, yet about 40% of the Earth's population lacks basic sanitation.

Wastewater includes sewage as well as industrial and agricultural effluent and street runoff collected in storm sewers. These waters often contain high levels of organic matter, heavy metals, nutrients, and particulates (**table 43.2**). We begin our discussion of wastewater treatment with an overview of large-scale wastewater treatment processes, followed by the means by which water quality is monitored. We then review home treatment systems.

Figure 43.4 Aerial View of a Conventional Sewage Treatment Plant. Sewage treatment plants allow natural processes of self-purification that occur in rivers and lakes to be carried out under more intense, managed conditions in large concrete vessels.

MICRO INQUIRY *This plant does not use an anaerobic digester. What would be the advantage of this additional step?*

Wastewater Treatment Processes

An aerial photograph of a modern sewage treatment plant is shown in **figure 43.4**. Wastewater treatment involves at least three spatially segregated steps: primary, secondary, and tertiary treatment (**table 43.3**). At the end of the process, the water is usually chlorinated or treated with ozone before it is released.

Primary treatment prepares wastewater for treatment by physically removing much of the solid material. This can be accomplished in several ways, including screening, precipitation of small particulates, and settling in basins or tanks (**table 43.4**).

Table 43.3 Major Steps in Primary, Secondary, and Tertiary Treatment of Wastes

Treatment Step	Processes
Primary	Removal of insoluble particulate materials by settling, screening, addition of alum and other coagulation agents, and other physical procedures
Secondary	Biological removal of dissolved organic matter Trickling filters Activated sludge Lagoons Extended aeration systems Anaerobic digesters
Tertiary	Biological removal of inorganic nutrients Chemical removal of inorganic nutrients Virus removal/inactivation Trace chemical removal

Table 43.4 Wastewater Treatment Methods

Nature of Operation	Process	Brief Explanation
Physical operations	Screening	Mechanical removal of large suspended materials with parallel bars, rods, wires, grating, wire mesh, or perforated plates
	Comminution	Comminutors are cutting instruments used to pulverize large floating material before wastewater enters primary settling tank.
	Flow equalization	A basin or basins used to adjust the rate of wastewater entry into secondary and tertiary treatment facilities
	Sedimentation	Also called clarification, this widely used procedure is based on the gravitational separation of large particles. Used in primary settling basins and to separate biological floc in activated sludge settling basins. Also used to precipitate chemically treated particulates when chemical coagulation is employed.
	Flotation	The removal of particles by bubbling air or other gas into the water. Particles float to the surface and are collected by skimming; removes fine particles more efficiently than sedimentation. Chemical additives can be added to improve particle removal.
	Granular-medium filtration	Wastewater is passed through a filter bed composed of granular material such as sand; used to remove suspended solids and chemically precipitated phosphorus.
Chemical operations	Chemical precipitation	Addition of coagulants such as alum, ferric chloride, ferric sulfate, or lime to wastewater prior to sedimentation; facilitates the flocculation of finely divided solids into flocs that will settle
	Adsorption	Soluble material is collected by adsorption of activated carbon; usually performed after biological treatment to remove remaining dissolved organic carbon
	Disinfection	Elimination of pathogens (and other microbes) by a variety of methods including UV light, heat, gamma radiation, and chemical agents such as chlorine, bromine, ozone, phenolic compounds, and others
	Dechlorination	Removal of all chlorine residues before discharge into receiving waters. These compounds are reactive and potentially dangerous.
Biological operations	Activated sludge process	An aerobic, continuous flow system that uses microbes to aerobically degrade organic matter; occurs after primary settling. Material is mechanically mixed to maintain aeration and prevent settling (figure 43.6*a*).
	Aerated lagoon	A basin 1 to 4 m in depth where wastewater is treated in a process similar to activated sludge treatment. Turbulence created by aeration keeps the contents of the lagoon mixed.
	Trickling filters	Most commonly used aerobic attached-growth biological treatment. A large basin filled with rock or plastic packing material provides a substrate for microbial biofilm growth and increased contact area for wastewater (figure 43.6*b*).
	Rotating biological contractors	Attached growth process that features large cylinders partially submerged in wastewater. Biofilms form on the cylinders, which are continuously rotated.
	Stabilization ponds	Shallow basin that is mixed naturally or mechanically. Aerobic ponds treat soluble organic wastes and effluents from wastewater treatment facilities; anaerobic ponds stabilize organic wastes. Wastewater retention times from 1 to 3 months
	Anaerobic digestion	Used for treatment of sludge and wastewater with high organic content (figure 43.7)
	Biological nutrient removal	Removal of nitrogen by nitrification-denitrification and anammox reaction (*see figure 21.15*) and phosphorus, often by proprietary processes (e.g., A/O, PhoStrip, and SBR process)

Modified from Water-Water Treatment Technologies: A General Review. *New York: United Nations, 2003.*

The resulting solid material is usually called **sludge.** In general, the goal of primary treatment is to generate water (effluent) that can be further purified by biological treatment and produce sludge that can be treated before disposal.

Secondary treatment of the effluent promotes the biological transformation of dissolved organic matter (DOM) into microbial biomass and carbon dioxide. In addition to reducing degradable DOM by about 90 to 95%, many bacterial pathogens are removed by this process. Several approaches can be used in secondary treatment to remove DOM. When microbial growth is completed, under ideal conditions the microorganisms will aggregate and form stable flocs, also called **granular sludge,** that settle. As shown in **figure 43.5**, commercial coagulants are often added to wastewater effluent to increase rate of flocculation and the amount of material that settles. Efficient flocculation is important because a sewage treatment facility that generates stable granular sludge requires up to 75% less space and reduces cost by as much as 25%.

When these processes occur with lower O_2 levels or with a microbial community that is too young or too old, unsatisfactory floc formation and settling can occur. The result is a **bulking sludge,** caused by the massive development of filamentous bacteria such as those in the genera *Sphaerotilus* and *Thiothrix,* together with many poorly characterized filamentous microbes. These filamentous microorganisms form flocs that do not settle well and thus produce effluent quality problems. ◀◀ *Order* Thiotrichales *includes large filamentous bacteria (section 22.3)*

An aerobic **activated sludge** system (**figure 43.6*a***) involves the horizontal flow of materials with recycling of sludge—the active biomass that is formed when organic matter is oxidized and degraded by microorganisms. Activated sludge systems can be designed with variations in mixing. In addition, the ratio of organic matter added to the active microbial biomass can be varied. A low-rate system (low nutrient input per unit of microbial biomass), with slower growing microorganisms, will produce an effluent with low residual levels of dissolved organic matter. A high-rate system (high nutrient input per unit of microbial biomass), with faster growing microorganisms, will remove more dissolved organic carbon per unit time but produce a poorer quality effluent.

Aerobic secondary treatment is often carried out with a **trickling filter** (figure 43.6*b*). The waste effluent is passed over rocks or other solid materials upon which microbial biofilms have developed, and the microbial community degrades the organic waste. A sewage treatment plant can be operated to produce less sludge by employing the **extended aeration** process (figure 43.6*c*). Microorganisms grow on the dissolved organic matter, and the newly formed microbial biomass is eventually consumed to meet maintenance energy requirements. This requires extremely large aeration basins and long aeration times. In addition, with the biological self-utilization of the biomass, minerals originally present in the microorganisms are again released to the water.

All aerobic processes produce excess microbial biomass, or sewage sludge, which contains many recalcitrant organics. Often the sludge from aerobic sewage treatment, together with the materials that settled in primary treatment, are further treated by anaerobic digestion. **Anaerobic digestion** occurs in large tanks designed to operate with continuous input of untreated sludge and removal of the final, stabilized sludge product (**figure 43.7**). Methane, the major component of natural gas, is vented and often burned for heat and electricity production. Within the anaerobic digester, at least three processes occur: (1) the fermentation of the sludge components to form organic acids, including acetate; (2) production of the methanogenic substrates acetate, CO_2, and hydrogen; and finally, (3) methanogenesis by methane producers. These methanogenic processes involve critical balances between electron acceptors and donors (**table 43.5**). To function most efficiently, the hydrogen concentration must be maintained at a low level (*see p. 693*). If hydrogen and organic acids accumulate, the drop in pH will inhibit methane production, resulting in a stuck digester. Often lime is added to neutralize the pH and restore methanogen function. ◀◀ *Methanogens and methanotrophs (section 20.4)*

Anaerobic digestion has many advantages. Most of the microbial biomass produced in aerobic growth is degraded in the anaerobic digester. Also, because the process of methanogenesis is energetically very inefficient, methanogenic archaea consume about twice as many nutrients to produce an equivalent biomass as that of aerobic systems. Consequently less sludge is produced and it can be easily dried. Dried sludge removed from well-operated anaerobic systems can even be sold as organic garden fertilizer. However, sludge from poorly managed systems may contain high levels of heavy metals and other contaminants, which require removal prior to release into the environment.

Tertiary treatment further purifies wastewaters by removing nitrogen and phosphorus compounds that can promote eutrophication. It also removes heavy metals, biodegradable organics,

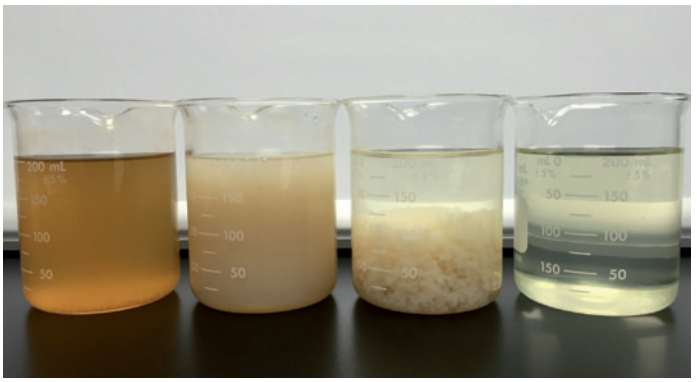

Figure 43.5 Proper Floc Formation in Activated Sludge.
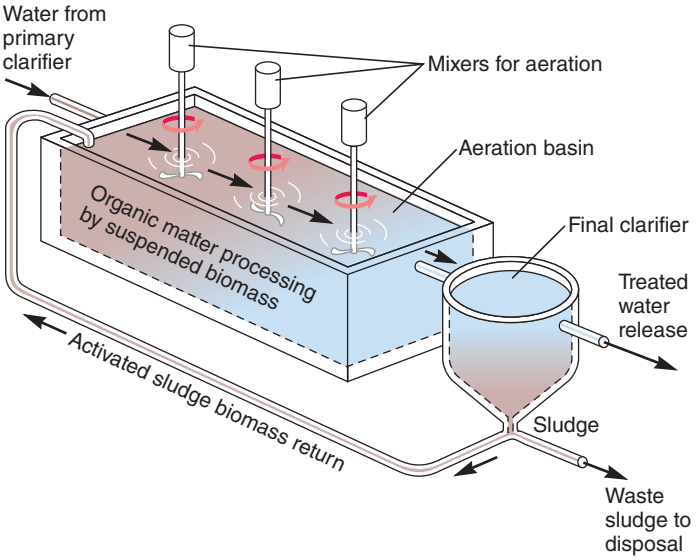
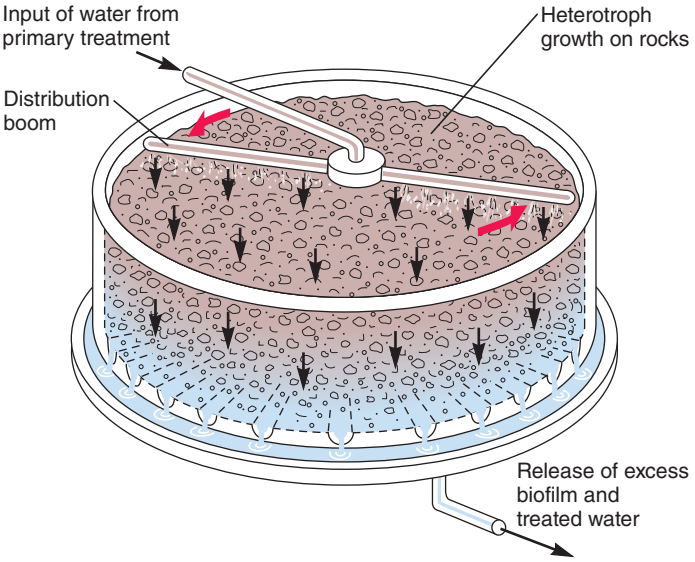
Microorganisms play a critical role in the functioning of activated sludge systems. Wastewater effluent in the beaker on the far left contains bacteria and other organic materials that resist settling. In this case, a commercial coagulant containing ferric chloride is added (second beaker from left). This accelerates the formation of stable flocs, which settle at the bottom of the beaker. The beaker on the far right shows the effluent after the settled material has been removed.

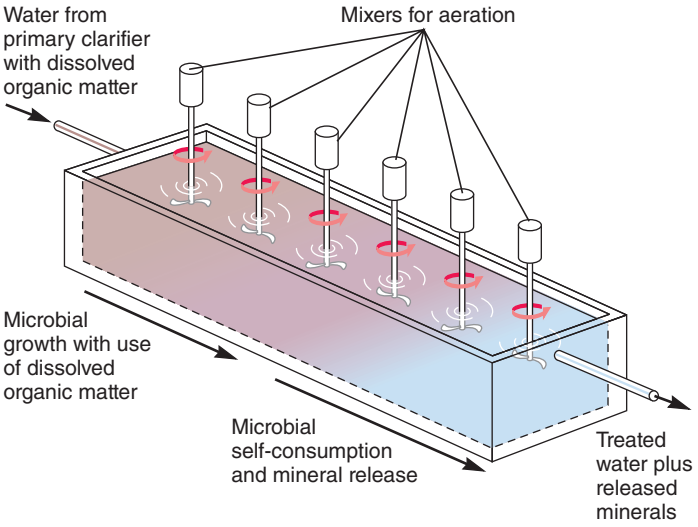
MICRO INQUIRY *Why is proper floc formation critical to the function of a treatment facility?*



(a) Aerobic activated sludge system



(b) Trickling filter



(c) Extended aeration system

Figure 43.6 Aerobic Secondary Sewage Treatment. (a) Activated sludge with microbial biomass recycling. The biomass is maintained in a suspended state to maximize oxygen, nutrient, and waste transfer processes. (b) Trickling filter, where wastewater flows over biofilms attached to rocks or other solid supports, resulting in transformation of dissolved organic matter to new biofilm biomass and carbon dioxide. Excess biomass and treated water flow to a final clarifier. (c) An extended aeration process, where aeration is continued beyond the point of microbial growth, allows the microbial biomass to self-consume due to microbial maintenance energy requirements. (The extended length of the reactor allows this process of biomass self-consumption to occur.) Minerals originally incorporated in the microbial biomass are released to the water as the process occurs.

and many remaining microbes, including viruses. Organic pollutants can be removed with activated carbon filters. Phosphate usually is precipitated as calcium or iron phosphate (e.g., by the addition of lime). To remove phosphorus, oxic and anoxic conditions are used alternately in a series of treatments, and phosphorus accumulates in microbial biomass as polyphosphate. Excess nitrogen may be removed by "stripping," volatilization of NH_3 at high pH. Ammonia itself can be chlorinated to form dichloramine, which is then converted to molecular nitrogen. In some cases, microbial processes can be used to remove nitrogen and phosphorus. A widely used process for nitrogen removal is denitrification, whereby nitrate produced by microbes under aerobic conditions, serves as an electron acceptor during anaerobic respiration. Nitrate reduction yields nitrogen gas (N_2) and nitrous oxide (N_2O) as the major products. In addition to denitrification, the anammox process is also important. In this reaction, ammonium ion (used as the electron donor) reacts with nitrite (the electron acceptor) to yield N_2. The anammox process can convert up to 80% of the initial ammonium ion to N_2 gas. Tertiary treatment is expensive and is usually not employed except where necessary to prevent obvious ecological disruption. ⏮ *Phylum Planctomycetes (section 21.5); Nitrogen cycle (section 28.1)*

Measuring Treated Wastewater Quality

The process of wastewater treatment must be monitored to ensure that waters released into the environment do not pose environmental and health risks. Successfully treated water should have very little organic carbon. The amount of carbon during and after wastewater treatment can be measured as **total organic carbon**

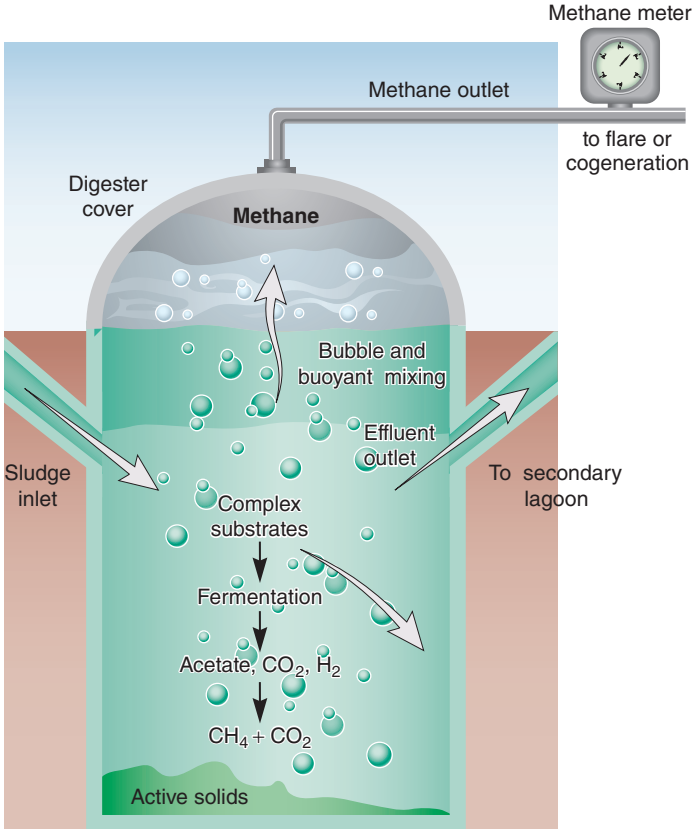


Figure 43.7 Anaerobic Digesters Generate Methane for Local or Municipal Use. The basic design of an anaerobic digester includes an inlet for the delivery of waste. Fermentation of complex substrates yields acetate, CO_2 and H_2, which archaea convert to CH_4. The effluent outlet functions to optimize the retention time (usually from 22 to 28 days) to maximize CH_4 capture.

(**TOC**), as chemically oxidizable carbon by the **chemical oxygen demand** (**COD**) test, or as biologically usable carbon by the **biochemical oxygen demand** (**BOD**) test. The TOC includes all carbon, whether or not it can be used by microorganisms. It is assayed by oxidizing all organic matter in a sample to CO_2 at high temperature in an oxygen stream. The CO_2 produced is measured by infrared or potentiometric techniques. The COD gives a similar measurement, except that lignin (*see figure 31.2*) often does not react with the oxidizing chemical used in this procedure.

The BOD test measures only that portion of total carbon oxidized (i.e., consumed) by microorganisms in a 5-day period at 20°C. It measures the amount of dissolved O_2 needed for microbial oxidation of biodegradable organic material. Ammonia released during organic matter oxidation can also consume O_2 in the BOD test. To prevent this "bottle effect," nitrification is often inhibited by the addition of 2-chloro-6-(trichloromethyl) pyridine (nitrapyrin). Except when treated effluents are analyzed, nitrification is not a major concern.

In terms of speed, the TOC is fastest, but it is less informative with regard to biological processes. The COD involves the use of wet chemicals with higher waste chemical disposal costs. It is critical to note that TOC, COD, and BOD measurements are concerned only with carbon removal. They do not directly address the removal of minerals such as nitrate, phosphate, and sulfate. These impact cyanobacterial and algal growth in lakes, rivers, and oceans by contributing to the process of eutrophication. ⏮ *Biogeochemical cycling sustains life on earth (section 28.1); Microorganisms in coastal ecosystems are adapted to a changeable environment (section 30.2)*

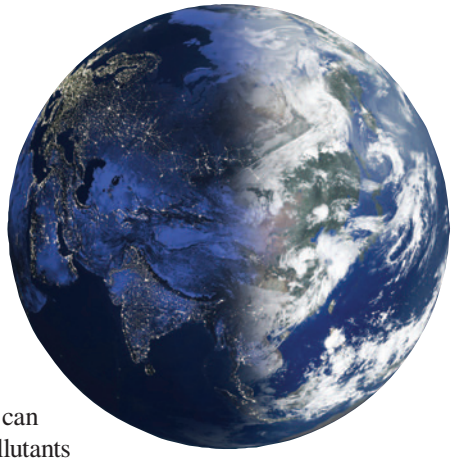
Home Treatment Systems

In the absence of municipal sewage systems, a **septic tank** is most commonly used. A conventional septic tank system functions as a simple anaerobic digester, with an anaerobic liquefaction and digestion step. This is followed by organic matter adsorption and entrapment of microorganisms in an aerobic leach field, where biological oxidation occurs. Pathogenic microorganisms and dissolved organic matter are removed from the wastewater in home septic systems during subsurface passage through adsorption and trapping by fine sandy materials, clays, and organic matter (**figure 43.8**). Microorganisms associated with these materials—including predators such as protozoa—can use the trapped pathogens as food. This results in purified water with a lower microbial population.

Because groundwater—the water in gravel beds and fractured rocks below the surface soil—is an important source of potable water, it is imperative that home septic systems be located far above the water table. Thus not all sites are suitable for septic systems. Prior to septic tank installation, a percolation test (or "perc test") must be performed. Perc tests determine if the surrounding soil can absorb the liquid produced by the septic tank, thereby preventing it from contaminating the groundwater beneath. Local governments develop specific protocols for perc tests, which are often witnessed when performed as the outcome of a perc test often determines if a piece of real estate can be developed.

A septic tank may not operate correctly for several reasons. If the retention time of the waste in the septic tank is too short, undigested solids move into the leach field, plugging the system. If the leach field floods and becomes anoxic, biological oxidation does not occur, and effective treatment ceases. Other problems can occur, especially when a suitable soil is not present and the septic tank outflow from a conventional system drains too rapidly to the deeper subsurface. Fractured rocks and coarse gravel materials do not effectively adsorb or filter wastewater. This may result in contamination of well water with pathogens. In addition, nitrogen and phosphorus from waste can pollute groundwater. This leads to nutrient enrichment of ponds, lakes, rivers, and estuaries as the subsurface water enters these environmentally sensitive ecosystems.

Domestic and commercial septic systems can be designed with nitrogen and phosphorus removal steps. Nitrogen is usually removed by nitrification and denitrification, with organic matter provided by sawdust or a similar material. A reductive iron dissolution process can be used for phosphorus removal. Nitrogen and phosphorus releases from septic systems must be controlled to prevent eutrophication of local surface waters.



Subsurface zones also can become contaminated with pollutants from other sources. Land disposal of sewage sludge, illegal dumping of septic tank sludge, improper toxic waste disposal, and runoff from agricultural operations all contribute to groundwater contamination with chemicals and microorganisms. Many pollutants that reach the subsurface will persist and may affect the quality of groundwater for extended periods. Much research is being conducted to find ways to treat groundwater in place—in situ treatment. As discussed in section 43.4, microorganisms and microbial processes are critical in many of these remediation efforts.

Future Challenges

Our planet now has over 7 billion people, and the needs for clean drinking water and wastewater treatment have become ever more pressing. In an effort to address both needs at once, water reuse or recycling has become a reality for many. Water reuse is the purification of wastewater so that it can serve as drinking water. This is not just for the developing world; a southern California municipality began operation of one of the largest water reclamation plants in the United States in 2012.

Not surprisingly, such water reclamation is complex. Not only must the obvious contaminants be removed (i.e., pathogens, heavy metals, nutrients that cause eutrophication), but twenty-first–century sewage also carries alarming levels of pharmaceuticals, introduced by both industry and the households. This has stimulated the development of methods to detect and remove the vast array of drugs that are common in sewage. In addition to recycling water, recent technologies enable the reclamation of biopolymers, plastics, and cellulose fibers in an economically

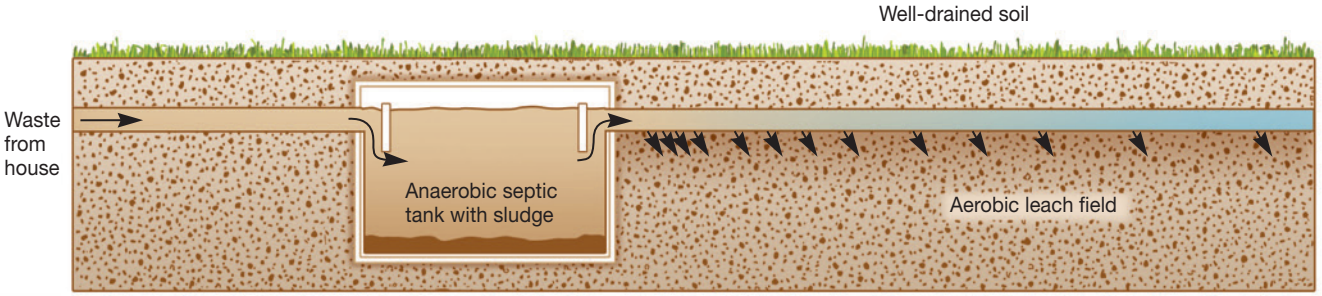


Figure 43.8 The Conventional Septic Tank Home Treatment System. This system combines an anaerobic waste liquefaction unit (the septic tank) with an aerobic leach field. Biological oxidation of the liquefied waste takes place in the leach field, unless the soil becomes flooded.

MICRO INQUIRY *Why would flooding halt biological oxidation of waste in the leach field?*

viable fashion. The current challenge is the widespread application of these technologies.

Population growth also stresses the capacity of municipal systems to carry and treat the ever-increasing volume of wastewater. This leads to sewage overflows during storms. The frequency of sewage overflow and the associated public health risks have resulted in a reexamination of current infrastructure and, in some cases, the construction of overflow basins.

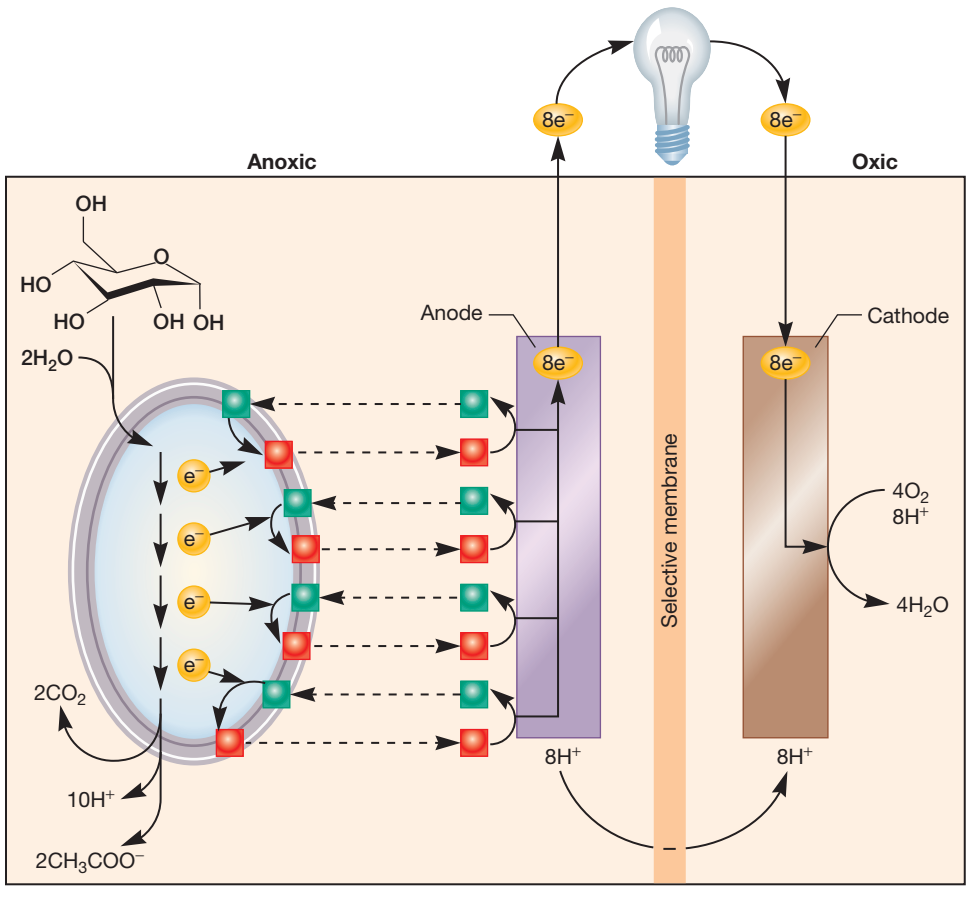
43.3 Microbial Fuel Cells: Batteries Powered by Microbes

After reading this section, you should be able to:

- Diagram the basic design of a microbial fuel cell
- Explain potential applications of microbial fuels cells

An exciting and emerging field in microbiology is the use of bacteria to generate electricity, not through the production of methane (as in anaerobic digesters, figure 43.7) but by directly capturing electrons from the microbe's electron transport chain (ETC). This is possible because when some heterotrophic microorganisms oxidize organic material, they can pass the electrons directly to an electrode. A **microbial fuel cell** (MFC) captures these electrons to generate electricity. To accomplish this, the microbes are continuously fed a rich diet of organic substrates so that very little biosynthesis is required (recall that anabolic reactions require electrons carried by NADPH). In this way, much of the organic substrate is oxidized during catabolism and electrons are donated to the ETC. The basic design of a MFC is relatively simple (**figure 43.9**). It consists two chambers, one oxic and the other anoxic, divided by a membrane through which protons can pass. Biomass is delivered to the bacteria in the anoxic side. The oxidation of this organic matter yields protons and electrons. The protons diffuse across the membrane to the oxic chamber. The electrons are deposited on an anode that connects the two chambers. Electrons flow toward the cathode but can be used to generate electricity while in transit. A catalyst in the oxic chamber combines the protons, electrons, and oxygen to generate water.



(a)

(b)

Figure 43.9 Microbial Fuel Cells. (a) Sugar is catabolized anaerobically by microbes in the anoxic chamber. The resulting protons flow to the oxic chamber, and the electrons are shuttled from the cell membrane to an anode, where they travel to the oxic chamber. During electron transit, they can be used to generate electricity. Green boxes represent oxidized electron shuttles and red boxes represent reduced shuttles. (b) A prototypical two-chambered microbial fuel cell.

MICRO INQUIRY *Why must the membrane between the two chambers be selectively permeable?*

Many different types of heterotrophic microbes can produce power in MFCs. The only requirement is that they oxidize organic matter anaerobically. In fact, communities of microbes can be employed. The largest constraint to obtaining maximum efficiency appears to be delivery of electrons to the electrode. There are several ways this can be accomplished. Often a chemical mediator is used to shuttle electrons from inside the cell, across the cellular membrane, to the anode (figure 43.9). Some microbes, such as the γ-proteobacterium *Shewanella oneidensis,* produce "nanowires" to transmit electrons to the anode (in nature, these nanowires shuttle electrons to external electron acceptors such as Fe^{3+}; *see figure 22.28*).

MFC development is ongoing, and great strides have been made to maximize power output, which has increased orders of magnitude in just a decade. Applications of MFCs include drinking water purification and the treatment of landfill leachate: in both cases, unwanted organic material is used to feed the bacteria in the MFC. MFCs can also be used when energy requirements are small but batteries cannot be used. Environmental monitoring instruments that need to be left in the field for years at a time are good examples. In addition, because MFCs are self-contained, they are attractive for developing countries that lack well-developed power grids. ⏮ *Order* Alteromonadales *includes anaerobes that use a range of electron acceptors (section 22.3); Order* Desulfuromonales *includes metabolically flexible anaerobes (section 22.4)*

1. How does a microbial fuel cell work?
2. Why is it important to supply a high level of organic nutrients to the bacteria in the fuel cell?
3. How might microbial fuel cells be involved in wastewater management?

43.4 Biodegradation and Bioremediation Harness Microbes to Clean the Environment

After reading this section, you should be able to:

- Describe the importance of reductive dehalogenation in bioremediation
- Discuss factors that influence the rate of biodegradation and bioremediation of a compound
- Explain how endogenous microbes can be stimulated to degrade environmental pollutants
- Summarize the rationale on which the addition of microbes and microbial products to contaminated soils and waters is based

The metabolic activities of microbes can also be exploited in complex natural environments for beneficial outcomes. Examples are the use of resident microbial communities to carry out biodegradation, bioremediation, and environmental maintenance processes (see chapter opener), and the addition of microorganisms to soils or plants for the improvement of crop production. We discuss both of these applications, with an emphasis on bioremediation in this section.

Biodegradation Processes

Before discussing biodegradation, it is important to consider its definition. **Biodegradation** has at least three outcomes (**figure 43.10**): (a) a minor change in an organic molecule, leaving the main structure still intact; (b) fragmentation of a complex organic molecule in such a way that the fragments could be reassembled to yield the original structure; and (c) complete mineralization, which is the transformation of organic molecules to inorganic forms.

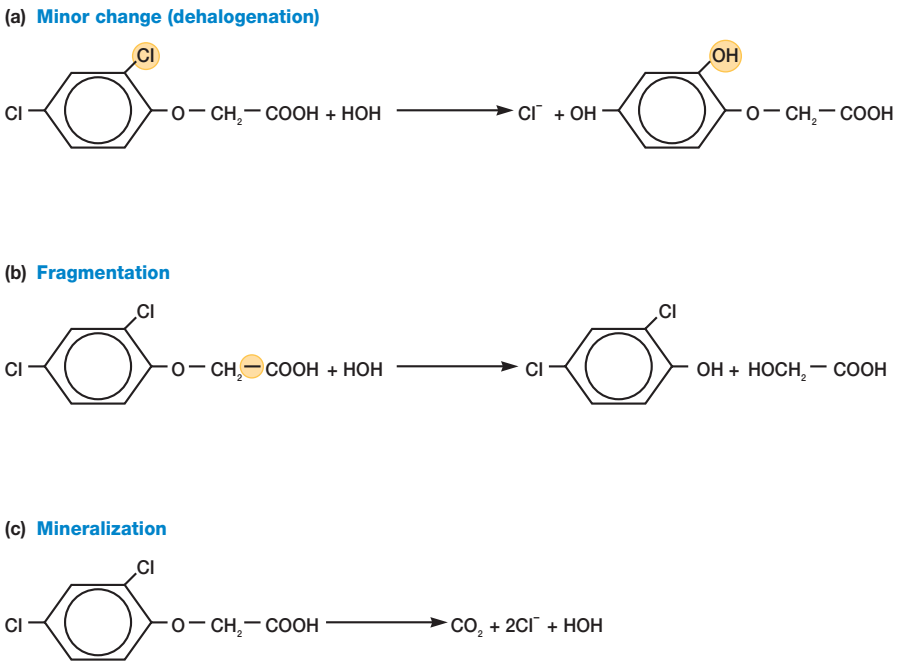

Figure 43.10 Biodegradation Has Several Meanings. Biodegradation is a term that can be used to describe three major types of changes in a molecule: (a) a minor change in the functional groups attached to an organic compound, such as the substitution of a hydroxyl group for a chlorine group; (b) an actual breaking of the organic compound into organic fragments in such a way that the original molecule could be reconstructed; and (c) the complete degradation of an organic compound to minerals.

MICRO INQUIRY *Why does dehalogenation increase the likelihood that the carbon compound will be degraded?*

The removal of toxic industrial products in soils and aquatic environments is a daunting and necessary task. Compounds such as perchloroethylene (PCE), trichloroethylene (TCE), and polychlorinated biphenyls (PCBs) are common contaminants. These compounds adsorb onto organic matter in the environment, making decontamination using traditional approaches difficult or ineffective. The use of microbes to transform these contaminants to nontoxic degradation products is called **bioremediation.** To understand how bioremediation takes place at the level of an ecosystem, we first must consider the biochemistry of biodegradation.

Degradation of complex compounds requires several discrete stages, usually performed by different microbes. Initially contaminants are converted to less toxic compounds that are more readily degraded. The first step for many contaminants, including organochloride pesticides, alkyl solvents, and aryl halides, is **reductive dehalogenation.** This is the removal of a halogen substituent (e.g., chlorine, bromine, fluorine) while at the same time adding electrons to the molecule. This can occur in two ways. In hydrogenolysis, the halogen substituent is replaced by a hydrogen atom (**figure 43.11*a***). Alternatively dihaloelimination removes two halogen substituents from adjacent carbons while inserting an additional bond between the carbons (figure 43.11*b*). Both processes require an electron donor. The dehalogenation of PCBs uses electrons derived from water; alternatively hydrogen can be the electron donor for the dehalogenation of different chlorinated compounds. Major genera with species that carry out this process include *Desulfitobacterium, Dehalospirillum,* and *Desulfomonile.*

Reductive dehalogenation usually occurs under anoxic conditions. In fact, humic acids (polymeric residues of lignin decomposition that accumulate in soils and waters) can serve as terminal electron acceptors under what are called humic acid–reducing conditions. The use of humic acids as electron acceptors has been observed with the anaerobic dechlorination of vinyl chloride and dichloroethylene. Once the anaerobic dehalogenation steps are completed, degradation of the main structure of many pesticides and other xenobiotics (foreign compounds) often proceeds more rapidly in the presence of O_2. Thus the degradation of halogenated toxic compounds generally requires the action of several microbial genera, sometimes referred to as a consortium.

Structure and stereochemistry are critical in predicting the fate of a specific chemical in nature. When a constituent is in the *meta* as opposed to the *ortho* position, the compound will be degraded at a much slower rate. This stereochemical difference is the reason that the common lawn herbicide 2,4-dichlorophenoxyacetic acid (2,4-D), with a chlorine in the *ortho* position, will be largely degraded in a single summer. In contrast, 2,4,5-trichlorophenoxyacetic acid, with a constituent in the *meta* position, will persist in the soils for several years and thus is used for long-term brush control.

Another important factor that influences biodegradation is a compound's chirality or handedness *(see figure AI.8).* Microorganisms often degrade one isomer of a substance but not the other. At least 25% of herbicides are chiral. Thus it is critical to add the herbicide isomer that is effective and also degradable. However, populations that make up a microbial community can change in response to the addition of inorganic or organic substrates. If a particular compound, such as a herbicide, is added repeatedly to a microbial community, the community changes and faster rates of degradation can occur—a process of acclimation. Eventually a microbial community can become so efficient at herbicide degradation that herbicide effectiveness is diminished. To counteract this process, herbicides can be switched to alter the microbial community.

Degradation processes that occur in soils also can be used in large-scale degradation of hydrocarbons or wastes from agricultural operations. The waste material is incorporated into soil or allowed to flow across the soil surface, where degradation occurs. While this is often very effective, sometimes such degradation processes do not reduce toxicity. An example of this problem is the microbial metabolism of 1,1,1-trichloro-2,2-bis-(p-chlorophenyl) ethane (DDT), a pesticide once commonly used in the United States. Degradation removes a chlorine function to give 1,1-dichloro-2,2-bis-(p-chlorophenyl) ethylene (DDE), which is also an environmental toxin (**figure 43.12*a***). Another important example is the degradation of trichloroethylene (TCE), a widely used solvent.

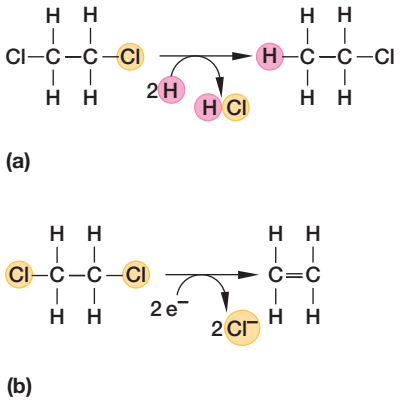

Figure 43.11 Reductive Dehalogenation. In these two examples, 1,2 dichlorobenzoate is dehalogenated by (a) alkyl hydrogenolysis and (b) dihaloelimination. Note that although the substrate is the same, these strategies result in different products.

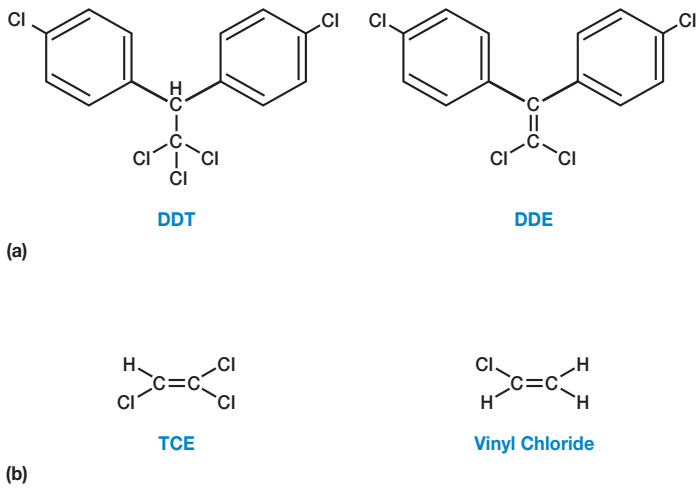

Figure 43.12 Toxic Degradation Products. The parent compounds DDT and TCE are metabolized to the toxins DDE and vinyl chloride, respectively.

Figure 43.13 Bioremediation of the *Exxon Valdez* Oil Spill. Workers sprayed the coastline with nitrogen and phosphorus-containing fertilizer to provide limiting nutrients to hydrocarbon-degrading microorganisms. This increased the rate at which oil was degraded.

When degraded under anoxic conditions, the dangerous carcinogen vinyl chloride can be formed (figure 43.12*b*).

An emerging approach to the bioremediation of contaminants in soils is the use of microbial fuel cells (figure 43.9). One of the major challenges to the microbial degradation of subsurface organic compounds and heavy metals is the provision of an electron acceptor that will participate in the oxidation of the contaminant. For instance, the biodegradation of petroleum in soils is frequently limited because it is very difficult and expensive to introduce oxygen into sediments. Microbial fuel cells can be inserted in sediments such that the anode can serve as the terminal electron acceptor by bacteria in the community during biodegradation. Several innovative applications of microbial fuel cells have been demonstrated, including the oxidation of toluene by *Geobacter metallireducens*. ◀◀ *Order* Desulfuromonales *includes metabolically flexible anaerobes (section 22.4)*

Bioremediation

Bioremediation usually involves stimulating the degradative activities of microorganisms already present in contaminated waters or soils. These existing microbial communities typically cannot carry out biodegradation processes at the desired rate due to limiting physical or nutritional factors. For example, biodegradation may be limited by low levels of oxygen, nitrogen, phosphorus, or other nutrients. In these cases, it is necessary to determine the limiting factors and supply the needed materials or modify the environment. Often the addition of easily metabolized organic matter such as glucose increases biodegradation of recalcitrant compounds that otherwise would not be used as carbon and energy sources by microorganisms. This process is called **cometabolism.**

Stimulating Hydrocarbon Degradation in Waters and Soils

Experience with oil spills in marine environments illustrates how effective stimulating natural microbial communities can be. Hydrocarbons lack phosphorus and nitrogen, so these elements limit their degradation. One of the first demonstrations that simple fertilization accelerates hydrocarbon degradation by natural populations occurred in 1989 following the *Exxon Valdez* oil spill in Prince Williams Sound, Alaska. As seen in **figure 43.13**, the addition of nitrogen and phosphorus-containing fertilizer significantly diminished the oil in coastal sediments. Since that time, it has been recognized that another key variable in promoting bioremediation is the degree of contact between microorganisms and the hydrocarbon substrate. To increase hydrocarbon accessibility by microbes, pellets containing nutrients and an oleophilic (hydrocarbon soluble) preparation are often used. This technique accelerates the degradation of different crude oil slicks by 30 to 40%, in comparison with control oil slicks where additional nutrients are not available. More recent research also focuses on the entire microbial community involved in the bioremediation process. Oil, which is a complex mixture of organic molecules, is degraded by a variety of bacteria (so far, archaea do not appear to degrade oil), but their capacity to do so is influenced by rates of predation by viruses and protists, the rate of nutrient recycling, and even the release of biosurfactants by other microbes (**figure 43.14**). Surfactants

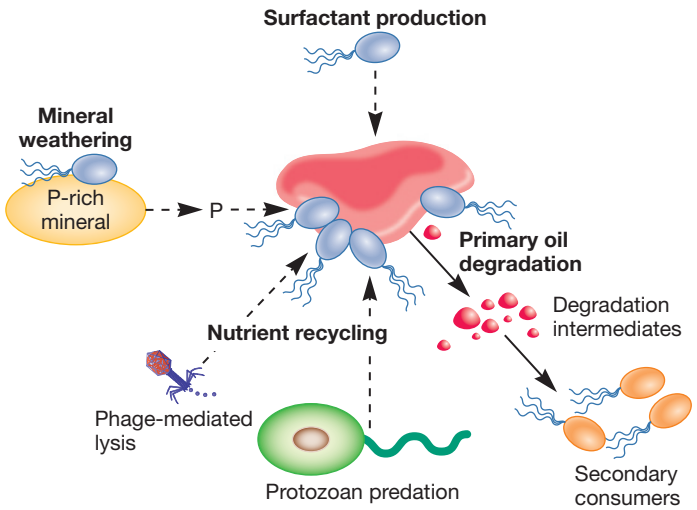

Figure 43.14 Oil Degradation Requires a Microbial Community. Primary oil degradation involves bacteria that begin oil degradation (blue microbes). These bacteria release a variety of degradation products that are further broken down by secondary consumers (yellow microbes). Dashed lines represent indirect interactions that influence the rate of bioremediation, such as phage lysis and protozoan grazing.

serve to disperse the oil; so-called dispersants used during the BP oil spill in the Gulf of Mexico in 2010 became almost as controversial as the oil itself. This has prompted the development of microbial-based oil dispersants, described next.

Bioaugmentation

The acceleration of microbiological processes by the addition of known active microorganisms to soils, waters, or other complex systems is called **bioaugmentation.** This is not a new concept; commercial culture preparations have long been available to facilitate silage formation and to improve septic tank performance. However, the magnitude of contamination coupled with an increased awareness of some of the dangers cleanup can introduce has stimulated the growth of the bioremediation industry. For instance, an oil dispersant consisting of several nonpathogenic *Bacillus* species, wetting agents, and nutrients is now commercially available.

Microorganisms can be added directly to natural communities, where they create their own microhabitats. For example, microorganisms in the water column overlying PCB-contaminated sand-clay soils have been observed to create their own "clay hutches" by binding clays to their outer surfaces with exopolysaccharides. However, in most cases, microbes are added with other components to ensure their viability. A blend of microorganisms can be purchased from commercial bioremediation engineering companies to treat petrochemical contamination of soils and water. These microbes are most often added in a slurry along with nutrients, enzymes, surfactants, and chemicals that release oxygen to promote aerobiosis. In other cases, microbes are introduced with protective inert microhabitats. This helps the foreign microbes establish an effective population in the face of competition from the natural, endogenous microbial community. Thus the application of principles of microbial physiology and ecology can facilitate the successful management of microbial communities in nature.

Metal Bioleaching

Bioleaching is the use of microorganisms that produce acids from reduced sulfur compounds to create acidic environments that solubilize desired metals for recovery. This approach is used to recover metals from ores and mining tailings with metal levels too low for smelting. Bioleaching carried out by natural populations of *Leptospirillum*-like species and thiobacilli, for example, allow recovery of up to 70% of the copper in low-grade ores. This involves the biological oxidation of copper present in these ores to produce soluble copper sulfate. In fact, this process is now used for copper mining.

Retrieve, Infer, Apply

1. List alternative definitions for the term biodegradation.
2. Explain the two mechanisms of reductive dehalogenation. Describe humic acids and the role they can play in anaerobic degradation processes.
3. Discuss chirality and isomerization and their importance for understanding biodegradation.
4. What components are commonly added to microbes used to treat petrochemical contamination? Why are these added?
5. How is bioleaching carried out, and what microbes are involved?

Key Concepts

43.1 Purification and Sanitary Analysis Ensure Safe Drinking Water

- Water purification can involve the use of sedimentation, coagulation, chlorination, and rapid and slow sand filtration. Chlorination may lead to the formation of organic disinfection by-products, including trihalomethane compounds, which are potential carcinogens (**figure 43.1**).
- *Cryptosporidium, Cyclospora, Giardia* spp., and viruses are of concern, as conventional water purification and chlorination will not always ensure their removal and inactivation to acceptable limits.
- Indicator organisms are used to assess the presence of pathogenic microorganisms. Most probable number (MPN) and membrane filtration procedures are employed to estimate the number of indicator organisms present. The presence-absence (P-A) test is used for coliforms and defined substrate tests, for coliforms and *E. coli* (**figures 43.2** and **43.3**).

43.2 Wastewater Treatment Maintains Human and Environmental Health

- Conventional sewage treatment is a controlled intensification of natural self-purification processes, and it can involve primary, secondary, and tertiary treatment steps (**figures 43.4** and **43.5; tables 43.3** and **43.4**).
- The biochemical oxygen demand (BOD) test is an indirect measure of the organic matter that can be oxidized by the aerobic microbial community. The chemical oxygen demand (COD) and total organic carbon (TOC) tests provide information on carbon that is not biodegraded in the 5-day BOD test.
- Home treatment systems operate on general self-purification principles. The conventional septic tank provides anaerobic liquefaction and digestion, whereas the aerobic leach field allows oxidation of the soluble effluent. These systems are now designed to provide nitrogen and phosphorus removal to lessen impacts of on-site sewage treatment systems on vulnerable marine and freshwaters (**figure 43.8**).

43.3 Microbial Fuel Cells: Batteries Powered by Microbes

- Microbial fuel cells are an emerging technology whereby electrons are donated to an anode during heterotrophic bacterial respiration. MFCs have a variety of applications, including the purification of waters while generating power and providing energy for monitoring environmental processes (**figure 43.9**).

43.4 Biodegradation and Bioremediation Harness Microbes to Clean the Environment

- Biodegradation is a critical part of natural systems mediated largely by microorganisms. This can involve minor changes in a molecule, fragmentation, or mineralization (**figure 43.10**).
- Biodegradation can be influenced by many factors, including oxygen levels, humic acids, and the presence of readily usable organic matter. Reductive dehalogenation occurs best under anoxic conditions (**figure 43.11**), and the presence of organic matter can facilitate modification of recalcitrant compounds in the process of cometabolism.
- Degradation management can be carried out in place, whether this be large marine oil spills, soils, or the subsurface. Such large-scale efforts often involve the use of natural microbial communities (**figures 43.13** and **43.14**).
- Bioremediation can also be accomplished by adding microbes directly to contaminated environments. These microbes are usually introduced with other components such as nutrients and dispersants to ensure their success despite competition from endogenous microbial communities.

Compare, Hypothesize, Invent

1. You wish to build a house in a rural community where you will need to install a septic system and drill a well for drinking water. Where will you site the well in relation to the septic system? Following the perc test, you discover that the town will allow you to build your house only if you install a sand filter in addition to your septic tank. Why do you think this might be the case?
2. You are responsible for the bioremediation of soil contaminated by jet fuel. Your coworker suggests you fertilize the soil with nitrogen and phosphorus to promote the growth of naturally occurring hydrocarbon-degrading microbes. However, you just read about a new mixture of microbes sold in a slurry with nutrients and a surfactant. What data do you need to collect to decide which approach would be best? How will you obtain these data?
3. Biofilms are known to form on surfaces in drinking water distribution networks. It is therefore important to understand how such biofilms develop and how long they last. A recent study followed the development of biofilms populated by the protists in the genera *Giardia* and *Cryptosporidium,* as well as a strain of *Poliovirus* and several bacteriophages. Attachment to, growth within, and detachment from model biofilms were measured in tap water flowing through a special reactor designed to simulate the type of turbulence found in a water distribution network.

   Why were the investigators especially interested in biofilm stability? Also, why were they interested in bacteriophages? What special considerations do you think need to be addressed when studying protists with relatively complex life cycles? What method do you think would be most appropriate to detect the protists? What about detecting the viruses?

Appendix One

A Review of the Chemistry of Biological Molecules

Appendix I provides a brief summary of the chemistry of organic molecules with particular emphasis on the molecules present in microbial cells. Only basic concepts and terminology are presented; introductory textbooks in biology and chemistry should be consulted for a more extensive treatment of these topics.

Atoms and Molecules

Matter is made of elements that are composed of atoms. An element contains only one kind of atom and cannot be broken down to simpler components by chemical reactions. An atom is the smallest unit characteristic of an element and can exist alone or in combination with other atoms. When atoms combine, they form molecules. Molecules are the smallest particles of a substance. They have all the properties of the substance and are composed of two or more atoms.

Although atoms contain many subatomic particles, three directly influence their chemical behavior: protons, neutrons, and electrons. The atom's nucleus is located at its center and contains varying numbers of protons and neutrons (**figure AI.1**). Protons have a positive charge, and neutrons are uncharged. The mass of these particles and the atoms that they compose is given in terms of the atomic mass unit (AMU), which is 1/12 the mass of the most abundant carbon isotope. Often the term *dalton* (Da) is used to express the mass of molecules. It also is 1/12 the mass of an atom of ^{12}C or 1.661×10^{-24} grams. Both protons and neutrons have a mass of about 1 dalton. The atomic weight is the actual measured weight of an element and is almost identical to the mass number for the element, the total number of protons and neutrons in its nucleus. The mass number is indicated by a superscripted number preceding the element's symbol (e.g., ^{12}C, ^{16}O, and ^{14}N).

Negatively charged particles called electrons circle the atomic nucleus (figure AI.1). The number of electrons in a neutral atom equals the number of its protons and is given by the atomic number, the number of protons in an atomic nucleus. The atomic number is characteristic of a particular type of atom. For example, carbon has an atomic number of six, hydrogen's number is one, and oxygen's is eight (**table AI.1**).

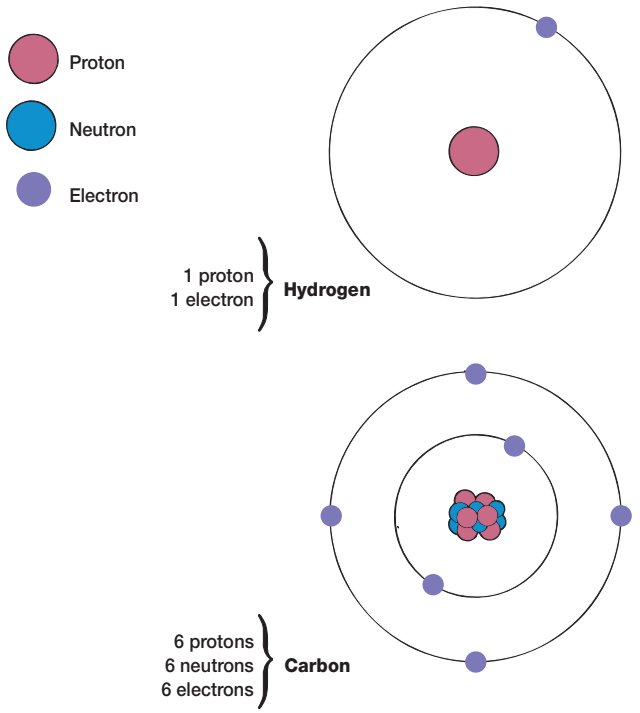

Figure AI.1 Diagrams of Hydrogen and Carbon Atoms. The electron orbitals are represented as concentric circles.

Table AI.1 Atoms Commonly Present in Organic Molecules

Atom	Symbol	Atomic Number	Atomic Weight	Number of Chemical Bonds
Hydrogen	H	1	1.01	1
Carbon	C	6	12.01	4
Nitrogen	N	7	14.01	3
Oxygen	O	8	16.00	2
Phosphorus	P	15	30.97	5
Sulfur	S	16	32.06	2

The electrons move constantly within a volume of space surrounding the nucleus, even though their precise location in this volume cannot be determined accurately. This volume of space in which an electron is located is called its orbital. Each orbital can contain two electrons. Orbitals are grouped into shells of different energy that surround the nucleus. The first shell is closest to the nucleus and has the lowest energy; it contains only one orbital. The second shell contains four orbitals, one circular and three shaped like dumbbells (**figure AI.2*a***). It can contain up to eight electrons. The third shell has even higher energy and holds more than eight electrons. Shells are filled beginning with the innermost and moving outward. For example, carbon has six electrons, two in its first shell and four in the second (figures AI.1 and AI.2*b*). The electrons in the outermost shell are the ones that participate in chemical reactions. The most stable condition is achieved when the outer shell is filled with electrons. Thus the number of bonds an element can form depends on the number of electrons required to fill the outer shell. Since carbon has four electrons in its outer shell and the shell is filled when it contains eight electrons, it can form four covalent bonds (table AI.1).

Chemical Bonds

Molecules are formed when two or more atoms associate through chemical bonding. Chemical bonds are attractive forces that hold together atoms, ions, or groups of atoms in a molecule or other substance. Many types of chemical bonds are present in organic molecules; three of the most important are covalent bonds, ionic bonds, and hydrogen bonds.

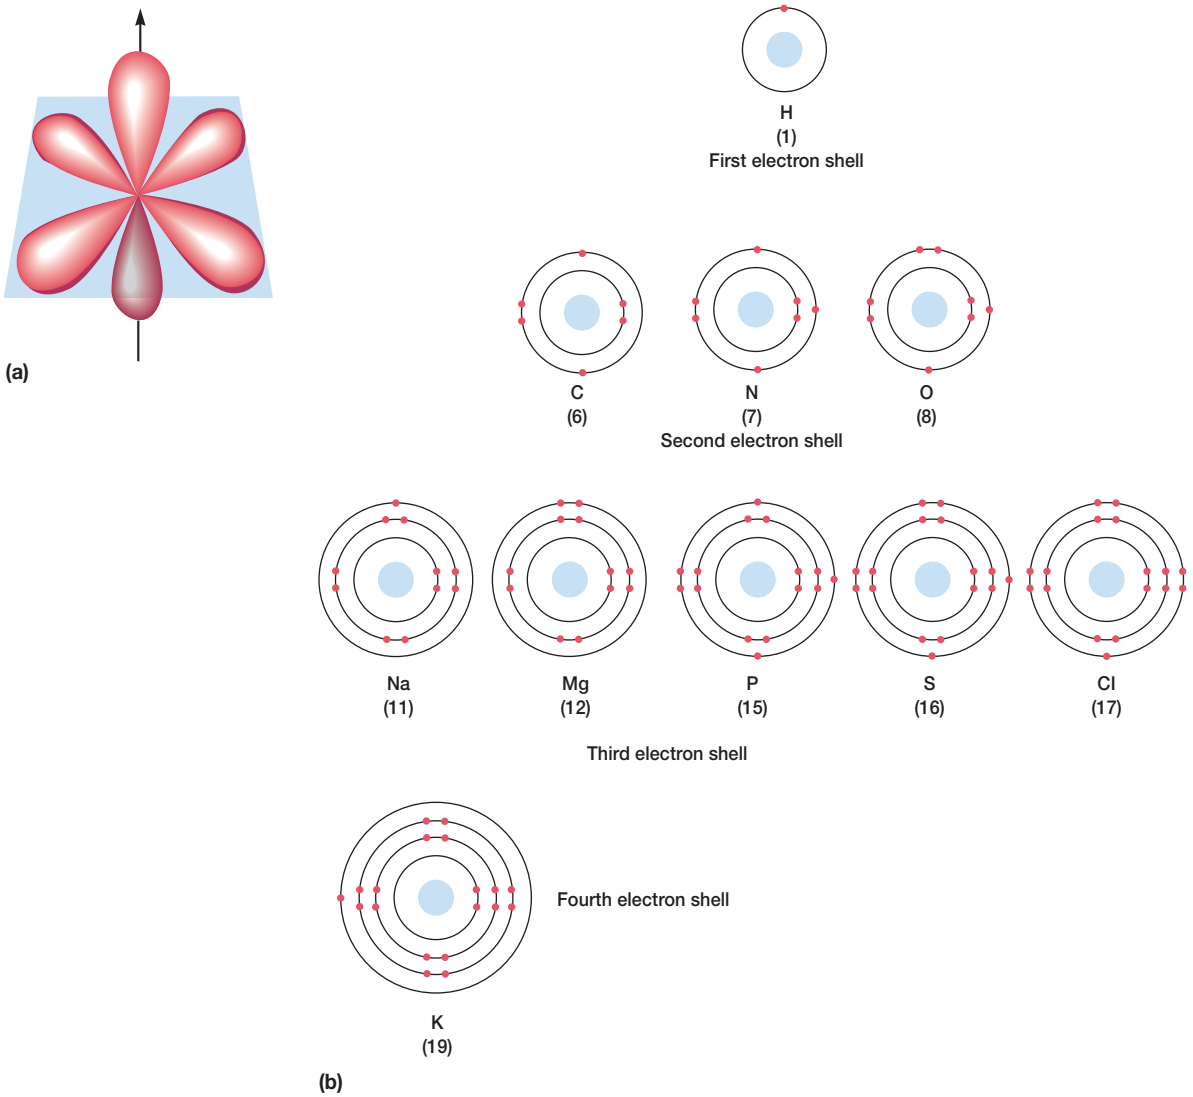

Figure AI.2 Electron Orbitals. (a) The three dumbbell-shaped orbitals of the second shell. The orbitals lie at right angles to each other. (b) The distribution of electrons in some common elements. Atomic numbers are given in parentheses.

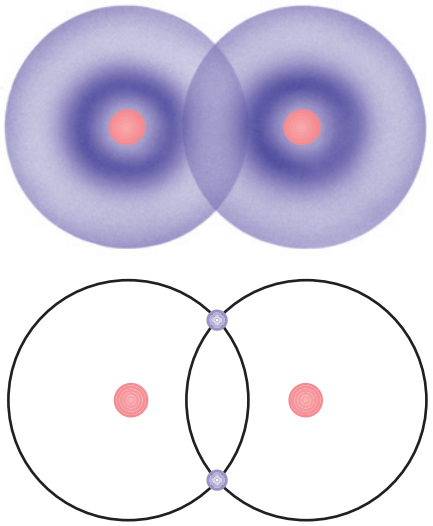

Figure AI.3 The Covalent Bond. A hydrogen molecule is formed when two hydrogen atoms share electrons.

In covalent bonds, atoms are joined together by sharing pairs of electrons (**figure AI.3**). If the electrons are equally shared between identical atoms (e.g., in a carbon-carbon bond), the covalent bond is strong and nonpolar. When two different atoms such as carbon and oxygen share electrons, the covalent bond formed is polar because the electrons are pulled toward the more electronegative atom, the atom that more strongly attracts electrons (the oxygen atom). A single pair of electrons is shared in a single bond; a double bond is formed when two pairs of electrons are shared.

Atoms often contain either more or fewer electrons than the number of protons in their nuclei. When this is the case, they carry a net negative or positive charge and are called ions. Cations carry positive charges and anions have a net negative charge. When a cation and an anion approach each other, they are attracted by their opposite charges. This ionic attraction that holds two groups together is called an ionic bond. Ionic bonds are much weaker than covalent bonds and are easily disrupted by a polar solvent such as water. For example, the Na^+ cation is strongly attracted to the Cl^- anion in a sodium chloride crystal, but sodium chloride dissociates into separate ions (ionizes) when dissolved in water. Ionic bonds are important in the structure and function of proteins and other biological molecules.

When a hydrogen atom is covalently bonded to a more electronegative atom such as oxygen or nitrogen, the electrons are unequally shared and the hydrogen atom carries a partial positive charge. It will be attracted to an electronegative atom such as oxygen or nitrogen, which carries an unshared pair of electrons; this attraction is called a hydrogen bond (**figure AI.4**). Although an individual hydrogen bond is weak, there are so many hydrogen bonds in proteins and nucleic acids that they play a major role in determining protein and nucleic acid structure.

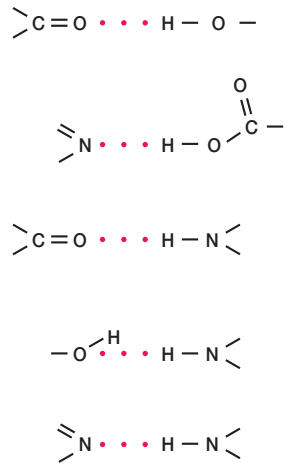

Figure AI.4 Hydrogen Bonds. Representative examples of hydrogen bonds present in biological molecules.

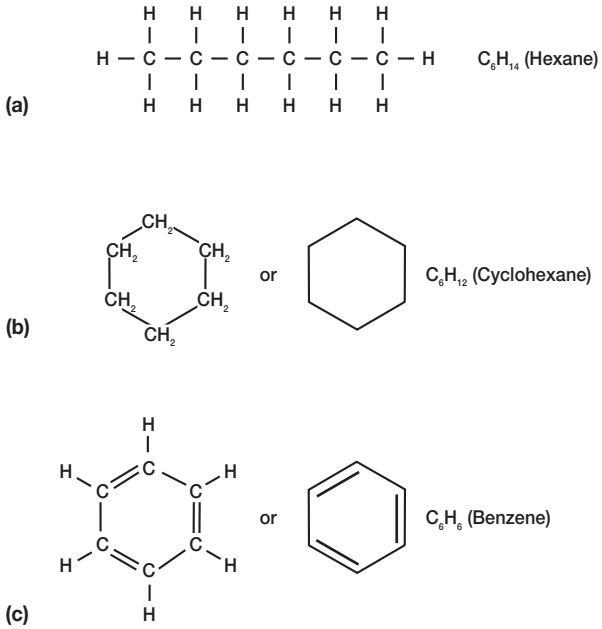

Figure AI.5 Hydrocarbons. Examples of hydrocarbons that are (a) linear, (b) cyclic, and (c) aromatic.

Organic Molecules

Most molecules in cells are organic molecules, molecules that contain carbon. Since carbon has four electrons in its outer shell, it tends to form four covalent bonds in order to fill its outer shell with eight electrons. This property makes it possible to form chains and rings of carbon atoms that also can bond with hydrogen and other atoms (**figure AI.5**). Although adjacent carbons usually are connected by single bonds, they may be joined by double or triple bonds. Rings that have alternating single and double bonds, such as the benzene ring, are called aromatic

rings. The hydrocarbon chain or ring provides a chemically inactive skeleton to which more reactive groups of atoms may be attached. These reactive groups with specific properties are known as functional groups. They usually contain atoms of oxygen, nitrogen, phosphorus, or sulfur (**figure AI.6**) and are largely responsible for most characteristic chemical properties of organic molecules.

Organic molecules are often divided into classes based on the nature of their functional groups. Ketones have a carbonyl group within the carbon chain, whereas alcohols have a hydroxyl on the chain. Organic acids have a carboxyl group, and amines have an amino group (**figure AI.7**).

Organic molecules may have the same chemical composition and yet differ in their molecular structure and properties. Such molecules are called isomers. One important class of isomers is the stereoisomers. Stereoisomers have the same atoms arranged in the same nucleus-to-nucleus sequence but differ in the spatial arrangement of their atoms. For example, an amino acid such as alanine can form stereoisomers (**figure AI.8**). L-Alanine and other L-amino acids are the stereoisomer forms normally present in proteins.

Carbohydrates

Carbohydrates are aldehyde or ketone derivatives of polyhydroxy alcohols. The smallest and least complex carbohydrates are the simple sugars or monosaccharides. The most common sugars have five or six carbons. A sugar in its ring form has two isomeric structures, the α and β forms, that differ in the orientation of the hydroxyl on the aldehyde or ketone carbon, which is

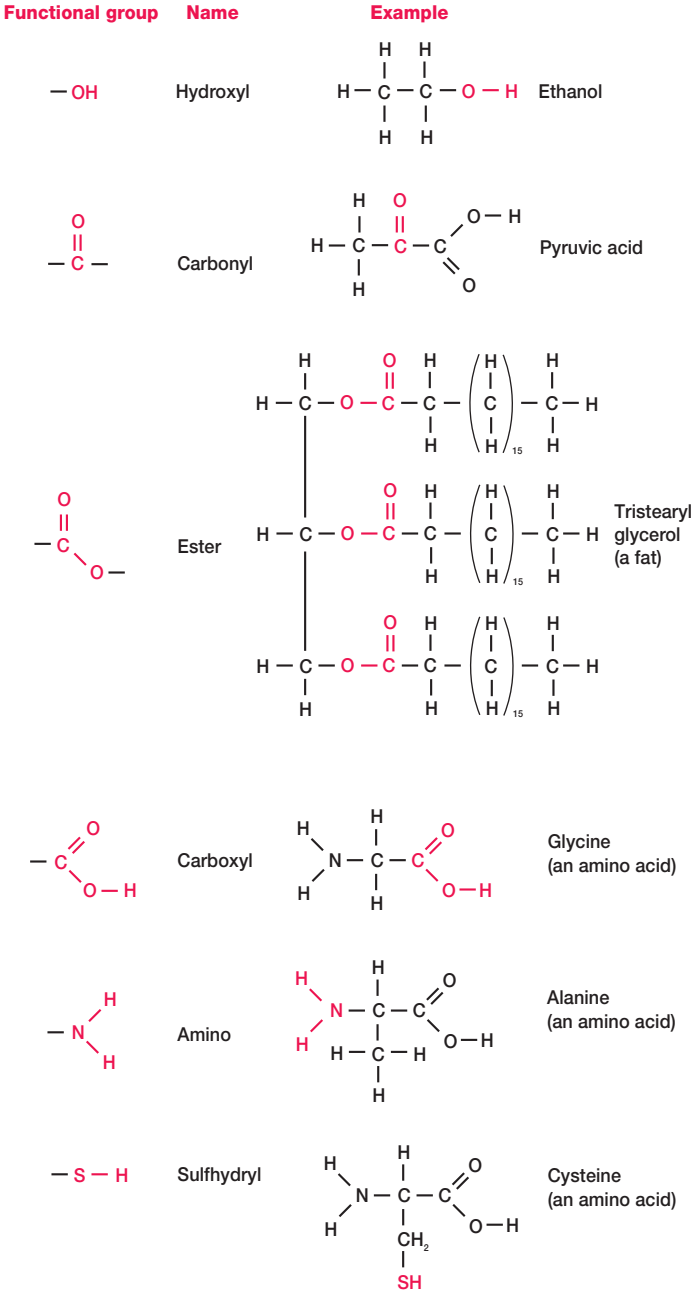

Figure AI.6 Functional Groups. Some common functional groups in organic molecules. The groups are shown in red.

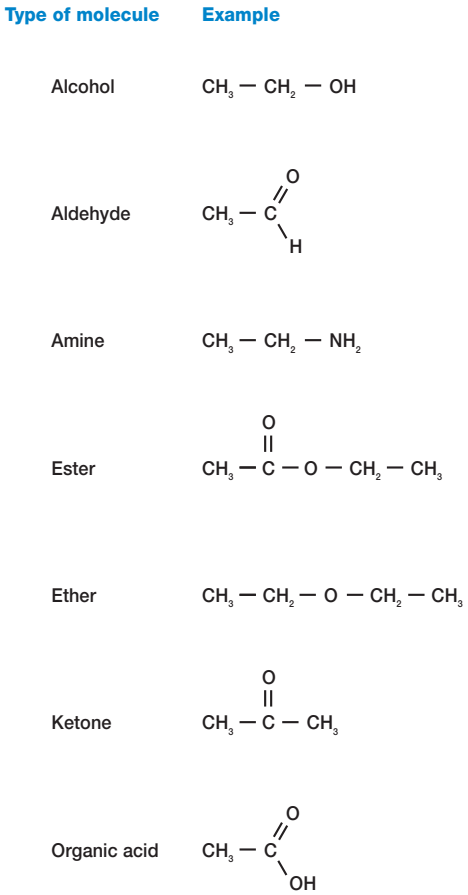

Figure AI.7 Types of Organic Molecules. These are classified on the basis of their functional groups.

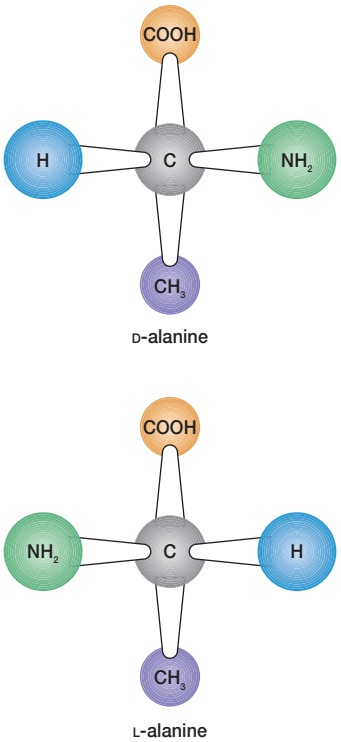

Figure AI.8 **The Stereoisomers of Alanine.** The α-carbon is in gray. L-alanine is the form usually present in proteins.

called the anomeric or glycosidic carbon (**figure AI.9**). Microorganisms have many sugar derivatives in which a hydroxyl is replaced by an amino group or some other functional group (e.g., glucosamine).

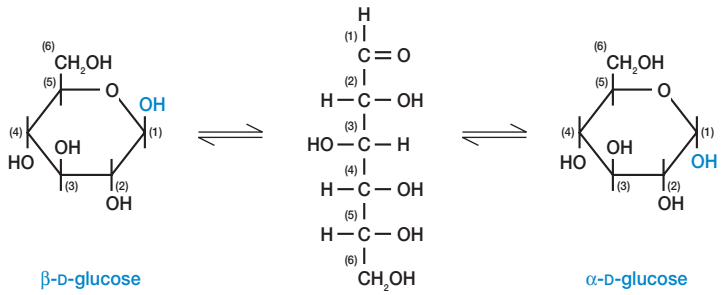

Figure AI.9 **The Interconversion of Monosaccharide Structures.** The open chain form of glucose and other sugars is in equilibrium with closed ring structures (depicted here with Haworth projections). Aldehyde sugars form cyclic hemiacetals, and keto sugars produce cyclic hemiketals. When the hydroxyl on carbon one of cyclic hemiacetals projects above the ring, the form is known as a β form. The α form has a hydroxyl that lies below the plane of the ring. The same convention is used in showing the α and β forms of hemiketals such as those formed by fructose.

Two monosaccharides can be joined by a bond between the anomeric carbon of one sugar and a hydroxyl or the anomeric carbon of the second (**figure AI.10**). The bond joining sugars is a glycosidic bond and may be either α or β depending on the orientation of the anomeric carbon. Two sugars linked in this way constitute a disaccharide. Some common disaccharides are maltose (two glucose molecules), lactose (glucose and galactose), and sucrose (glucose and fructose). If 10 or more sugars are linked together by glycosidic bonds, a polysaccharide is formed. For example, starch and glycogen are common polymers of glucose that are used as sources of carbon and energy (**figure AI.11**).

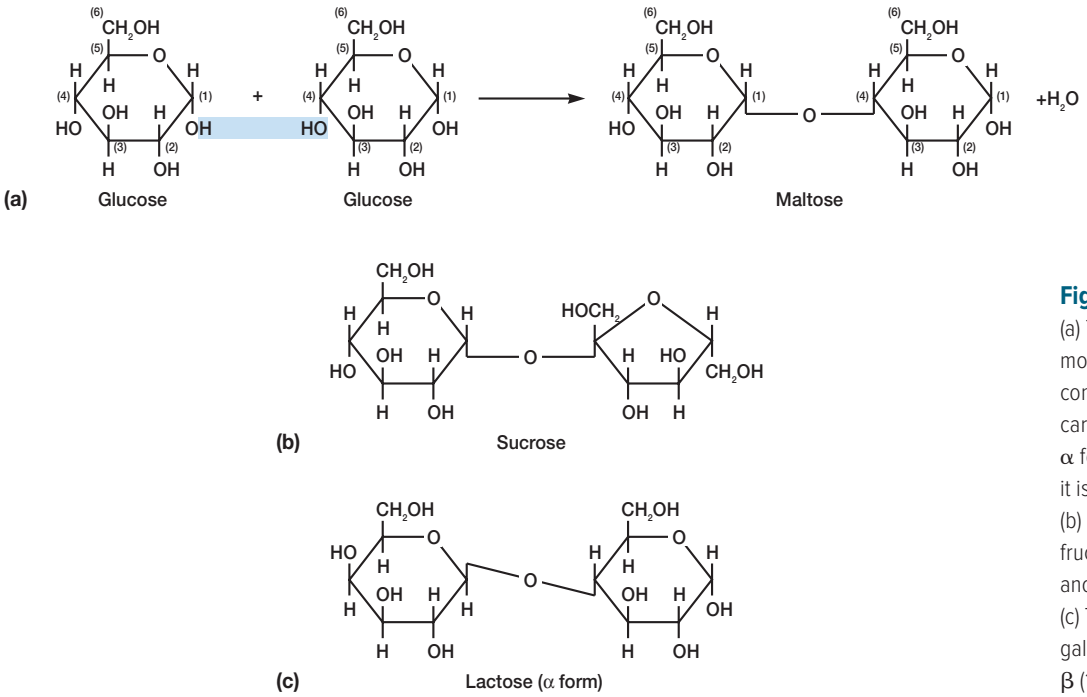

Figure AI.10 **Common Disaccharides.** (a) The formation of maltose from two molecules of an α-glucose. The bond connecting the glucose extends between carbons one and four, and involves the α form of the anomeric carbon. Therefore, it is called an α (1→4) glycosidic bond. (b) Sucrose is composed of a glucose and a fructose joined to each other through their anomeric carbons, and αβ (1→2) bond. (c) The milk sugar lactose contains galactose and glucose joined by a β (1→4) glycosidic bond.

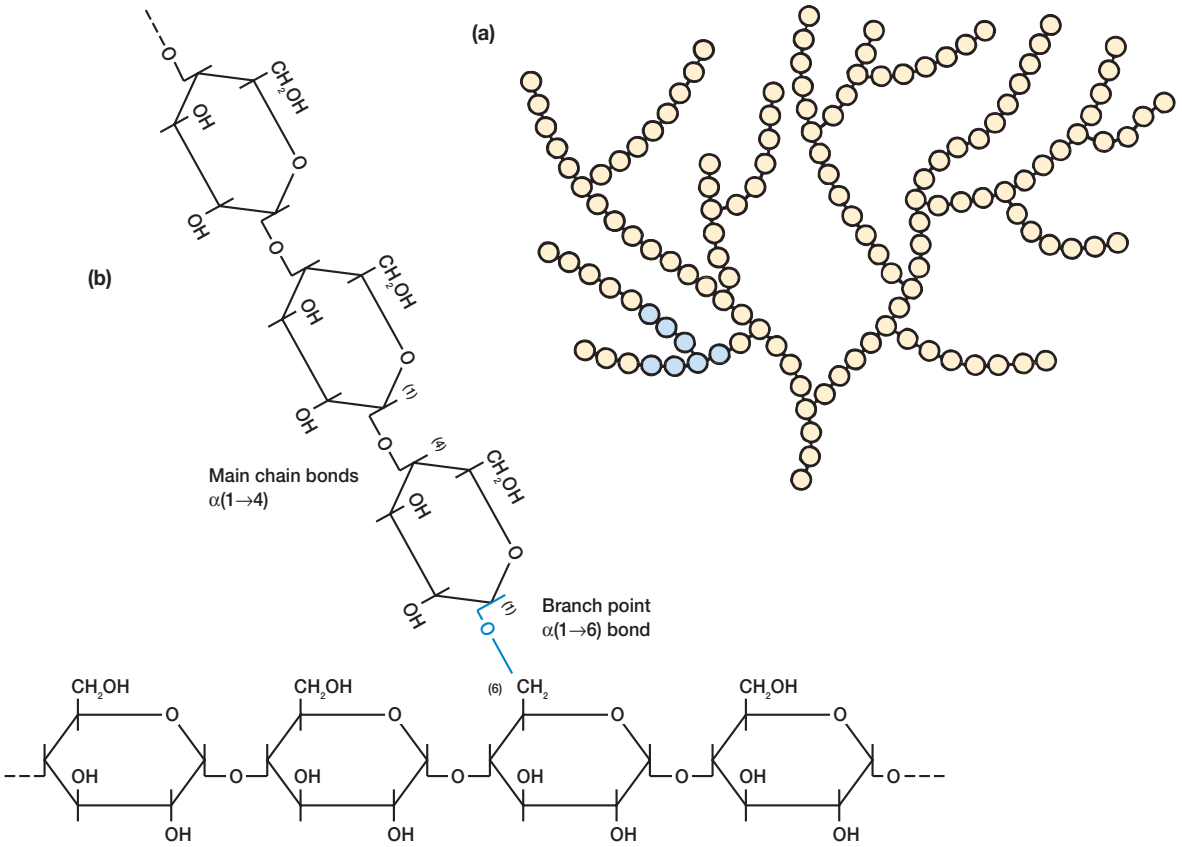

Figure AI.11 Glycogen and Starch Structure. (a) An overall view of the highly branched structure characteristic of glycogen and most starch. The circles represent glucose residues. (b) A close-up of a small part of the chain (shown in blue in part *a*) revealing a branch point with its α (1⟶6) glycosidic bond, which is colored blue.

Lipids

All cells contain a heterogeneous mixture of organic molecules that are relatively insoluble in water but very soluble in nonpolar solvents such as chloroform, ether, and benzene. These molecules are called lipids. Lipids vary greatly in structure and include triacylglycerols, phospholipids, steroids, carotenoids, and many other types. Among other functions, they serve as membrane components, storage forms for carbon and energy, precursors of other cell constituents, and protective barriers against water loss.

Most lipids contain fatty acids, which are monocarboxylic acids that often are straight chained but may be branched. Saturated fatty acids lack double bonds in their carbon chains, whereas unsaturated fatty acids have double bonds. The most common fatty acids are 16 or 18 carbons long.

Two good examples of common lipids are triacylglycerols and phospholipids. Triacylglycerols are composed of glycerol esterified to three fatty acids (**figure AI.12*a***). They are used to store carbon and energy. Phospholipids are lipids that contain at least one phosphate group and often have a nitrogenous constituent as well. Phosphatidylethanolamine is an important phospholipid frequently present in bacterial membranes (figure AI.12*b*). It is composed of two fatty acids esterified to glycerol. The third glycerol hydroxyl is joined with a phosphate group, and ethanolamine is attached to the phosphate. The resulting lipid is very asymmetric with a hydrophobic nonpolar end contributed by the fatty acids and a polar, hydrophilic end. In cell membranes, the hydrophobic end is buried in the interior of the membrane, while the polar-charged end is at the membrane surface and exposed to water.

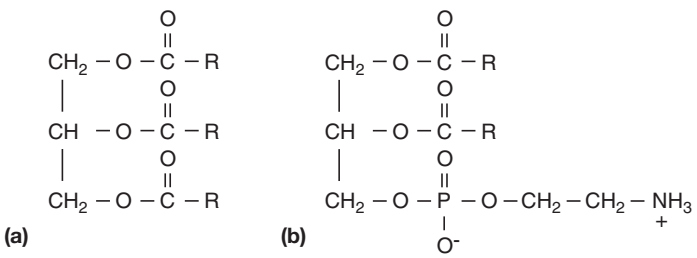

Figure AI.12 Examples of Common Lipids. (a) A triacylglycerol or neutral fat. (b) The phospholipid phosphatidylethanolamine. The R groups represent fatty acid side chains.

Proteins

The basic building blocks of proteins are amino acids. An amino acid contains a carboxyl group and an amino group on its alpha carbon (**figure AI.13**). About 20 amino acids are normally found in proteins; they differ from each other with respect to their side chains. In proteins, amino acids are linked together by peptide bonds between their carboxyls and α-amino groups to form linear polymers called peptides. If a peptide contains more than 50 amino acids, it usually is called a polypeptide. Each protein is composed of one or more polypeptide chains and has a molecular weight greater than about 6,000 to 7,000.

Proteins have three or four levels of structural organization and complexity. The primary structure of a protein is the sequence of the amino acids in its polypeptide chain or chains. The structure of the polypeptide chain backbone is also considered part of the primary structure. Each different polypeptide has its own amino acid sequence that is a reflection of the nucleotide sequence in the gene that codes for its synthesis. The polypeptide chain can coil along one axis in space into various shapes such as the α-helix (**figure AI.14**). This arrangement of the polypeptide in space around a single axis is called the secondary structure. Secondary structure is formed and stabilized by the interactions of amino acids that are fairly close to one another on the polypeptide chain. The polypeptide with its primary and secondary structure can be coiled or organized in space along three axes to form a more complex, three-dimensional shape (**figure AI.15**). This level of organization is the tertiary structure (**figure AI.16**). Amino acids more distant from one another on the polypeptide chain contribute to tertiary structure. Secondary and tertiary structures are examples of conformation, molecular shape that can be changed by bond rotation and without breaking covalent bonds. When a protein contains more than one polypeptide chain, each chain with its own primary, secondary, and tertiary structure associates with the other chains to form the final molecule. The way in which polypeptides associate with each other

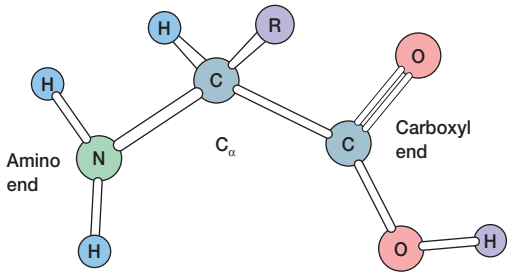

Figure AI.13 L-Amino Acid Structure. The uncharged form is shown.

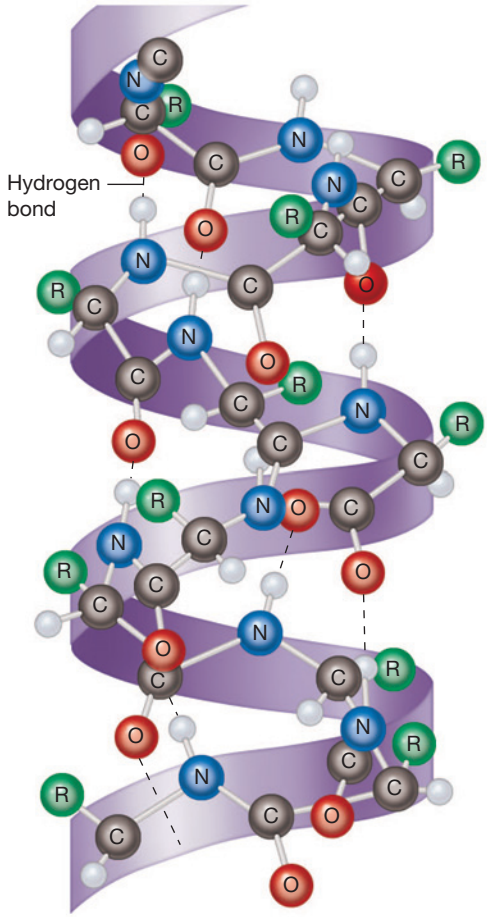

Figure AI.14 The β-Helix. A polypeptide twisted into one type of secondary structure, the α-helix. The helix is stabilized by hydrogen bonds joining peptide bonds that are separated by three amino acids.

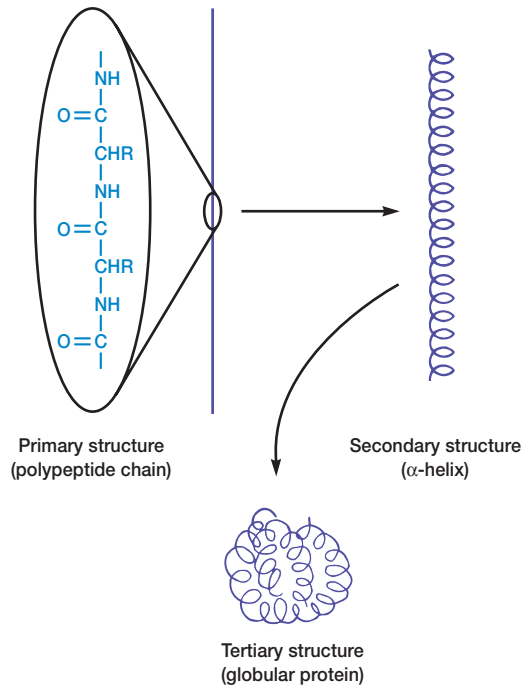

Figure AI.15 Secondary and Tertiary Protein Structures. The formation of secondary and tertiary protein structures by folding a polypeptide chain with its primary structure.

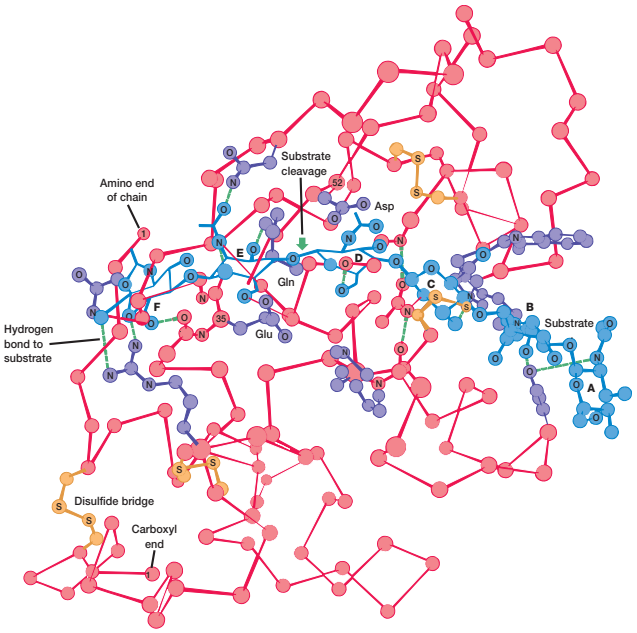

Figure AI.16 Lysozyme. The tertiary structure of the enzyme lysozyme. (a) A diagram of the protein's polypeptide backbone with the substrate hexasaccharide shown in blue. The point of substrate cleavage is indicated.

in space to form the final protein is called the protein's quaternary structure (**figure AI.17**). The final conformation of a protein is ultimately determined by the amino acid sequence of its polypeptide chains.

Protein secondary, tertiary, and quaternary structure is largely determined and stabilized by many weak noncovalent forces such as hydrogen bonds and ionic bonds. Because of this, protein shape often is very flexible and easily changed. This flexibility is very important in protein function and in the regulation of enzyme activity. Because of their flexibility, however, proteins readily lose their proper shape and activity when exposed to harsh conditions. The only covalent bond commonly involved in the secondary and tertiary structure of proteins is the disulfide bond. The disulfide bond is formed when two cysteines are linked through their sulfhydryl groups. Disulfide bonds generally strengthen or stabilize protein structure.

Nucleic Acids

The nucleic acids, deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), are polymers of deoxyribonucleosides and ribonucleosides joined by phosphate groups. The nucleosides in DNA contain the purines adenine and guanine, and the pyrimidine bases thymine and cytosine. In RNA the pyrimidine uracil is substituted for thymine. Because of their importance for genetics and molecular biology, the chemistry of nucleic acids is introduced earlier in the text. The structure and synthesis of purines and pyrimidines are discussed in chapter 12 (section 12.6). The structures of DNA and RNA are described in chapter 13 (section 13.2).

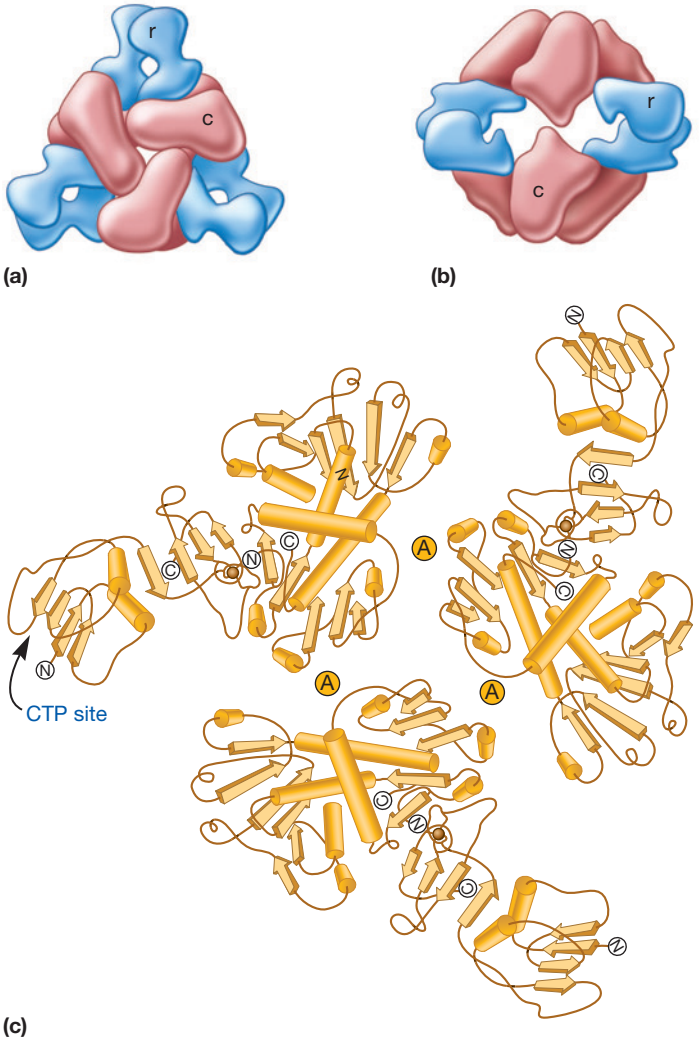

Figure AI.17 An Example of Quaternary Structure. The enzyme aspartate carbamoyltransferase from *Escherichia coli* has two types of subunits, catalytic and regulatory. The association between the two types of subunits is shown: (a) a top view, and (b) a side view of the enzyme. The catalytic (C) and regulator (r) subunits are shown in different colors. (c) The peptide chains shown when viewed from the top as in (a). The active sites of the enzyme are located at the positions indicated by A.

(a and b) Adapted from Krause, et al., in Proceedings of the National Academy of Sciences, *V. 82, 1985, as appeared in* Biochemistry, *3d edition, by Lubert Stryer. Copyright © 1975, 1981, 1988. Appendix Two

Common Metabolic Pathways

This appendix contains a few of the more important pathways discussed in the text, particularly those involved in carbohydrate catabolism. Enzyme names and final end products are given in color. Consult the text for a description of each pathway and its physiologic role.

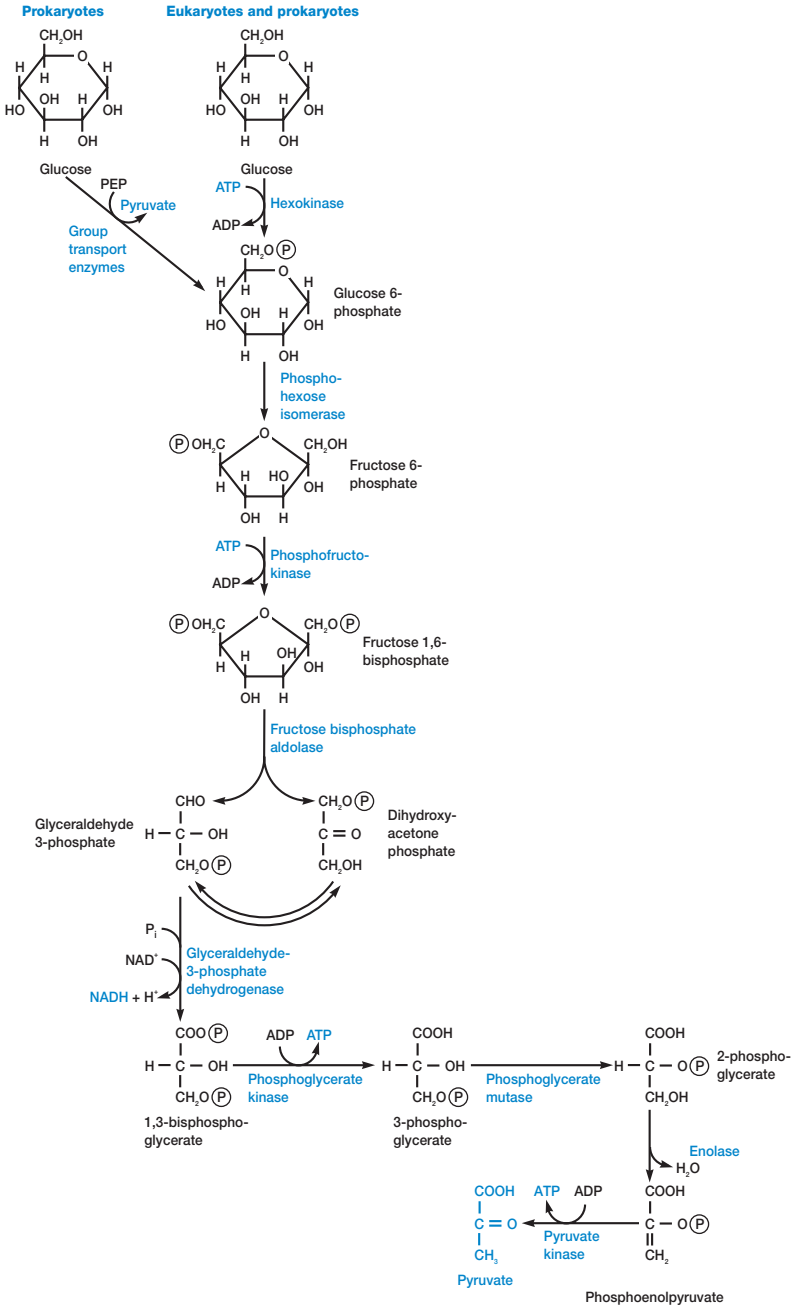

Figure AII.1 The Embden-Meyerhof Pathway. This pathway converts glucose and other sugars to pyruvate and generates NADH and ATP. In some prokaryotes, glucose is phosphorylated to glucose 6-phosphate during group translocation transport across the plasma membrane.

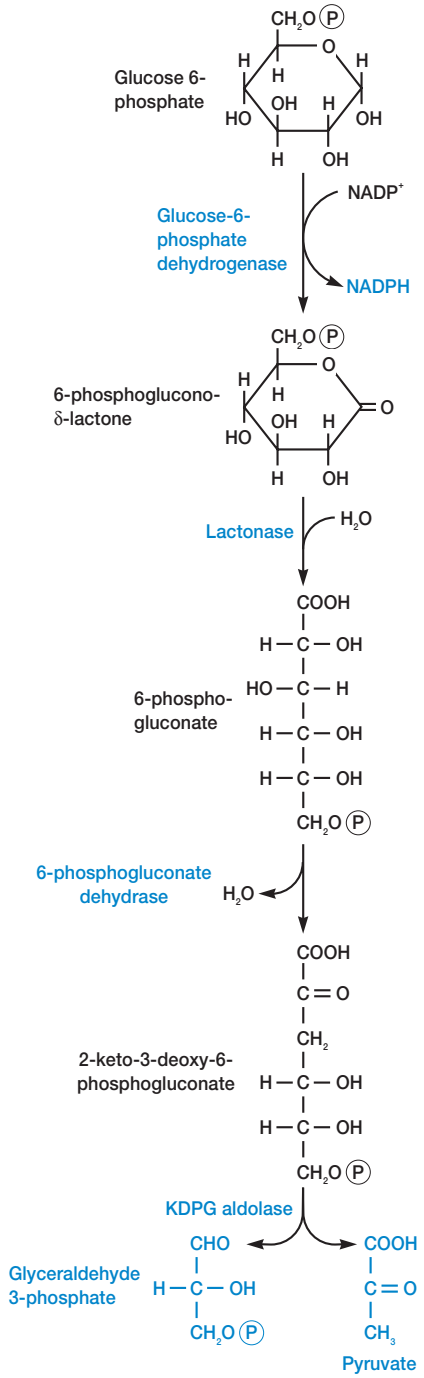

Figure AII.2 The Entner-Doudoroff Pathway.

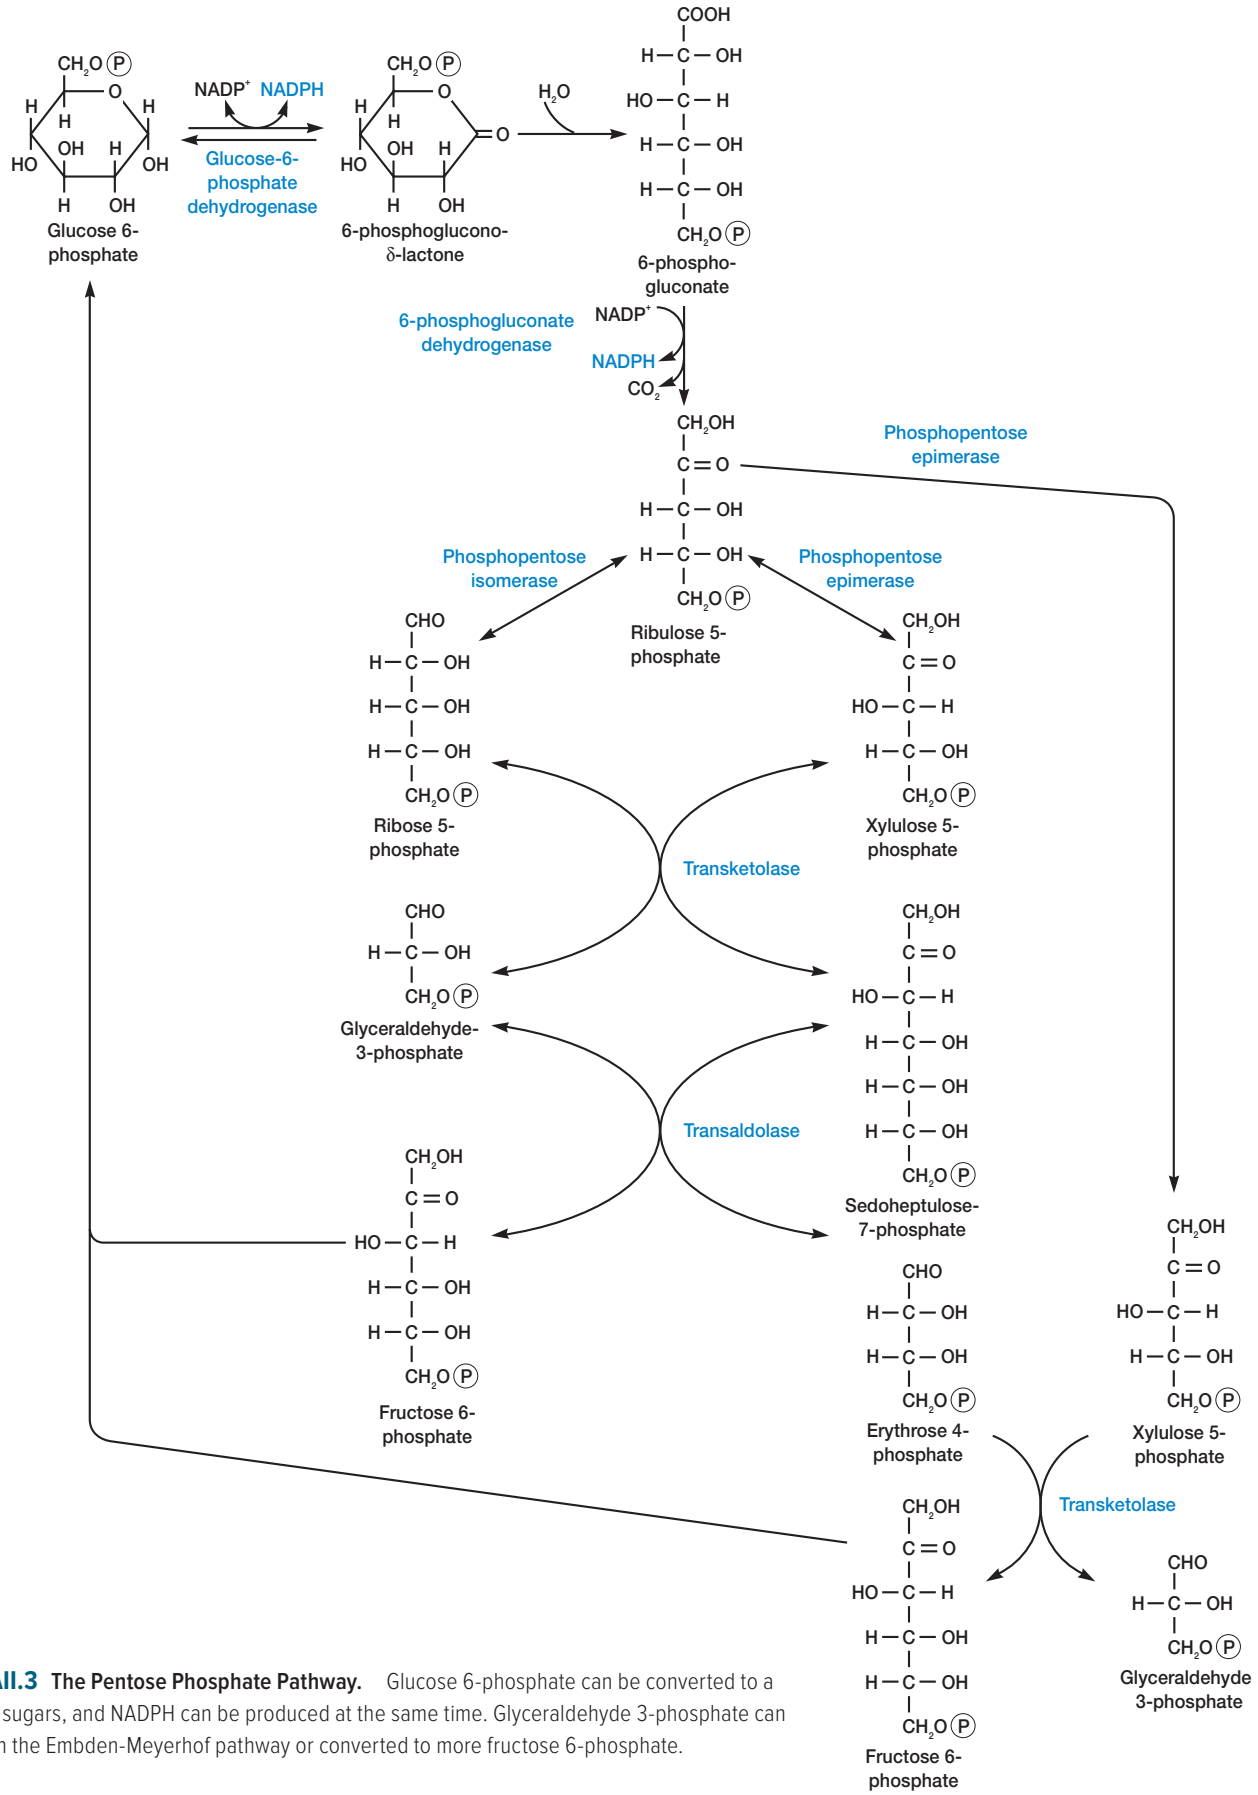

Figure AII.3 The Pentose Phosphate Pathway. Glucose 6-phosphate can be converted to a variety of sugars, and NADPH can be produced at the same time. Glyceraldehyde 3-phosphate can be used in the Embden-Meyerhof pathway or converted to more fructose 6-phosphate.

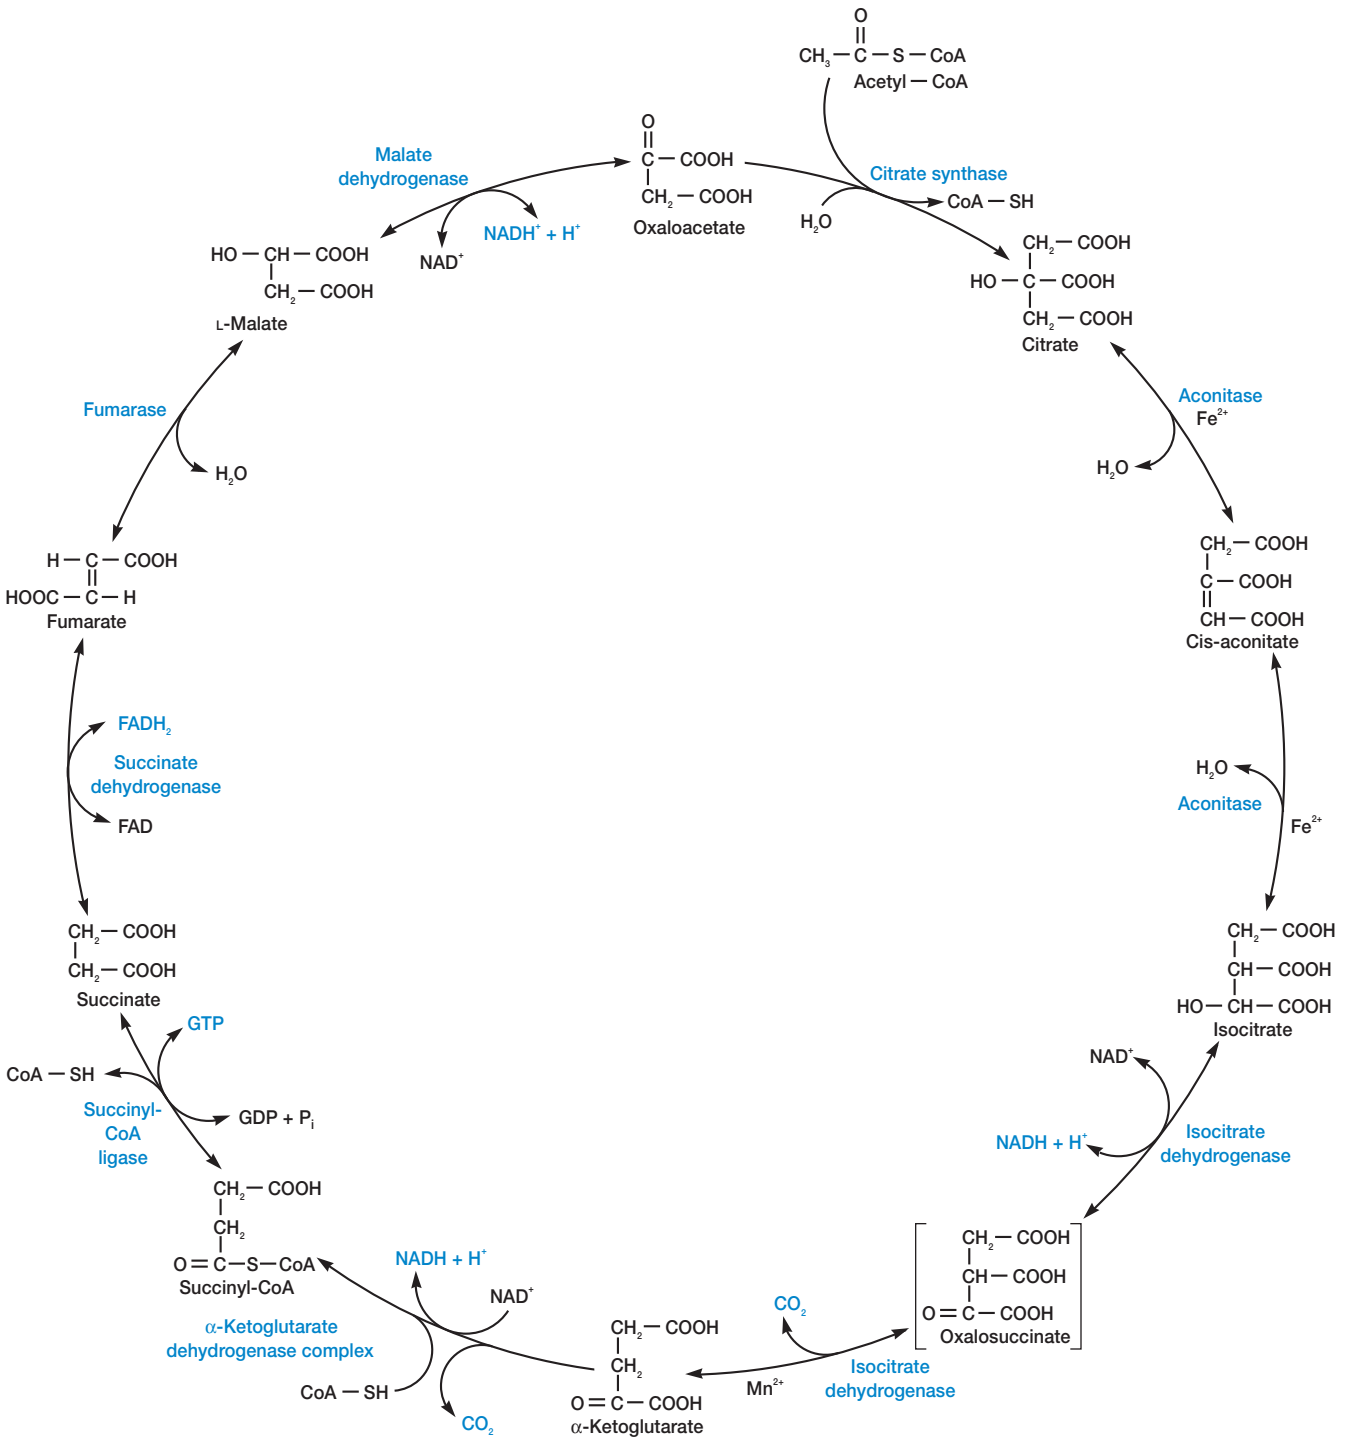

Figure AII.4 The Tricarboxylic Acid Cycle. Cis-aconitate and oxalosuccinate remain bound to aconitase and isocitrate dehydrogenase. Oxalosuccinate has been placed in brackets because it is so unstable.

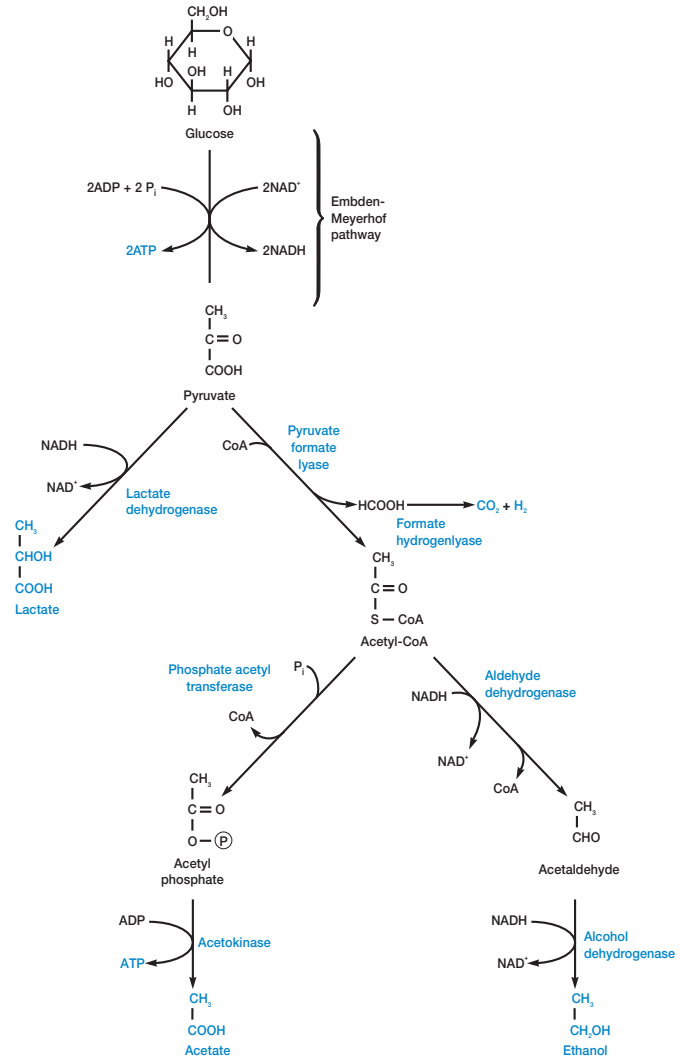

Figure AII.5 The Mixed Acid Fermentation Pathway. This pathway is characteristic of many members of the *Enterobacteriaceae* such as *Escherichia coli*.

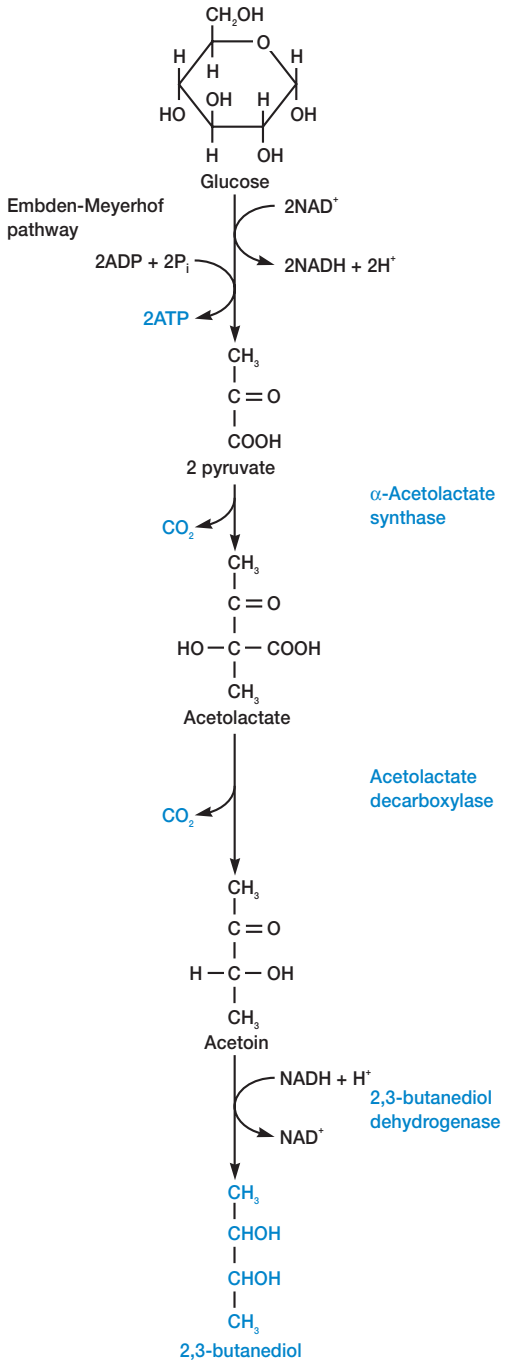

Figure AII.6 The Butanediol Fermentation Pathway. This pathway is characteristic of members of the *Enterobacteriaceae* such as *Enterobacter*. Other products may also be formed during butanediol fermentation.

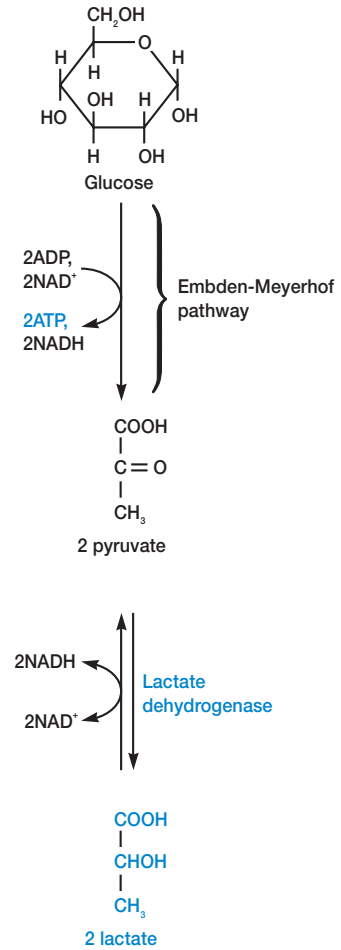

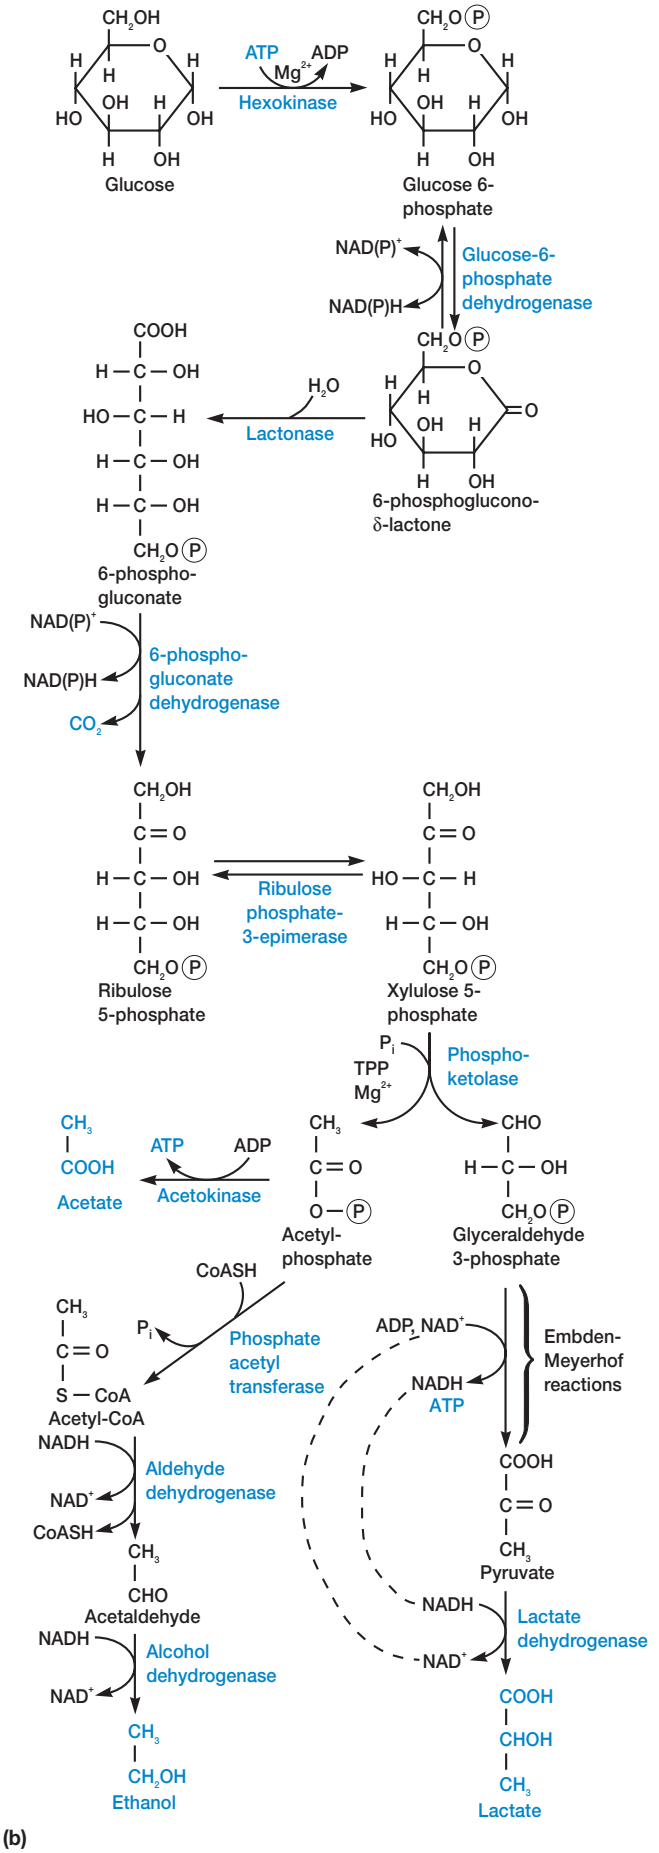

Figure AII.7 Lactic Acid Fermentations. (a) Homolactic fermentation pathway. (b) Heterolactic fermentation pathways.

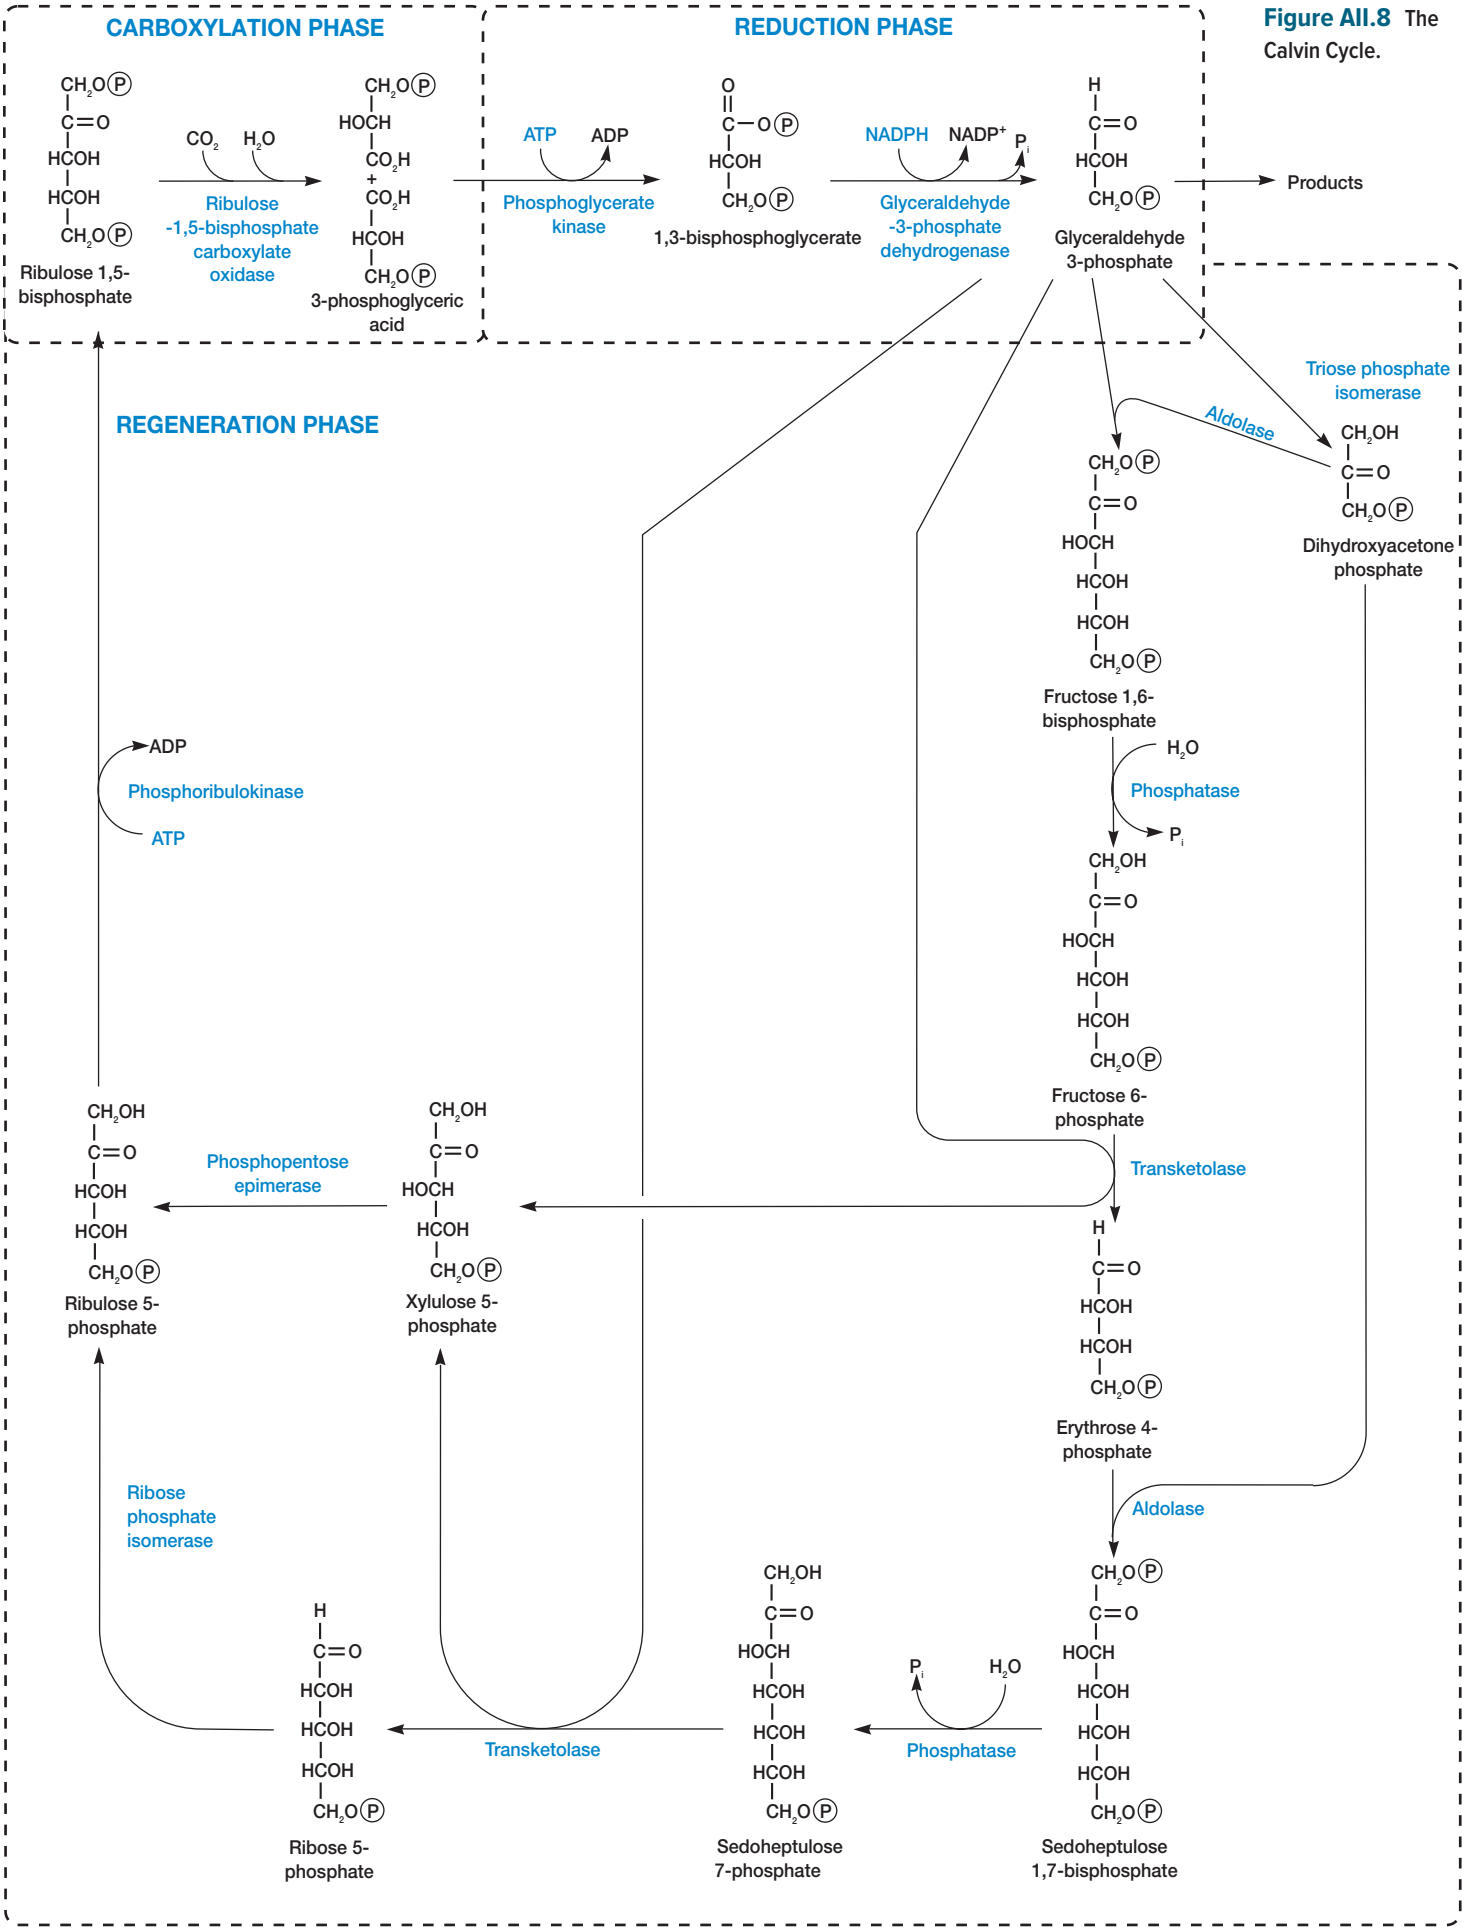

Figure AII.8 The Calvin Cycle.

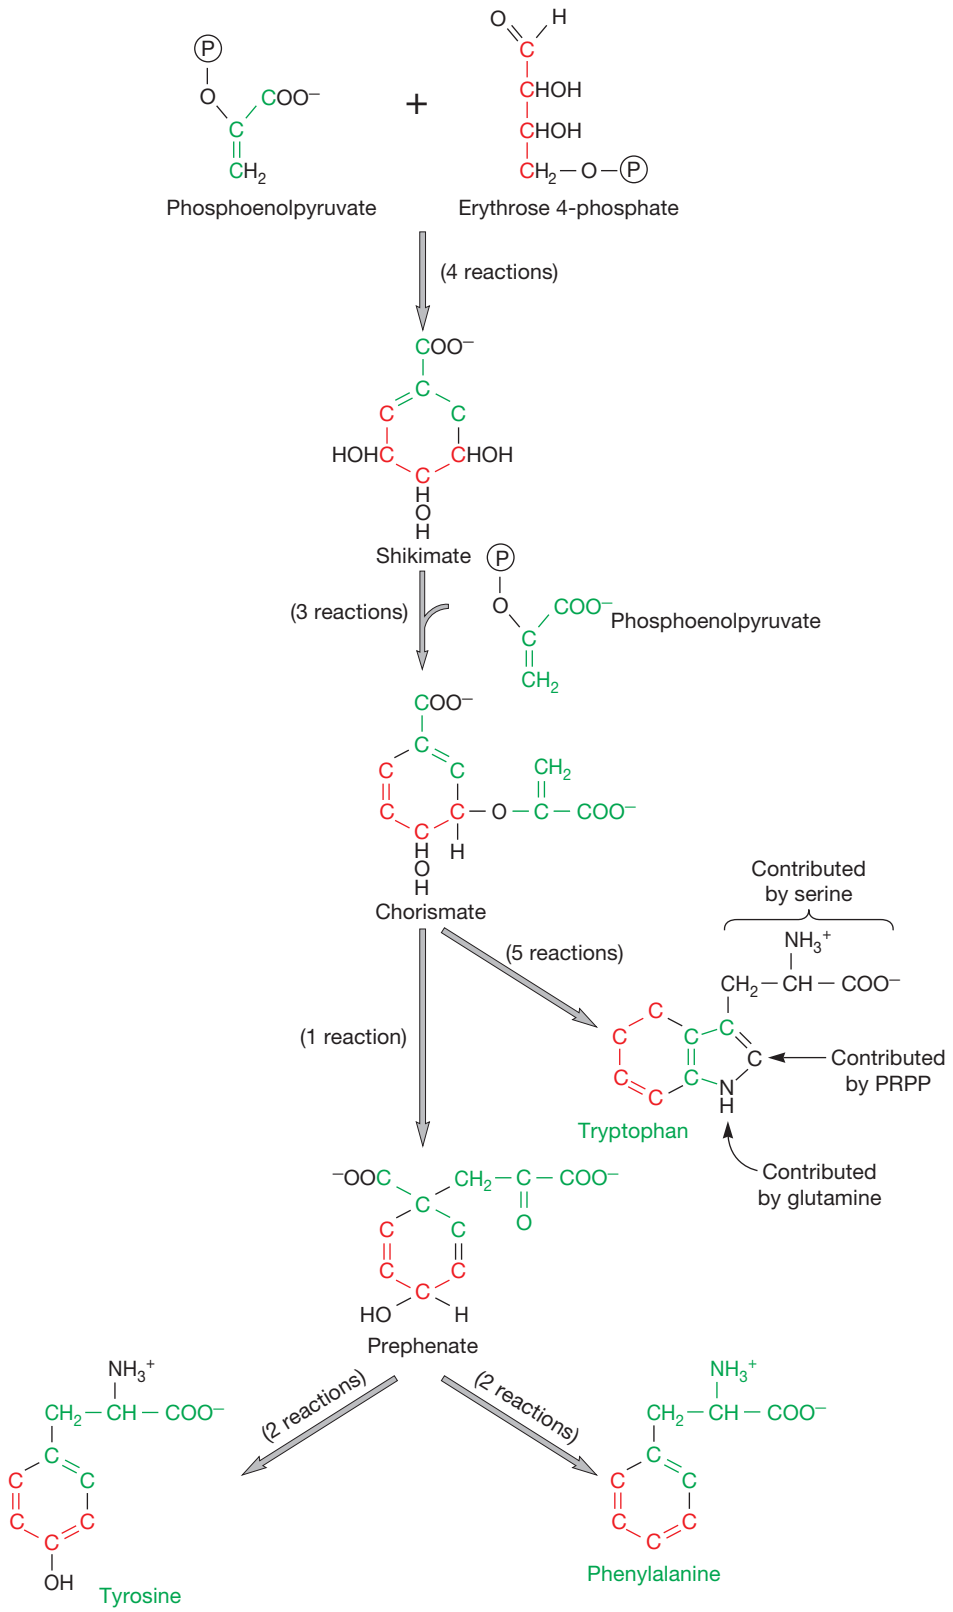

Figure AII.9 Aromatic Amino Acid Synthesis. The carbons arising from phosphoenolpyruvate (green) and erythrose 4-phosphate (red) are shown. The remaining carbons present in tryptophan are provided by 5-phosphoribosyl-1-pyrophosphate (PRPP) and the amino acid serine. PRPP is also important in purine biosynthesis (figure AII.10).

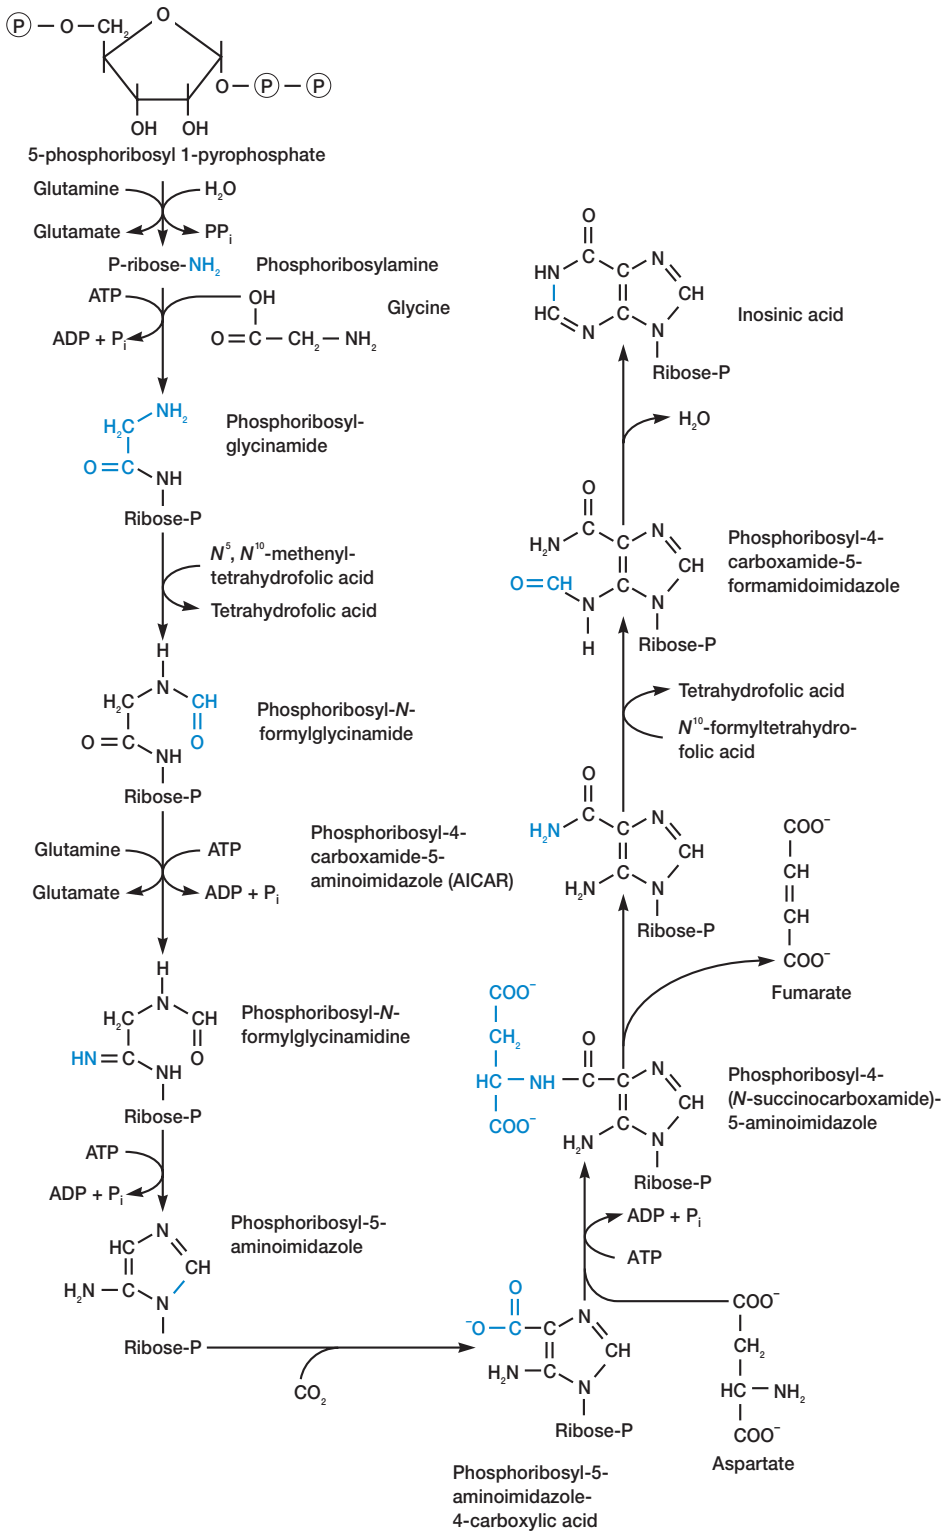

Figure AII.10 The Pathway for Purine Biosynthesis. Inosinic acid is the first purine end product. The purine skeleton is constructed while attached to a ribose phosphate.

Appendix Three

Microorganism Pronunciation Guide

The pronunciation of each name is given in parentheses. The phonetic spelling system is explained at the beginning of the glossary (p. G-1)

Bacteria

Acetobacter (ah-se″to-bak′ter)
Acinetobacter (as″ĭ-net″o-bak′ter)
Actinomyces (ak″ti̇-no-mi′sēz)
Agrobacterium (ag″ro-bak-te′re-um)
Alcaligenes (al″kah-lij′ĕ-nēz)
Anabaena (ah-nab′ē-nah)
Arthrobacter (ar″thro-bak′ter)
Bacillus (bah-sil′lus)
Bacteroides (bak″tĕ-roi′dēz)
Bdellovibrio (del″o-vib′re-o)
Beggiatoa (bej″je-ah-to′ah)
Beijerinckia (bi″jer-ink′e-ah)
Bifidobacterium (bi″fid-o-bak-te′re-um)
Bordetella (bor″dĕ-tel′lah)
Borrelia (bŏ-rel′e ah)
Brucella (broo-sel′lah)
Campylobacter (kam″pi̇-lo-bak′ter)
Caulobacter (kaw″lo-bak′ter)
Chlamydia (klah-mid′e-ah)
Chlorobium (klo-ro′be-um)
Chromatium (kro-ma′te-um)
Citrobacter (sit″ro-bak′ter)
Clostridium (klo-strid′e-um)
Corynebacterium (ko-ri″ne-bak-te′re-um)
Coxiella (kok″se-el′lah)
Cytophaga (si̇-tof′ah-gah)
Desulfovibrio (de-sul″fo-vib′re-o)
Enterobacter (en″ter-o-bak′ter)
Erwinia (er-win′e-ah)
Escherichia (esh″er-i′ke-ah)
Flexibacter (flek″si̇-bak′ter)
Francisella (fran-si̇-sel′ah)
Frankia (frank′e-ah)
Gallionella (gal″le-o-nel′ah)
Haemophilus (he-mof′i̇-lus)
Halobacterium (hal″o-bak-te′re-um)
Hydrogenomonas (hi-dro″jĕ-no-mo′nas)
Hyphomicrobium (hi″fo-mi-kro′be-um)
Klebsiella (kleb″se-el′lah)
Lactobacillus (lak″to-bah-sil′lus)
Legionella (le″jun-el′ah)
Leptospira (lep″to-spi′rah)
Leptothrix (lep′to-thriks)
Leuconostoc (loo″ko-nos′tok)
Listeria (lis-te′re-ah)
Methanobacterium (meth″ah-no-bak-te′re-um)
Methylococcus (meth″il-o-kok′-us)
Methylomonas (meth″il-o-mo′nas)
Micrococcus (mi″kro-kok′us)
Mycobacterium (mi″ko-bak-te′re-um)
Mycoplasma (mi″ko-plaz′mah)
Neisseria (nīs-se′re-ah)
Nitrobacter (ni̇″tro-bak′ter)
Nitrosomonas (ni-tro″so-mo′nas)
Nocardia (no-kar′de-ah)
Pasteurella (pas″tĕ-rel′ah)
Photobacterium (fo″to-bak-te′re-um)
Propionibacterium (pro″pe-on″e-bak-te′re-um)
Proteus (pro′te-us)
Pseudomonas (soo″do-mo′nas)
Rhizobium (ri-zo′be-um)
Rhodopseudomonas (ro″do-soo″do-mo′nas)
Rhodospirillum (ro″do-spi-ril′um)
Rickettsia (ri̇-ket′se-ah)
Salmonella (sal″mo-nel′ah)
Sarcina (sar′si̇-nah)
Serratia (sĕ-ra′she-ah)
Shigella (shi̇-gel′ah)
Sphaerotilus (sfe-ro′ti̇-lus)
Spirillum (spi-ril′um)
Spirochaeta (spi″ro-ke′tah)
Spiroplasma (spi″ro-plaz′mah)
Staphylococcus (staf″i̇-lo-kok′us)
Streptococcus (strep″to-kok′us)
Streptomyces (strep″to-mi′sēz)
Sulfolobus (sul″fo-lo′bus)
Thermoactinomyces (ther″mo-ak″ti̇-no-mi′sēz)
Thermoplasma (ther″mo-plaz′mah)
Thiobacillus (thi″o-bah-sil′us)
Thiothrix (thi′o-thriks)
Treponema (trep″o-ne′mah)
Ureaplasma (u-re′ah-plaz″ma)
Veillonella (va″yon-el′ah)
Vibrio (vib′re-o)
Xanthomonas (zan″tho-mo′nas)
Yersinia (yer-sin′e-ah)
Zoogloea (zo″o-gle′ah)

Viruses

Vernacular, nonscientific virus names are not written in italics, and thus the following names are not italicized.

adenovirus (ad″ĕ-no-vi′rus)
arbovirus (ar″bo-vi′rus)
baculovirus (bak″u-lo-vi′rus)
coronavirus (kor″o-nah-vi′rus)
cytomegalovirus (si″to-meg″ah-lo-vi′rus)
Epstein-Barr virus (ep′stīn-bar′)
hepadnavirus (hep-ad″nə-vi′rus)
hepatitis virus (hep″ah-ti′tis)
herpesvirus (her″pēz-vi′rus)
influenza virus (in″flu-en′zah)
measles virus (me′zelz)
mumps virus (mumps)
orthomyxovirus (or″tho-mik″so-vi′rus)
papillomavirus (pap″ĭ-lo″mah-vi′rus)
paramyxovirus (par″ah-mik″so-vi′rus)
parvovirus (par″vo-vi′rus)
picornavirus (pi-kor″nah-vi′rus)
poliovirus (po″le-o-vi′rus)
polyomavirus (pol″e-o-mah-vi′rus)
poxvirus (poks-vi′rus)
rabies virus (ra′bēz)
reovirus (re″o-vi′rus)
retrovirus (re″tro-vi′rus)
rhabdovirus (rab″do-vi′rus)
rhinovirus (ri″no-vi′rus)
rotavirus (ro′tah-vi″rus)
rubella virus (roo-bel′ah)
togavirus (to″gah-vi′rus)
varicella-zoster virus (var″ĭ-sel′ah zos′ter)
variola virus (vah-ri′o-lah)

Fungi

Agaricus (ah-gar′ĭ-kus)
Amanita (am″ah-ni′tah)
Arthrobotrys (ar″thro-bo′tris)
Aspergillus (as″per-jil′us)
Blastomyces (blas″to-mi′sēz)
Candida (kan′dĭ-dah)
Cephalosporium (sef″ah-lo-spo′re-um)
Claviceps (klav′ĭ-seps)
Coccidioides (kok-sid″e-oi′dēz)
Cryptococcus (krip″to-kok′us)
Epidermophyton (ep″ĭ-der-mof′ĭ-ton)
Fusarium (fu-sa′re-um)
Histoplasma (his″to-plaz′mah)
Microsporum (mi-kros′po-rum)
Mucor (mu′kor)
Neurospora (nu-ros′po-rah)
Penicillium (pen″ĭ-sil′e-um)
Phytophthora (fi-tof′tho-rah)
Pneumocystis (noo″mo-sis′tis)
Rhizopus (ri-zo′pus)
Saccharomyces (sak″ah-ro-mi′sēz)
Saprolegnia (sap″ro-leg′ne-ah)
Sporothrix (spo′ro-thriks)
Trichoderma (trik-o-der′mah)
Trichophyton (tri-kof′ĭ-ton)

Protists

Acanthamoeba (ah-kan″thah-me′bah)
Acetabularia (as″ĕ-tab″u-la′re-ah)
Amoeba (ah-me′bah)
Balantidium (bal″an-tid′e-um)
Chlamydomonas (klah-mid″do-mo′nas)
Chlorella (klo-rel′ah)
Cryptosporidium (krip″to-spo-rid′e-um)
Entamoeba (en″tah-me′bah)
Euglena (u-gle′nah)
Giardia (je-ar′de-ah)
Gonyaulax (gon″e-aw′laks)
Leishmania (lēsh-ma′ne-ah)
Naegleria (na-gle′re-ah)
Paramecium (par″ah-me′she-um)
Plasmodium (plaz-mo′de-um)
Prototheca (pro″to-the′kah)
Spirogyra (spi″ro-ji′rah)
Tetrahymena (tet″rah-hi′mĕ-nah)
Toxoplasma (toks″o-plaz′mah)
Trichomonas (trik″o-mo′nas)
Trypanosoma (tri″pan-o-so′mah)
Volvox (vol′voks)

Glossary

Pronunciation Guide

Some of the boldface terms in this glossary are followed by a phonetic spelling in parentheses. These pronunciation aides usually come from *Dorland's Illustrated Medical Dictionary.* The following rules are taken from this dictionary and will help in using its phonetic spelling system.

1. An unmarked vowel ending a syllable (an open syllable) is long; thus, *ma* represents the pronunciation of *may; ne,* that of *knee; ri,* of *wry; so,* of *sew; too,* of *two;* and *vu,* of *view.*
2. An unmarked vowel in a syllable ending with a consonant (a closed syllable) is short; thus, *kat* represents *cat; bed, bed; hit, hit; not, knot; foot, foot;* and *kusp, cusp.*
3. A long vowel in a closed syllable is indicated by a macron; thus, *māt* stands for *mate; sēd,* for *seed; bīl,* for *bile; mōl,* for *mole; fūm,* for *fume;* and *fo͞ol,* for *fool.*
4. A short vowel that ends or itself constitutes a syllable is indicated by a breve; thus, *ĕ-fekt′* for *effect, ĭ-mūn′* for *immune,* and *ŭ-klo͞od′* for *occlude.*

Primary (′) and secondary (″) accents are shown in polysyllabic words. Unstressed syllables are followed by hyphens.

Some common vowels are pronounced as indicated here.

ə	sof<u>a</u>	ē	m<u>e</u>t	ŏ	g<u>o</u>t
ā	m<u>a</u>te	ī	b<u>i</u>te	ū	f<u>u</u>el
ă	b<u>a</u>t	ĭ	b<u>i</u>t	ŭ	b<u>u</u>t
ē	b<u>ea</u>m	ō	h<u>o</u>me		

From Dorland's Illustrated Medical Dictionary. *Copyright © 1988 W. B. Saunders, Philadelphia, Pa. Reprinted by permission.*

A

AB toxins Exotoxins composed of two parts (A and B). The B portion is responsible for toxin binding to a cell but does not directly harm it; the A portion enters the cell and disrupts its function.

ABC protein secretion pathway *See* ATP-binding cassette transporters.

accessory pigments Photosynthetic pigments such as carotenoids and phycobiliproteins that aid chlorophyll in trapping light energy.

acellular slime mold *See* plasmodial slime mold.

acetyl-CoA pathway A biochemical pathway used by methanogens to fix CO_2 and by acetogens to generate acetic acid.

acetyl-coenzyme A (acetyl-CoA) A molecule made of acetic acid and coenzyme A that is energy rich; it is produced by many catabolic pathways and is the substrate for the tricarboxylic acid cycle, fatty acid biosynthesis, and other pathways.

acid-fast Refers to bacteria (e.g., mycobacteria) that cannot be easily decolorized with acid alcohol after being stained with dyes such as basic fuchsin.

acid-fast staining A staining procedure that differentiates between bacteria based on their ability to retain a dye when washed with an acid alcohol solution.

acidophile (as′id-o-fīl″) A microorganism that has its growth optimum between about pH 0 and 5.5.

acquired immune tolerance The ability to produce antibodies against nonself antigens while "tolerating" (not producing antibodies against) self antigens.

acquired immunity *See* adaptive immunity.

actin filaments One of the proteinaceous components of the eukaryotic cytoskeleton; also called microfilaments.

actinobacteria (ak″tĭ-no-bak-tēr-e-ah) A group of Gram-positive bacteria containing actinomycetes and their high G + C relatives.

actinomycete (ak″tĭ-no-mi′sēt) An aerobic, Gram-positive bacterium that forms branching filaments (hyphae) and asexual spores.

actinorhizae Associations between actinomycetes and plant roots.

activated sludge Solid matter or sediment composed of actively growing microorganisms that participate in the aerobic portion of a biological sewage treatment process.

activation energy The energy required to bring reacting molecules together to reach the transition state in a chemical reaction.

activator-binding site *See* activator protein.

activator protein A transcriptional regulatory protein that binds to a specific site on DNA (activator-binding site) and enhances transcription initiation.

active (catalytic) site The part of an enzyme that binds the substrate to form an enzyme-substrate complex and catalyze the reaction. Also called the catalytic site.

active transport The transport of solute molecules across a membrane against a gradient; it requires a carrier protein and the input of energy. Three major types are primary active transport, which uses hydrolysis of ATP to power transport; secondary active transport, which uses ion gradients across a membrane to power active transport; and group translocation. *See also* group translocation.

acute-phase proteins Liver proteins that assist in the prevention of blood loss and ready the host for microbial invasion.

***N*-acylhomoserine lactone** *See* quorum sensing.

adaptive immunity Immunity that develops in response to a specific antigen; involves T and B lymphocyte differentiation and antibody production. Immunologic memory is formed to each antigen.

adaptive mutation The notion that mutations will arise when organisms are subjected to prolonged stress that will help the organism survive the stress.

adenine (ad′e-nēn) A purine derivative, 6-aminopurine, found in nucleosides, nucleotides, coenzymes, and nucleic acids.

adenosine diphosphate (ADP) (ah-den′o-sēn) The nucleoside diphosphate usually formed upon the breakdown of ATP when it provides energy for work.

adenosine 5′-triphosphate (ATP) A high energy molecule that serves as the cell's major form of energy currency.

adhesin (ad-he′zin) A molecule on the surface of a microorganism involved in adhesion to a substratum (e.g., host tissue).

adjuvant Material added to an antigen in a vaccine preparation that increases its immunogenicity.

aerial mycelium The mat of hyphae formed by actinomycetes or fungi that grows above the substrate, imparting a fuzzy appearance to colonies.

aerobic anoxygenic phototrophy (AAnP) Phototrophic process by which electron donors such as organic matter or sulfide are used under aerobic conditions.

aerobic respiration A metabolic process in which molecules, often organic, are oxidized with oxygen as the final electron acceptor.

aerotolerant anaerobes Microbes that grow equally well whether or not oxygen is present.

aflatoxin (af″lah-tok′sin) A polyketide secondary fungal metabolite that can cause cancer.

agar (ahg′ar) A complex sulfated polysaccharide, usually from red algae, that is used to solidify culture media.

agglutinates The visible aggregates or clumps formed by an agglutination reaction.

agglutination reaction The formation of an insoluble immune complex by the cross-linking of cells or particles.

airborne transmission The spread of a pathogen as it travels suspended in air over a meter or more from the source to the host.

akinetes (ā-kin′ēts) Specialized, nonmotile, dormant, thick-walled resting cells formed by some cyanobacteria.

alcoholic fermentation A fermentation process that produces ethanol and CO_2 from sugars.

alga (al′gah) A common term for several unrelated groups of photosynthetic eukaryotic microorganisms. Most are now considered protists.

alignment The comparison of gene, RNA, and protein sequences in a base-by-base (or amino acid by amino acid) fashion; used to calculate the degree of similarity between sequences.

alkaliphile (alkalophile) A microorganism that grows best at pHs from about 8.5 to 11.5.

allele An alternative form of a gene.

allergen An antigen that induces an allergic response.

allergy *See* Type I hypersensitivity.

allochthonous (ăl′ək-thə-nəs) Substances not native to a given environment (e.g., nutrient influx into freshwater ecosystems).

allograft A transplant between genetically different individuals of the same species.

allosteric effector *See* allosteric enzyme.

allosteric enzyme An enzyme whose activity is altered by the noncovalent binding of a small molecule (allosteric effector) at a regulatory site separate from the catalytic site; effector binding causes a conformational change in the enzyme's catalytic site, causing enzyme activation or inhibition.

α/β T cells CD4 or CD8 T cells that possess alpha/beta T-cell receptors.

α-hemolysis *See* hemolysis.

alphaproteobacteria Members of the bacterial class *Alphaproteobacteria*.

alternative complement pathway An antibody-independent pathway of complement activation.

alternate sigma factors Sigma is the subunit of bacterial RNA polymerase required for transcription initiation; alternate sigma factors direct the core RNA polymerase to transcribe distinct sets of inducible genes or operons, and is thereby a mechanism for global regulation.

alternative splicing The use of different exons during RNA splicing to generate different polypeptides from the same gene.

alveolar macrophage A vigorously phagocytic macrophage located on the epithelial surface of the lung alveoli, where it ingests inhaled particulate matter and microorganisms.

amensalism A relationship in which the product of one organism has a negative effect on another organism.

amino acid activation The preparatory step of protein synthesis in which amino acids are attached to transfer RNA molecules. The reaction is catalyzed by aminoacyl-tRNA synthetases.

aminoacyl or **acceptor site (A site)** The ribosomal site that contains an aminoacyl-tRNA at the beginning of the elongation cycle during protein synthesis.

aminoacyl-tRNA synthetases *See* amino acid activation.

aminoglycoside antibiotics A group of antibiotics that contain a cyclohexane ring and amino sugars; all aminoglycoside antibiotics inhibit protein synthesis by binding to the small ribosomal subunit.

amphibolic pathways Metabolic pathways that function both catabolically and anabolically.

amphipathic Term describing a molecule that has both hydrophilic and hydrophobic regions (e.g., phospholipids).

amphitrichous (am-fit′rĕ-kus) A cell with a single flagellum at each end.

anabolism The synthesis of complex molecules from simpler molecules with the input of energy and reducing power.

anaerobic digestion (an″a-er-o′bik) The microbiological treatment of sewage wastes under anoxic conditions to produce methane.

anaerobic respiration An energy-conserving process in which the terminal electron transport chain acceptor is a molecule other than oxygen.

anagenesis Changes in gene frequencies and distribution among species; the accumulation of small genetic changes within a population that introduces genetic variability but is not enough to result in either speciation or extinction.

anammoxosome The compartment within a planctomycete cell in which the anammox reaction occurs.

anammox reaction The coupled use of nitrite as an electron acceptor and ammonium ion as an electron donor under anoxic conditions to yield nitrogen gas.

anaphylaxis (an″ah-fĭ-lak′sis) A severe, immediate type I hypersensitivity reaction following exposure of a sensitized individual to the appropriate antigen.

anaplasia The reversion of an animal cell to a more primitive, undifferentiated state.

anaplerotic reactions (an′ah-plĕ-rot′ik) Reactions that replenish depleted tricarboxylic acid cycle intermediates.

anergy (an′ər-je) A state of immune cell unresponsiveness to antigens.

anoxic Without oxygen present.

anoxygenic photosynthesis Photosynthesis that does not oxidize water to produce oxygen.

antibiotic A microbial product or its derivative that kills susceptible microorganisms or inhibits their growth.

antibody (immunoglobulin) A glycoprotein made by plasma cells in response to the introduction of an antigen.

antibody affinity The strength of binding between an antigen and an antibody.

antibody-dependent cell-mediated cytotoxicity (ADCC) The killing of antibody-coated target cells by immune cells with Fc receptors that recognize the Fc region of the bound antibody.

antibody-mediated immunity *See* humoral immunity.

antibody class switching The process by which plasma cells change their expression from one isotype of immunoglobulin to a second isotype.

antibody titer An approximation of the antibody concentration.

anticodon The three bases on a tRNA that are complementary to the codon on mRNA.

antigen A substance (such as a protein, nucleoprotein, polysaccharide, or sometimes a glycolipid) to which lymphocytes respond.

antigen-binding fragment (Fab) "Fragment antigen binding." A monovalent antigen-binding fragment of an immunoglobulin molecule that consists of one light chain and part of one heavy chain, linked by interchain disulfide bonds.

antigen-presenting cells (APCs) Cells that take in protein antigens, process them, and present peptide fragments bound to MHC molecules to T cells; includes macrophages, dendritic cells, and B cells.

antigen processing The hydrolytic digestion of antigens to produce peptide fragments, which are collected and presented by class I or class II MHC molecules on the surface of an antigen-presenting cell.

antigenic determinant site *See* epitope.

antigenic drift A small change due to mutation in the antigenic character of an organism.

antigenic shift A major change in the antigenic character of an organism that makes it unrecognized by host immune mechanisms. This term is most often used to describe an antigenically distinct virus that results when two different strains of virus recombine genetic material.

antigenic variation The capacity of some microbes to change surface proteins when in a host organism, thereby evading the host immune system.

antimetabolite A compound that blocks metabolic pathway function by competitively inhibiting a key enzyme because it closely resembles the normal enzyme substrate.

antimicrobial agent An agent that kills microorganisms or inhibits their growth.

antiport Coupled transport of two molecules in which one molecule enters the cell as the other leaves the cell.

antisense RNA A single-stranded RNA with a base sequence complementary to a segment of a target RNA molecule; when bound to the target RNA, the target's activity is altered.

antisepsis The prevention of infection or sepsis.

antiseptic Chemical agent applied to tissue to prevent infection by killing or inhibiting pathogens.

antitoxin An antibody to a microbial toxin, usually a bacterial exotoxin, that binds and neutralizes the toxin.

apical complex A set of organelles characteristic of members of the protist subdivision *Apicomplexa*: includes polar rings, subpellicular microtubules, conoid, rhoptries, and micronemes.

apicomplexan (a′pĭ-kom-plek′san) A protist that has an apical complex and a spore-forming stage. It is either an intra- or extracellular parasite of animals; a member of the taxon *Apicomplexa*.

apicoplast (a′pĭ-ko-plast) Organelles in apicomplexan protists derived from cyanobacterial endosymbionts. Apicoplasts, however, are not involved in phototrophy; rather, they are the site of fatty acid, isoprenoid, and heme biosythesis.

apoenzyme (ap″o-en′zīm) The protein part of an enzyme that also has a nonprotein component.

apoptosis (ap″o-to′sis) Programmed cell death. A physiological suicide mechanism that results in fragmentation of a cell into membrane-bound particles that are eliminated by phagocytosis.

aporepressor The inactive form of a repressor protein; the repressor becomes active when the corepressor binds to it.

appressorium A flattened region of hypha found in some plant-infecting fungi that aids in penetrating the host plant cell wall. Occurs in both pathogenic fungi and nonpathogenic mycorrhizal fungi.

aptamer (ap'tăm-er) A single-stranded DNA or RNA molecule engineered to bind to a target protein to modify the activity of the protein.

arbuscular mycorrhizae (AM) The mycorrhizal fungi in a fungus-root association that penetrate the outer layer of the root, grow intracellularly, and form characteristic much-branched hyphal structures called arbuscules.

arbuscules *See* arbuscular mycorrhizal fungi.

archaea Members of the domain *Archaea*.

archaerhodopsin A transmembranous protein to which retinal is bound; it functions as a light-driven proton pump resulting in photophosphorylation without chlorophyll or bacteriochlorophyll. Found in the purple membrane of halophilic archaea.

arthroconidia (arthrospores) Fungal spores formed by fragmentation.

artificially acquired active immunity The type of immunity that results from immunizing an animal with a vaccine. The immunized animal produces its own antibodies and activated lymphocytes.

artificially acquired passive immunity The temporary immunity that results from introducing into an animal antibodies that have been produced either in another animal or by in vitro methods.

ascocarp A multicellular structure in ascomycete fungi lined with specialized cells called asci.

ascogenous hypha A specialized hypha that gives rise to one or more asci.

ascomycetes (as″ko-mi-se′tēz) A group of fungi that form ascospores.

ascospore (as′ko-spor) A spore contained or produced in an ascus.

ascus (pl., asci) A specialized cell, characteristic of the ascomycetes, in which two haploid nuclei fuse to produce a zygote, which often immediately divides by meiosis; at maturity, an ascus contains ascospores.

aseptate (coenocytic) hypha A multinucleate hypha (filament) that lacks cross walls.

assimilatory reduction (e.g., assimilatory nitrate reduction and assimilatory sulfate reduction) The reduction of an inorganic molecule to incorporate it into organic material. No energy is conserved during this process.

associative nitrogen fixation Nitrogen fixation by bacteria in the plant root zone (rhizosphere).

atomic force microscope *See* scanning probe microscope.

atopic reaction *See* localized anaphylaxis.

ATP *See* adenosine 5′-triphosphate.

ATP-binding cassette transporters (ABC transporters) Transport systems that use ATP hydrolysis to drive translocation across the plasma membrane; can be used for nutrient uptake (ABC importer) or export of substances (ABC exporter), including protein secretion (ABC protein secretion pathway).

ATP synthase An enzyme that catalyzes synthesis of ATP from ADP and P_i, using energy derived from the proton motive force.

attack rate The proportional number of cases that develop in a population exposed to an infectious agent.

attenuated vaccine Live, nonpathogenic organisms used to activate adaptive immunity.

attenuation 1. A mechanism for the regulation of transcription termination of some bacterial operons by aminoacyl-tRNAs. 2. A procedure that reduces or abolishes the virulence of a pathogen without altering its immunogenicity.

attenuator A factor-independent transcription termination site in the leader sequence that is involved in attenuation.

autochthonous (ô-tŏk-thə-nəs) Substances (nutrients) that originate in a given environment.

autoclave An apparatus for sterilizing objects by the use of steam under pressure.

autoimmune disease A disease produced by the immune system attacking self antigens.

autoimmunity A condition characterized by the presence of serum autoantibodies and self-reactive lymphocytes that may be benign or pathogenic.

autoinducer With respect to quorum sensing, a small molecule that induces synthesis of the enzyme responsible for the autoinducer's synthesis. *See also* quorum sensing.

autoinduction In general terms, any molecule that increases its own level of production.

autolysins (aw-tol′ĭ-sins or aw″to-lye′sins) Enzymes that partially digest peptidoglycan in growing bacteria so that the cell wall can be enlarged.

autophagocytosis Ancient means of homeostasis whereby intracellular components are recycled.

autophagosome *See* macroautophagy.

autophagy *See* autophagocytosis and macroautophagy.

autoradiography A procedure that detects radioactively labeled materials using a photographic process.

autotroph (aw′to-trōf) An organism that uses CO_2 as its sole or principal source of carbon.

auxotroph (awk′so-trōf) An organism with a mutation that causes it to lose the ability to synthesize an essential nutrient; because of the mutation, the organism must obtain the nutrient or a precursor from its surroundings.

average nucleotide identity (ANI) A pairwise comparison between the whole or partial genome sequences of two microorganisms; expressed as percent identity.

avidity The combined strength of binding between an antigen and all the antibody-binding sites.

axenic (a-zen′ik) Not contaminated by any foreign organisms; the term is used in reference to pure microbial cultures. *See also* pure culture.

axial fibrils *See* periplasmic flagella.

axial filament *See* periplasmic flagella.

axopodium A thin, needlelike type of pseudopodium with a central core of microtubules.

B

B7 (CD80, CD86) proteins Glycoproteins on the surface of antigen-presenting cells (B cells, macrophages, dendritic cells, as well as T cells); it binds CD28 on T cells, resulting in second signal activation.

bacillus (bah-sil′lus) A rod-shaped bacterium or archaeon.

bacteremia The presence of viable bacteria in the blood.

bacteria Members of the domain *Bacteria*.

bacterial artificial chromosome (BAC) A cloning vector constructed from the *Escherichia coli* F-factor plasmid.

bactericide An agent that kills bacteria.

bacteriochlorophyll (bak-te″re-o-klo′ro-fil) A modified chlorophyll that serves as the primary light-trapping pigment in purple and green photosynthetic bacteria and heliobacteria.

bacteriocin (bak-te′re-o-sin) A secreted bacterial protein that kills other closely related bacteria.

bacteriophage (bak-te′re-o-fāj″) A virus that uses bacteria as its host; often called a phage.

bacteriostatic Inhibiting the growth and reproduction of bacteria.

bacteroid A modified, often pleomorphic, bacterial cell within the root nodule cells of legumes; it carries out nitrogen fixation.

baeocytes Small, spherical, reproductive cells produced by some cyanobacteria through multiple fission.

barophilic (bar″o-fil′ik) or **barophile** *See* piezophilic.

barotolerant Organisms that can grow and reproduce at high pressures but do not require them.

basal body *See* flagellum.

base analogues Molecules that resemble normal DNA nucleotides and can substitute for them during DNA replication, leading to mutations. Also used as antiviral agents.

base excision repair *See* excision repair.

basic dyes Dyes that are cationic, or have positively charged groups, and bind to negatively charged cell structures.

basidiocarp (bah-sid′e-o-karp″) The fruiting body of a basidiomycete that contains the basidia.

basidiomycetes (bah-sid″e-o-mi-se′tēz) A group of fungi in which the spores are borne on club-shaped organs called basidia.

basidiospore (bah-sid′e-ō-spōr) A spore borne on the outside of a basidium.

basidium (bah-sid′e-um; pl., **basidia)** A structure formed by basidiomycetes; it bears on its surface basidiospores (typically four) that are formed following karyogamy and meiosis.

basophil A weakly phagocytic white blood cell in the granulocyte lineage. It synthesizes and stores vasoactive molecules (e.g., histamine) that are released in response to external triggers.

batch culture Growth of microorganisms in a closed culture vessel without adding fresh or removing old (spent) medium.

B cell (B lymphocyte) A type of lymphocyte that, following interaction with antigen, becomes a plasma cell, which synthesizes and secretes antibody molecules involved in humoral immunity.

B-cell receptor (BCR) A transmembrane immunoglobulin complex on the surface of a B cell that binds an antigen and stimulates the B cell. It is composed of a membrane-bound immunoglobulin, usually IgD or a modified IgM, complexed with the Ig-α/Ig-β heterodimer.

benthic Pertaining to the bottom of the sea or other body of water.

β-hemolysis *See* hemolysis.

β-lactam Referring to antibiotics containing a β-lactam ring (e.g., penicillins and cephalosporins).

β-lactam ring The cyclic chemical structure composed of one nitrogen and three carbon atoms. It has antibacterial activity, interfering with bacterial cell wall synthesis.

β-lactamase An enzyme that hydrolyzes the β-lactam ring, rendering the antibiotic inactive. Sometimes called penicillinase.

β-oxidation pathway The major pathway of fatty acid oxidation to produce NADH, $FADH_2$, and acetyl coenzyme A.

betaproteobacteria Members of the bacterial class *Betaproteobacteria.*

binal symmetry The symmetry of some virus capsids (e.g., those of complex phages) that is a combination of icosahedral and helical symmetry.

binary fission Asexual reproduction in which a cell separates into two identical daughter cells.

binomial system The nomenclature system in which an organism is given two names; the first is the capitalized generic name, and the second is the uncapitalized specific epithet.

bioaugmentation Addition of pregrown microbial cultures to an environment to perform a specific task.

biochemical oxygen demand (BOD) The amount of oxygen used by organisms in water under standard conditions; it provides an index of the amount of microbially oxidizable organic matter present.

biochemical pathways Sets of chemical reactions performed by organisms that convert a starting substrate into one or more products.

biocide Chemical or physical agent, usually with a broad spectrum of biological activity, that inactivates microorganisms.

biodegradation The breakdown of a complex chemical through biological processes that results in minor loss of functional groups, fragmentation into smaller constituents, or complete breakdown to CO_2 and minerals.

biofilms Organized microbial communities encased in extracellular polymeric substances and associated with surfaces, often with complex structural and functional characteristics.

biofuels Energy-dense compounds (i.e., fuels) produced by microbes, usually by the degradation of plant substrates.

biogeochemical cycling The oxidation and reduction of substances carried out by living organisms and abiotic processes that results in the cycling of elements within and between different parts of the ecosystem and the atmosphere.

bioinformatics The interdisciplinary field that manages and analyzes large biological data sets, including genome and protein sequences.

bioinsecticide A microbe or microbial product used to kill or disable unwanted insect pests.

biological safety cabinets Cabinets that use HEPA filters to project a curtain of sterile air across its opening, preventing microbes from entering or exiting.

biomagnification The increase in concentration of a substance in higher-level consumer organisms.

bioprospecting The collection, cataloging, and analysis of organisms, including microorganisms and plants, with the intent of finding a useful application and/or to document biodiversity.

bioremediation The use of biologically mediated processes to remove or degrade pollutants from specific environments.

biosensor A device for the detection of a particular substance (an analyte) that combines a biological receptor with a physicochemical detector.

biotechnology The process in which living organisms are manipulated, particularly at the molecular genetic level, to form useful products.

bioterrorism The intentional or threatened use of microorganisms or organic toxins to produce death or disease in humans, animals, and plants.

biotransformation (microbial transformation) The use of living organisms to modify substances that are not normally used for growth.

biovar Variant strains of microbes characterized by biological or physiological differences.

BLAST (basic local alignment search tool) A publicly available computer program that identifies regions of similarity between nucleotide or amino acid sequences. It compares input or query sequences with sequence databases and determines the statistical significance of matches. Homologies can be used to infer gene or protein function and evolutionary relationships.

blastospores Fungal spores produced from a vegetative mother cell by budding.

bloom The growth of a single microbial species or a limited number of species in an aquatic environment, usually in response to a sudden pulse of nutrients. *See also* harmful algal bloom.

B lymphocyte *See* B cell.

bright-field microscope A microscope that illuminates the specimen directly with bright light and forms a dark image on a brighter background.

broad-spectrum drugs Chemotherapeutic agents that are effective against many different kinds of pathogens.

bronchial-associated lymphoid tissue (BALT) *See* mucosal-associated lymphoid tissue.

Bt An insecticide that consists of a toxin produced by *Bacillus thuringiensis.*

bubo (bu′bo) A tender, inflamed, enlarged lymph node that results from a variety of infections.

budding A vegetative outgrowth of yeast and some bacteria as a means of asexual reproduction; the daughter cell is smaller than the parent.

bulking sludge Sludge produced in sewage treatment that does not settle properly, usually due to the development of filamentous microorganisms.

butanediol fermentation A type of fermentation most often found in members of the family *Enterobacteriaceae* in which 2,3-butanediol is a major product; acetoin is an intermediate in the pathway and may be detected by the Voges-Proskauer test.

C

calorie The amount of heat needed to raise one gram of water from 14.5 to 15.5°C.

Calvin-Benson cycle The main pathway for the fixation (reduction and incorporation) of CO_2 into organic material by photoautotrophs and chemolithoautotrophs.

cancer A malignant tumor that expands locally by invasion of surrounding tissues and systemically by metastasis.

cannulae Tubelike structures extending from the surface of some archaeal cells. They are thought to function in attachment to surfaces.

5′ cap *See* pre-mRNA.

capsid The protein coat or shell that surrounds a virion's nucleic acid.

capsomer The ring-shaped morphological unit of icosahedral capsids.

capsule A layer of well-organized material, not easily washed off, lying outside the cell wall.

carbonate equilibrium system The interchange among CO_2, HCO_3^-, and CO_3^{2-} that keeps oceans buffered between pH 7.6 to 8.2.

carbon to nitrogen ratio The ratio of carbon to nitrogen in a soil; it can be used to predict rates of organic decomposition and thus the cycling of nutrients in the system.

carboxysomes Polyhedral inclusions where CO_2 fixation occurs; contain the CO_2-fixation enzyme

ribulose 1,5-bisphosphate carboxylase/oxygenase. They are a type of microcompartment.

cardinal temperatures The minimal, maximal, and optimum temperatures for growth.

caseous lesion (ka′se-us) A lesion containing necrotic cells with cheesy appearance and texture; often caused by *Mycobacterium tuberculosis.*

catabolism That part of metabolism in which larger, more complex molecules are broken down into smaller, simpler molecules with the release of energy.

catabolite activator protein (CAP) A protein that regulates the expression of genes encoding catabolite repressible enzymes; also called cyclic AMP receptor protein (CRP).

catabolite repression Inhibition of the synthesis of several catabolic enzymes by a preferred carbon and energy source (e.g., glucose).

catalase An enzyme that catalyzes the destruction of hydrogen peroxide.

catalyst A substance that accelerates a reaction without being permanently changed itself.

catalytic site *See* active site.

catalyzed reporter deposition-fluorescent in situ hybridization (CARD-FISH) A FISH technique in which the signal is amplified so that low levels of fluorescence can be detected. *See also* fluorescent in situ hybridization (FISH).

catenanes (kăt′ə-nānz′) Circular, covalently closed nucleic acid molecules that are locked together like the links of a chain.

cathelicidins Antimicrobial cationic peptides that are produced by a variety of cells (e.g., neutrophils, respiratory epithelial cells, and alveolar macrophages).

caveolin-dependent endocytosis *See* endocytosis.

$CD4^+$ cell *See* T-helper cell.

$CD8^+$ cell *See* cytotoxic T lymphyocyte.

CD95 pathway *See* Fas-FasL pathway.

cell cycle The sequence of events in a cell's growth-division cycle between the end of one division and the end of the next.

cell envelope The plasma membrane plus all other external layers.

cellular (cell-mediated) immunity The type of immunity mediated by T cells.

cellular slime molds Protists with a vegetative phase consisting of amoeboid cells that aggregate to form a multicellular pseudoplasmodium. They belong to the taxon *Dictyostelia;* formerly considered fungi.

cell wall The strong structure that lies outside the plasma membrane; it supports and protects the membrane and helps maintain cell shape.

Centers for Disease Control and Prevention (CDC) Public health agency of the United States, headquartered in Atlanta, GA; serves as the national agency for developing and carrying out disease prevention and control, environmental health, and health promotion and education.

central metabolic pathways Those pathways central to the metabolism of an organism because they function catabolically and anabolically (e.g., glycolytic pathways and tricarboxylic acid cycle).

central tolerance The process by which self-reactive B cells are eliminated in the bone marrow and self-reactive T cells are eliminated in the thymus.

chain of infection *See* infectious disease cycle.

chain termination DNA sequencing method A DNA-sequencing method that uses dideoxynucleotides to cause termination of DNA replication at random sites.

chancre (shang′ker) The primary lesion of syphilis occurring at the site of entry of the pathogen.

chaperone proteins Proteins that assist in the folding and stabilization of other proteins. Some are also involved in directing newly synthesized proteins to protein secretion systems or to other locations in the cell.

chemical fixation *See* fixation.

chemical oxygen demand (COD) The amount of chemical oxidation required to convert organic matter in water and wastewater to CO_2.

chemiosmotic hypothesis (kem″e-o-os-mot′ik) The hypothesis that proton and electrochemical gradients are generated by electron transport and then used to drive ATP synthesis by oxidative phosphorylation or photophosphorylation.

chemoheterotroph (ke″mo-het′er-o-trōf″) *See* chemoorganoheterotroph.

chemokine A type of cytokine that stimulates chemotaxis and chemokinesis of immune cells.

chemolithoautotroph A microorganism that oxidizes reduced inorganic compounds to derive both energy and electrons; CO_2 is the carbon source.

chemolithoheterotroph A microorganism that uses reduced inorganic compounds to derive both energy and electrons; organic molecules are used as the carbon source.

chemolithotroph A microorganism that uses reduced inorganic compounds as a source of energy and electrons.

chemoorganoheterotroph An organism that uses organic compounds as sources of energy, electrons, and carbon for biosynthesis. Also called chemoheterotroph and chemoorganotrophic heterotroph.

chemoreceptors Proteins in the plasma membrane or periplasmic space that bind chemicals and trigger the appropriate chemotactic response.

chemostat A continuous culture apparatus that feeds medium into the culture vessel at the same rate as medium containing microorganisms is removed; the medium in a chemostat contains one essential nutrient in a limiting quantity.

chemotaxins Agents that cause white blood cells to migrate up its concentration gradient.

chemotaxis The pattern of cellular behavior in which the cell moves toward chemical attractants and away from repellents.

chemotherapy The use of chemical agents to treat disease.

chemotrophs Organisms that obtain energy from the oxidation of chemical compounds.

chlamydiae (klə-mid′e-e) Members of the genera *Chlamydia* and *Chlamydiophila:* Gram-negative, obligate intracellular pathogens.

chlorophyll The green photosynthetic pigment that consists of a large tetrapyrrole ring with a magnesium atom in the center.

chloroplast A eukaryotic plastid that contains chlorophyll and is the site of photosynthesis.

chlorosomes Elongated, intramembranous vesicles found in the green sulfur and nonsulfur bacteria; they contain light-harvesting pigments. Sometimes called chlorobium vesicles.

choleragen (kol′er-ah-gen) The cholera toxin.

chromatic adaptation The ability of cyanobacteria to change the relative concentrations of light-harvesting pigments in response to changes in wavelengths of incident light.

chromatin The complex of DNA and proteins, including histones, from which eukaryotic chromosomes are made.

chromatin immunoprecipitation (ChIP) A technique that enables the identification of protein-DNA interactions.

chromatin modification The addition of acetyl, methyl, phosphoryl, and other groups to a histone protein. These modifications change the level of transcription of nearby genes.

chromatin remodeling The alteration of chromatin structure by inserting or removing variant histone proteins from a nucleosome.

chromogen (kro′me-jen) A colorless substrate that is acted on by an enzyme to produce a colored end product.

chromophore group A chemical group with double bonds that absorbs visible light and gives a dye its color.

chromosomes The bodies that have most or all of the cell's DNA and contain most of its genetic information (mitochondria and chloroplasts also contain DNA).

chronic inflammation Inflammation that is characterized by a dense tissue infiltration of lymphocytes and macrophages into the affected site and the formation of new connective tissue, which usually causes permanent tissue damage.

chytrids A term used to describe members of *Chytridiomycota,* fungi that produce motile zoospores with single, posterior, whiplash flagella.

cidal Causing death.

cilia Threadlike appendages extending from the surface of some protists that beat rhythmically to propel them; cilia are membrane-bound cylinders with a complex internal array of microtubules, usually in a 9 + 2 pattern.

ciliates (*Ciliophora*) Protists that move by rapidly beating cilia and belong to *Alveolata*.

citric acid cycle *See* tricarboxylic acid cycle.

class I MHC molecule *See* major histocompatibility complex.

class II MHC molecule *See* major histocompatibility complex.

class switching *See* antibody class switching.

classical complement pathway The antibody-dependent pathway of complement activation; it stimulates lysis of pathogens, phagocytosis, and other host defenses.

clathrin-dependent endocytosis *See* endocytosis.

clonal selection The process by which an antigen binds to the best-fitting B-cell receptor, activating that B cell, resulting in the synthesis of that specific antibody and clonal expansion.

clone (1) A group of genetically identical cells or organisms derived by asexual reproduction from a single parent. (2) A DNA sequence that has been isolated and replicated using a cloning vector.

cloning vector A DNA molecule that can replicate independently of the host chromosome and maintain a piece of inserted foreign DNA, such as a gene, into a recipient cell. It may be a plasmid, phage, cosmid, or artificial chromosome.

club fungi Common name for members of *Basidiomycota*.

cluster of differentiation molecules (CDs) Functional cell surface proteins that can be used to identify leukocyte subpopulations (e.g., interleukin-2 receptor, CD4, and CD8).

coagulase (ko-ag′u-las) An enzyme that induces blood clotting; it is characteristically produced by pathogenic staphylococci.

coagulation The process of adding chemicals to precipitate impurities from water during purification; also called flocculation.

coccolithophores Photosynthetic protists belonging to the group *Stramenopila;* characterized by coccoliths—intricate cell walls made of calcite.

coccus (kok′us, pl., **cocci**, kok′si) A roughly spherical bacterial or archaeal cell.

code degeneracy The presence of more than one codon for each amino acid.

coding sequences (CDS) In genomic analysis, open reading frames presumed to encode proteins but not tRNA or rRNA.

codon (ko′don) A sequence of three nucleotides in mRNA that directs the incorporation of an amino acid during protein synthesis or signals the stop of translation.

coenocytic (se″no-sit′ik) *See* aseptate hypha.

coenzyme A loosely bound cofactor that often dissociates from the enzyme active site after product has been formed.

coenzyme Q (CoQ, ubiquinone) *See* electron transport chain.

coevolution The evolution of two interacting organisms such that they optimize their survival with one another; that is, they develop reciprocal adaptations.

cofactor The nonprotein component of an enzyme required for catalytic activity.

colicin (kol′ĭ-sin) A plasmid-encoded protein produced by enteric bacteria; binds to receptors on the cell envelope of sensitive target bacteria, where it may cause lysis or attack specific intracellular sites such as ribosomes.

coliform A Gram-negative, nonsporing, facultative rod that ferments lactose with gas formation within 48 hours at 35°C.

Colilert defined substrate test An assay designed to detect the presence of coliforms in water.

colonization The establishment of a site of microbial reproduction on an inanimate surface or organism without necessarily resulting in tissue invasion or damage.

colony An assemblage of microorganisms growing on a solid surface; the assemblage often is directly visible.

colony forming units (CFU) The number of microorganisms that form colonies when cultured using spread plates or pour plates, an indication of the number of viable microorganisms in a sample.

colony stimulating factor (CSF) A protein that stimulates the growth and development of specific cell populations (e.g., granulocyte-CSF stimulates granulocytes to be made from precursor stem cells).

colorless sulfur bacteria A diverse group of nonphotosynthetic proteobacteria that can oxidize reduced sulfur compounds such as hydrogen sulfide. Many are chemolithotrophs and derive energy from sulfur oxidation.

cometabolism The modification of a compound not used for growth by a microorganism, which occurs in the presence of another organic material that serves as a carbon and energy source.

commensal Living on or within another organism without injuring or benefiting the other organism.

commensalism A type of symbiosis in which one individual gains from the association (the commensal) and the other is neither harmed nor benefited.

common-source epidemic An epidemic characterized by a sharp rise to a peak and then a rapid but not as pronounced decline in the number of individuals infected; it usually involves a single contaminated source that infects individuals.

communicable disease A disease associated with a pathogen that can be transmitted from one host to another.

comparative genomics Comparison of genomes from different organisms to discern differences and similarities.

compartmentation The differential distribution of enzymes and metabolites to separate cell structures or organelles.

compatible solute A low molecular weight molecule used to protect cells against changes in solute concentrations (osmolarity) in their habitat; it can exist at high concentrations within the cell without hindering metabolism or growth.

competent cell A cell that can take up free DNA fragments and incorporate them into its genome during transformation.

competition An interaction between two organisms attempting to use the same resource (nutrients, space, etc.).

competitive exclusion principle Two competing organisms overlap in resource use, which leads to the exclusion of one of the organisms.

competitive inhibitor A molecule that inhibits enzyme activity by binding the enzyme's active site.

complementary Refers to the matching of two strands of DNA or RNA based on the base-pairing rules.

complementary DNA (cDNA) A DNA copy of an RNA molecule (e.g., a DNA copy of an mRNA).

complement system A group of plasma proteins that plays a major role in innate immunity.

complex medium Culture medium that contains some ingredients of unknown chemical composition.

compromised host A host with lowered resistance to infection and disease.

concatemer A long DNA molecule consisting of several genomes linked together in a row.

conditional mutations Mutations with phenotypes that are expressed only under certain environmental parameters (e.g., temperature).

confocal microscope A light microscope in which monochromatic laser derived light scans across the specimen at a specific level. Stray light from above and below the plane of focus is blocked out to give an image with excellent contrast and resolution.

conidiospore (ko-nid′e-o-spōr) An asexual, thin-walled spore borne on hyphae and not contained within a sporangium; it may be produced singly or in chains.

conidium (ko-nid′e-um; pl., **conidia**) *See* conidiospore.

conjugate redox pair The electron acceptor and electron donor of a redox half reaction.

conjugation (1) The form of gene transfer and recombination in bacteria and archaea that requires direct cell-to-cell contact. (2) A complex form of sexual reproduction commonly employed by protists.

conjugative plasmid A plasmid that carries the genes that enable its transfer to other bacteria during conjugation (e.g., F plasmid).

conjugative transposon A mobile genetic element that is able to transfer itself from one bacterium to another by conjugation.

consensus sequence A commonly occurring sequence of nucleotides within a genetic element.

conserved hypothetical proteins In genomic analysis, proteins of unknown function for which at least one match exists in a database.

consortium A physical association of two or more different organisms, usually beneficial to all of the organisms.

constant region (C_L and C_H) The part of an antibody molecule that does not vary greatly in amino acid sequence among molecules of the same class, subclass, or type.

constitutive gene A gene that is expressed at nearly the same level at all times.

contact transmission Spread of a pathogen by contact of the source or reservoir of the pathogen.

contigs In genomic sequencing, fragments of DNA with identical sequences at the ends; that is, the ends of the fragments overlap in sequence.

continuous culture system A culture system with constant environmental conditions maintained through continual provision of nutrients and removal of wastes. *See also* chemostat and turbidostat.

continuous feed The constant addition of a carbon source during industrial fermentation.

contractile vacuole (vak′u-ōl) In protists and some animals, a clear fluid-filled vacuole that takes up water from within the cell and then contracts, releasing it to the outside through a pore in a cyclical manner. It functions primarily in osmoregulation and excretion.

cooperation A positive but not obligatory interaction between two different organisms.

coral bleaching The loss of photosynthetic pigments by either physiological inhibition

or expulsion of the coral photosynthetic endosymbiont, zooxanthellae, a dinoflagellate.

core genome The common set of genes found in all genomes in a species or other taxon.

core polysaccharide *See* lipopolysaccharide.

corepressor A small molecule that binds a transcription repressor protein, thereby activating the repressor and inhibiting the synthesis of a repressible enzyme.

cosmid A plasmid vector with lambda phage *cos* sites that can be packaged in a phage capsid; it is useful for cloning large DNA fragments.

coverage The number of times a nucleotide is sequenced in any given sequencing project. Synonymous with depth of coverage, so "depth" and "coverage" are used interchangeably. Breadth of coverage refers to the percentage of genome sequenced.

cristae (kris′te) Infoldings of the inner mitochondrial membrane.

cryophile *See* psychrophile.

cryptidins Antimicrobial peptides produced by Paneth cells in the intestines.

crystallizable fragment (Fc) The stem of the Y portion of an antibody molecule. Cells such as macrophages bind to the Fc region; it also is involved in complement activation.

culturomics An approach to isolating and identifying microbes that involves cultivation under many different conditions followed by identification by mass spectrometry and SSU rRNA gene sequencing.

curing The loss of a plasmid from a cell.

cut-and-paste transposition *See* simple transposition.

cyanobacteria A large group of Gram-negative, morphologically diverse bacteria that carry out oxygenic photosynthesis.

cyanophycin Inclusions that store nitrogen found in cyanobacteria.

3′, 5′-cyclic adenosine monophosphate (cAMP) A small nucleotide that is involved in regulating a number of cellular processes in bacteria and other organisms. In some bacteria, it functions in catabolite repression.

cyclic dimeric GMP (c-di-GMP) A small nucleotide consisting of two GMP molecules linked together by their phosphates. It functions as a second messenger in many bacteria and some eukaryotes.

cyclic photophosphorylation (fo″to-fos″for-ĭ-la′shun) The formation of ATP when light energy is used to move electrons cyclically through an electron transport chain during photosynthesis.

cyst A general term used for a specialized microbial cell enclosed in a wall. Cysts are formed by protists and a few bacteria. They may be dormant, resistant structures formed in response to adverse conditions or reproductive cysts that are a normal stage in the life cycle.

cytochromes (si′to-krōms) *See* electron transport chain.

cytokine (si′to-kīn) A general term for proteins released by immune cells in response to inducing stimuli; they mediate the activity of other cells.

cytokinesis Processes that apportion the cytoplasm and organelles, synthesize a septum, and divide a cell into two daughter cells during cell division.

cytopathic effect The observable change that occurs in cells as a result of viral replication.

cytoplasm All material in the cell enclosed by the plasma membrane, with the exception of the nucleus in eukaryotic cells.

cytoproct A specific site in certain protists (e.g., ciliates) where digested material is expelled.

cytosine (si′to-sēn) A pyrimidine 2-oxy-4-aminopyrimidine found in nucleosides, nucleotides, and nucleic acids.

cytoskeleton A network of structures made from filamentous proteins (e.g., actin and tubulin) and other components in the cytoplasm of cells.

cytosol Liquid component of the cytoplasm.

cytostome A permanent site in a ciliate protist in which food is ingested.

cytotoxic T lymphocyte (CTL) Effector T cell that can lyse target cells bearing class I MHC molecules complexed with antigenic peptides. CTLs arise from antigen-activated Tc cells.

D

Dane particle A 42-nm spherical particle that is one of three seen in Hepatitis B virus infections. The Dane particle is the complete virion.

dark-field microscopy Microscopy in which the specimen is brightly illuminated while the background is dark.

dark reaction *See* photosynthesis.

deamination The removal of amino groups from amino acids.

decimal reduction time (*D* or *D* value) The time required to kill 90% of the microorganisms or spores in a sample at a specified temperature.

defensins A large family of antimicrobial peptides produced by neutrophils, macrophages, lymphocytes, and a variety of other host cells.

defined (synthetic) medium Culture medium made with components of known composition.

deltaproteobacteria Members of the bacterial class *Deltaproteobacteria*.

denaturation A change in either protein shape or nucleic-acid structure.

denaturing gradient gel electrophoresis (DGGE) A technique by which DNA is rendered single stranded (denatured) while undergoing electrophoresis so that DNA fragments of the same size can be separated according to nucleotide sequence.

dendritic cell An antigen-presenting cell that has long membrane extensions resembling the dendrites of neurons.

denitrification The reduction of nitrate to gaseous products, primarily nitrogen gas, during anaerobic respiration.

deoxyribonucleic acid (DNA) (de-ok″se-ri″bo-nu-kle′ik) A polynucleotide that constitutes the genetic material of all cellular organisms. It is composed of deoxyribonucleotides connected by phosphodiester bonds.

depth filters Filters composed of fibrous or granular materials that are used to decrease microbial load and sometimes to sterilize solutions.

desensitization The process by which a sensitized or hypersensitive individual is made insensitive or nonreactive to a sensitizing agent (e.g., an allergen).

detergent An organic molecule, other than a soap, that serves as a wetting agent and emulsifier; it is normally used as cleanser, but some may be used as antimicrobial agents.

diatoms (*Bacillariophyta*) Photosynthetic protists with siliceous cell walls called frustules belonging to the group *Stramenopila*.

diauxic growth (di-awk′sik) Biphasic growth response in which a microorganism, when exposed to two nutrients, initially uses one of them for growth and then alters its metabolism to make use of the second.

differential interference contrast (DIC) microscope A light microscope that employs two beams of plane polarized light. The beams are combined after passing through the specimen and their interference is used to create the image.

differential media Culture media that distinguish between groups of microorganisms based on differences in their growth and metabolic products.

differential staining Staining procedures that divide bacteria into separate groups based on staining properties.

diglycerol tetraether lipids Archaeal lipids formed when isoprenoid hydrocarbons are linked to two glycerols by ether bonds.

dikaryotic stage (di-kar-e-ot′ik) In fungi, having two separate haploid nuclei, one from each parent.

dilution susceptibility tests A method by which antibiotics are evaluated for their ability to inhibit bacterial growth in vitro. A standardized concentration of bacteria is added to serially diluted antibiotics and incubated. Tubes lacking additional bacterial growth suggest antibiotic concentrations that are bacteriocidal or bacteriostatic.

dinoflagellate (di″no-flaj′e-lāt) A photosynthetic protist characterized by two flagella used in swimming in a spinning pattern; belong to the group *Alveolata*.

diplococcus (dip″lo-kok′us) A pair of cocci.

direct counts Methods for determining population size by examining a sample of the population and counting the cells within the sample.

direct immunofluorescence Technique for imaging of microscopic agents using fluorescently labeled antibodies to bind to the agent.

direct repair A type of DNA repair mechanism in which a damaged nitrogenous base is returned to its normal form (e.g., conversion of a thymine dimer back to two normal thymine bases).

directed evolution A variety of approaches used to mutate a specific gene or genes with the aim of increasing product yield or generating new molecules.

disease syndrome A set of signs and symptoms that are characteristic of a disease.

disinfectant An agent, usually chemical, that disinfects; normally, it is employed only with inanimate objects.

disinfection The killing, inhibition, or removal of microorganisms that may cause disease. It usually refers to the treatment of inanimate objects with chemicals.

disinfection by-products (DBPs) Chlorinated organic compounds such as trihalomethanes formed during chlorine use for water disinfection. Many are carcinogens.

dissimilatory reduction (e.g., dissimilatory nitrate reduction and dissimilatory sulfate reduction) The use of a substance as an electron acceptor for an electron transport chain. The acceptor (e.g., sulfate or nitrate) is reduced but not incorporated into organic matter.

dissolved organic matter (DOM) Nutrients that are available in the soluble, or dissolved, state.

divisome A collection of proteins that aggregate at the region in a dividing microbial cell where a septum will form.

DNA amplification The process of increasing the number of DNA molecules, usually by using the polymerase chain reaction.

DNA-dependent DNA polymerase An enzyme that catalyzes the synthesis of DNA using a DNA molecule as a template.

DNA-dependent RNA polymerase An enzyme that catalyzes the synthesis of RNA using a DNA molecule as a template.

DNA-DNA hybridization (DDH) An assay in which the single-stranded DNA of one organism is hybridized to that of another, and the percent that hybridizes is calculated. There must be at least 70% similarity between two genomes as determined by DDH for microbes to be considered the same species; however, this is only one criterion upon which species assignments are made.

DNA gyrase A topoisomerase enzyme that relieves tension generated by the rapid unwinding of DNA during DNA replication.

DNA ligase An enzyme that joins two DNA fragments together through the formation of a new phosphodiester bond.

DNA microarrays Solid supports that have DNA attached in organized arrays and are used to evaluate gene expression.

DNA polymerase (pol-im′er-ās) An enzyme that synthesizes new DNA using a parental nucleic acid strand (usually DNA) as a template.

double diffusion agar assay (Öuchterlony technique) An immunodiffusion reaction in which both antibody and antigen diffuse through agar to form stable immune complexes, which can be observed visually.

doubling time *See* generation time.

droplet nuclei Small particles (0 to 4 μm in diameter) that represent what is left from the evaporation of larger particles (10 μm or more in diameter) called droplets.

drug inactivation Physical or chemical alteration of chemotherapeutic agent resulting in its loss of biological activity.

D value *See* decimal reduction time.

E

ecotype A population of an organism that is genetically very similar but ecologically distinct from others of the same species.

ectomycorrhizae A mutualistic association between fungi and plant roots in which the fungus surrounds the root with a sheath.

ectoplasm In some protists, the cytoplasm directly under the cell membrane (plasmalemma) is divided into an outer gelatinous region, the ectoplasm, and an inner fluid region, the endoplasm.

efflux pumps Membrane-associated protein assemblies that transport amphiphilic molecules from cytoplasm to the extracellular environment.

electron acceptor A compound that accepts electrons in an oxidation-reduction reaction. Often called an oxidizing agent or oxidant.

electron cryotomography A specialized electron microscopy procedure that involves rapid freezing of intact specimens, maintenance of the specimen in a frozen state while being examined, and imaging from different angles. The information from each angle is used to create a three-dimensional reconstruction.

electron donor An electron donor in an oxidation-reduction reaction. Often called a reducing agent or reductant.

electron shuttle A substance or structure along which electrons are passed from the electron transport chain to an external terminal electron acceptor.

electron transport chain (ETC) A series of electron carriers that operate together to transfer electrons from donors to acceptors such as oxygen. Molecules involved in electron transport include nicotinamide adenine dinucleotide (NAD^+), NAD phosphate ($NADP^+$), cytochromes, heme proteins, nonheme proteins (e.g., iron-sulfur proteins and ferredoxin), coenzyme Q, flavin adenine dinucleotide (FAD), and flavin mononucleotide (FMN). Also called an electron transport system.

electroporation The application of an electric field to create temporary pores in the plasma membrane in order to render a cell temporarily transformation competent.

elementary body (EB) A small, dormant body that serves as the agent of transmission between host cells in the chlamydial life cycle.

elongation factors Proteins that function in the elongation cycle of protein synthesis.

Embden-Meyerhof pathway A pathway that degrades glucose to pyruvate (i.e., a glycolytic pathway).

encystment The formation of a cyst.

endemic disease A disease that exists at a steady, low-level frequency at a moderate, regular interval.

endergonic reaction (end″er-gon′ik) A reaction that does not spontaneously go to completion as written; the standard free energy change is positive, and the equilibrium constant is less than one.

endocytic pathways *See* endocytosis.

endocytosis The process in which a cell takes up solutes or particles by enclosing them in vesicles pinched off from its plasma membrane. It often occurs at regions of the plasma membrane coated by proteins such as clathrin and caveolin. Endocytosis involving these proteins is called clathrin-dependent endocytosis and caveolin-dependent endocytosis, respectively. When the substance endocytosed first binds to a receptor, the process is called receptor-mediated endocytosis.

endogenous antigen processing Antigen degradation by cytoplasmic proteasomes and subsequent complexing with class I MHC molecules for presentation on the processing cell's surface.

endogenous pyrogen A host-derived chemical mediator (e.g., interleukin-1) that acts on the hypothalamus, stimulating a rise in core body temperature (i.e., it stimulates the fever response).

endomycorrhizae Referring to a mutualistic association of fungi and plant roots in which the fungus penetrates into the root cells.

endophyte A microorganism living within a plant but not necessarily parasitic on it.

endoplasm *See* ectoplasm.

endoplasmic reticulum (ER) A system of membranous tubules and flattened sacs (cisternae) in eukaryotic cells. Rough endoplasmic reticulum (RER) bears ribosomes on its surface; smooth endoplasmic reticulum (SER) lacks them.

endosome A membranous vesicle formed by endocytosis. It undergoes a maturational process that starts with early endosomes and proceeds to late endosomes and finally lysosomes.

endospore An extremely heat- and chemical-resistant, dormant, thick-walled spore that develops within some members of the bacterial phylum *Firmicutes*. It has a complex structure that includes (from outermost to innermost) exosporium, spore coat, cortex, spore cell wall, and spore core.

endosymbiosis A type of symbiosis in which one organism is found within another organism.

endosymbiotic hypothesis The hypothesis that mitochondria, and related organelles (e.g., hydrogenosomes), and chloroplasts arose from bacterial endosymbionts of ancestral eukaryotic cells.

endotoxin The lipid A component of lipopolysaccharide (LPS) from Gram-negative bacterial cell walls. Nanogram quantities can induce fever, activate complement and coagulation cascades, act as a mitogen to B cells, and stimulate cytokine release from a variety of cells. Systemic effects of endotoxin are referred to as septic shock.

end product inhibition *See* feedback inhibition.

energy The capacity to do work or cause particular changes.

enhancer A site in DNA to which a eukaryotic activator protein binds.

enology The science of wine making.

enriched media Media that contain nutrients to encourage growth of fastidious microbes.

enrichment culture The growth of specific microbes from natural samples by including media components or manipulating environmental conditions to promote growth of the desired microbes while suppressing the growth of other microbes.

enteric bacteria (enterobacteria) Members of the family *Enterobacteriaceae*; also can refer to bacteria that live in the intestinal tract.

enterotoxin A toxin specifically affecting the cells of the intestinal mucosa, causing vomiting and diarrhea.

enthalpy Heat content of a system.

Entner-Doudoroff pathway A pathway that converts glucose to pyruvate and glyceraldehyde 3-phosphate by producing 6-phosphogluconate and then dehydrating it (i.e., a glycolytic pathway).

entropy A measure of the randomness or disorder of a system; a measure of that part of the total energy in a system that is unavailable for useful work.

envelope In virology, an outer membranous layer that surrounds the nucleocapsid of some viruses.

enveloped virus A virus having virions with a nucleocapsid enclosed within a lipid bilayer.

environmental microbiology The study of microbial processes that occur in soil, water, and other natural habitats. Specific microorganisms are not necessarily investigated; rather, the cumulative impact of the microbial community on the specific biome, as well as global implications, are assessed.

enzyme A protein catalyst with specificity for the reaction catalyzed and its substrates.

enzyme-linked immunosorbent assay (ELISA) A serological assay in which bound antigen or antibody is detected by another antibody that is conjugated to an enzyme. The enzyme converts a colorless substrate to a colored product reporting the antibody capture of the antigen.

eosinophil (e″o-sin′o-fil) A leukocyte that has a two-lobed nucleus and cytoplasmic granules that release chemical mediators in response to parasite infections.

epidemic A disease that suddenly increases in occurrence above the normal level in a given population.

epidemiologist A person who specializes in epidemiology.

epidemiology The study of the factors determining and influencing the frequency and distribution of disease, injury, and other health-related events and their causes in defined human populations.

epifluorescence microscopy The illumination of a microscope sample with a high-intensity light from above. The light is passed through an exciter filter so that when light of a specific wavelength is focused on the specimen, it emits light, thereby making the sample visible as a specific color on a black background.

epilimnion The upper, warmer layer of water in a stratified lake.

epiphyte An organism that grows on the surface of plants.

episome A plasmid that can either exist independently of the host cell's chromosome or be integrated into it.

epitope (ep′i-tōp) An area of an antigen that stimulates the production of, and combines with, specific antibodies; also known as the antigenic determinant site.

epsilonproteobacteria Members of the bacterial class *Epsilonproteobacteria*.

equilibrium The state of a system in which no net change is occurring and free energy is at a minimum; in a chemical reaction at equilibrium, the rates in the forward and reverse directions exactly balance each other out.

equilibrium constant (K_{eq}) A value that relates the concentration of reactants and products to each other when a reaction is at equilibrium.

ergot The dried sclerotium of *Claviceps purpurea*. Also, an ascomycete that parasitizes rye and other plants; production of an alkaloid causes an animal disease called ergotism.

erythroblastosis fetalis Hemolytic disease of the newborn whereby red blood cells are destroyed by maternal antibody.

eukaryotic cells Cells that have a membrane-delimited nucleus; all plants, fungi, protists and animals are eukaryotic.

eutrophic Nutrient enriched.

eutrophication The enrichment of an aquatic environment with nutrients.

excision repair A type of DNA repair mechanism in which a section of a strand of damaged DNA is excised and replaced, using the complementary strand as a template. Two types are recognized: base excision repair and nucleotide excision repair.

excystment The escape of one or more cells or organisms from a cyst.

exergonic reaction (ek″ser-gon′ik) A reaction that spontaneously goes to completion as written; the standard free energy change is negative, and the equilibrium constant is greater than one.

exfoliative toxin (exfoliatin) An exotoxin produced by *Staphylococcus aureus* that causes the separation of epidermal layers and the loss of skin surface layers; produces scalded skin syndrome.

exit site (E site) The location on a ribosome to which an empty (uncharged) tRNA moves from the P site before it finally leaves during protein synthesis.

exoenzymes Enzymes that are secreted by cells.

exogenous antigen processing Antigen degradation by phagolysosome enzymes and subsequent complexing with class II MHC molecules for presentation on the processing cell's surface.

exon The region in a gene that is retained in mRNA after introns are removed by splicing.

exospore A spore formed outside the mother cell.

exotoxin A heat-labile, toxic protein produced by a bacterium and usually released into the bacterium's surroundings.

exponential (log) phase The phase of the growth curve during which the microbial population is growing at a constant and maximum rate, dividing and doubling at regular intervals.

expression vector A plasmid into which a recombinant gene is cloned; when in host cells, the gene is transcribed and its protein synthesized.

extant organism An organism that exists on Earth today.

exteins Polypeptide sequences of precursor self-splicing proteins that are joined together during formation of the final, functional protein. They are separated from one another by intein sequences.

extended aeration process An approach that can be used during secondary sewage treatment to reduce the amount of sludge produced.

extinction culture technique A method for obtaining an axenic (pure) culture in which natural samples are serial diluted so that the final dilution has between 1 and 10 cells (i.e., diluted to extinction).

extreme environment An environment in which physical factors such as temperature, pH, salinity, and pressure are outside of the normal range for growth of most microorganisms; these conditions allow unique organisms to survive and function.

extreme halophiles *See* haloarchaea.

extremophiles Microorganisms that grow in extreme environments.

F

facilitated diffusion Diffusion across the plasma membrane that is aided by a channel protein or a carrier protein.

facultative anaerobes Microorganisms that do not require oxygen for growth, but grow better in its presence.

Fas-FasL pathway One of two pathways used by cytotoxic T cells to kill target cells. Fas (CD95 receptor) is located on target cells. FasL is the ligand to the CD95 receptor and is found on cytotoxic T cells.

fatty acid synthase The multienzyme complex that makes fatty acids.

fecal coliform Gram-negative, lactose-fermenting bacteria whose normal habitat is the intestinal tract and that can grow at 44.5°C. They are used as indicators of fecal pollution of water.

fecal enterococci (en″ter-o-kok′si) Enterococci found in the intestine of humans and other warm-blooded animals.

feedback inhibition A negative feedback mechanism in which an end product inhibits the activity of an enzyme in the pathway leading to its formation.

fermentation (1) An energy-yielding process in which an organic molecule is oxidized without an exogenous electron acceptor. Usually pyruvate or a pyruvate derivative serves as the electron acceptor. (2) The growth of microbes in very large volumes for the production of industrially important products.

fermenter In industrial microbiology, the large vessel used to culture microorganisms.

ferredoxin *See* electron transport chain.

F factor The fertility factor, a plasmid that carries genes for bacterial conjugation and makes its *Escherichia coli* host the gene donor during conjugation.

filopodia Long, narrow pseudopodia found in certain amoeboid protists.

fimbria (fim′bre-ah; pl., **fimbriae**) A fine, hairlike protein appendage on many bacteria, some archaea, and some fungi. They attach cells to surfaces, and some are involved in twitching motility.

first law of thermodynamics Energy can be neither created nor destroyed (although it can be changed in form or redistributed).

fixation (1) The process in which the internal and external structures of cells and organisms are preserved and fixed in position. (2) The conversion

of inorganic, gaseous elements such as carbon (CO_2) and nitrogen (N_2) to organic forms.

flagellin (flaj′ĕ-lin) A family of related proteins in motile bacteria used to construct the filament of a flagellum. An unrelated group of proteins, also called flagellins, are used to construct archaeal flagellar filaments.

flagellum (flah-jel′um; pl., **flagella**) A threadlike appendage on many cells that is responsible for motility. Bacterial flagella are composed of a basal body at the base of the flagellum, which attaches it to the cell, and a hook, which connects the basal body to the filament. The filament is the part of the flagellum that rotates and moves the bacterium.

flavin adenine dinucleotide (FAD) (fla′vin ad′ĕ-nēn) *See* electron transport chain.

flavin mononucleotide *See* electron transport chain.

flow cytometry A method for defining and enumerating cells by sending them in single file past a laser to detect cell size and morphology.

fluid mosaic model The model of cell membranes in which the membrane is a lipid bilayer with integral proteins buried in the lipid and peripheral proteins more loosely attached to the membrane surface.

fluorescence activated cell sorting (FACS) A form of flow cytometry that results in separating cells according to size or other quantifiable trait (e.g., DNA content).

fluorescence microscope A microscope that exposes a specimen to light of a specific wavelength and then forms an image from the fluorescent light produced.

fluorescent in situ hybridization (FISH) A technique for identifying certain genes or organisms in which single-stranded DNA fragments are labeled with fluorescent dye and hybridized to genes of interest.

fluorescent light The light emitted by a substance when it is irradiated with light of a shorter wavelength.

fluorochrome A fluorescent dye.

fomite (pl., **fomites**) Common inanimate materials that transmit pathogens to humans.

food-borne infection Gastrointestinal illness caused by ingestion of microorganisms, followed by their growth within the host.

food intoxication Food poisoning caused by microbial toxins produced in a food prior to consumption. The presence of living bacteria is not required.

food poisoning A general term usually referring to a gastrointestinal disease caused by the ingestion of food contaminated by pathogens or their toxins.

formate dehydrogenase An enzyme system that cleaves formic acid into H_2 and CO_2. It is used by enteric bacteria that perform mixed acid fermentation.

forward mutation A mutation from the wild type to a mutant form.

F′ plasmid An F plasmid that carries some bacterial genes and transmits them to recipient cells when the F′ cell carries out conjugation.

frameshift mutations Mutations arising from the loss or gain of a base or DNA segment, leading to a change in the codon reading frame and thus a change in the amino acids incorporated into protein.

free energy change The total energy change in a system that is available to do useful work as the system goes from its initial state to its final state at constant temperature and pressure.

fruiting body A specialized structure that holds sexually or asexually produced spores; found in fungi, some protists, and some bacteria (e.g., the myxobacteria).

frustule (frus′tūl) The silicified cell wall in the diatoms.

fueling reactions Chemical reactions that supply the ATP, precursor metabolites, and reducing power needed for biosynthesis.

fumonisins A family of toxins produced by molds belonging to the genus *Fusarium*. It primarily affects corn and it is known to be hepato- and nephrotoxic in animals.

functional gene array Microarrays designed to determine potential microbial activities in natural environments. The probes on the array represent genes whose products are involved in specific processes, such as nitrogen fixation.

functional genomics Genomic analysis concerned with determining the way a genome functions.

fungicide An agent that kills fungi.

fungistatic Inhibiting the growth and reproduction of fungi.

fungus (pl., **fungi**) Achlorophyllous, hetero-trophic, spore-bearing eukaryotes with absorptive nutrition and a walled thallus; sometimes called "true fungi" or *Eumycota*.

G

G + C content The percent of guanines and cytosines present in a genome; this percent is used for taxonomic purposes.

gametangium (gam-ĕ-tan′je-um; pl., **gametangia**) A structure that contains gametes or in which gametes are formed.

γ/δ T cells CD4 or CD8 T cells that possess gamma/delta T-cell receptors.

gammaproteobacteria Members of the bacterial class *Gammaproteobacteria*.

gamonts Gametic cells formed by protists when they undergo sexual reproduction.

gas vacuole A gas-filled vacuole found in cyanobacteria and some other aquatic bacteria and archaea that provides flotation. It is composed of gas vesicles, which are made of protein.

gas vesicle *See* gas vacuole.

gel electrophoresis The separation of molecules according to charge and size through a gel matrix.

Gell-Coombs classification System used to codify hypersensitivity reactions.

gene A DNA segment or sequence that codes for a polypeptide, rRNA, or tRNA.

gene ontology A structured vocabulary adopted for annotating functional gene product data.

generalized transduction The transfer of any part of a bacterial or archaeal genome when the DNA fragment is packaged within a virus's capsid by mistake.

generation (doubling) time The time required for a microbial population to double in number.

genetic complementation The capacity of a gene, when introduced into a cell lacking a functional copy of that gene, to restore the wild-type phenotype to the cell. *See also* phenotypic rescue.

genetic drift Changes in the genotype of an organism that collect over time. These changes are generally neutral mutations that occur and are maintained without selection.

genetic engineering The deliberate modification of an organism's genetic information by changing its nucleic acid genome.

genome The full set of genes present in a cell or virus; all the genetic material in an organism.

genome annotation The process of determining the location and potential function of specific genes and genetic elements in a genome sequence.

genomic analysis *See* genomics.

genomic fingerprinting A series of techniques based on restriction enzyme digestion patterns that enable the comparison of microbial species and strains, and is thus useful in taxonomic identification.

genomic island A region in a genome introduced in an ancestral microbe by horizontal gene transfer. Genomic islands often bring new phenotypic traits to the microbe; *see also* pathogenicity island.

genomic library A collection of clones that contains fragments that represent the complete genome of an organism.

genomic reduction The decrease in genomic information that occurs over evolutionary time as an organism or organelle becomes increasingly dependent on another cell or a host organism.

genomics The study of the molecular organization of genomes, their information content, and the gene products they encode.

genotype The specific set of alleles carried in the genome of an organism.

genotypic classification The use of genetic data to construct a classification scheme for the identification of an unknown species or the phylogeny of a group of microbes.

genus A well-defined group of one or more species that is clearly separate from other organisms.

geographic information system (GIS) Use of hardware, software, and data for the capture, management, and display of geographically referenced information.

germfree State of having no microbial flora; describing animals born by cesarean delivery and reared in sterile environments.

germination The stage following spore activation in which the spore breaks its dormant state. Germination is followed by outgrowth.

Ghon complex The initial focus of infection in primary pulmonary tuberculosis.

gliding motility A type of motility in which a microbial cell glides smoothly along a solid surface without the aid of flagella.

global regulatory protein A protein that affects the transcription of numerous operons or genes simultaneously.

global regulatory systems Regulatory systems that simultaneously affect many genes.

glomeromycetes Common name for members of the fungal taxon *Glomeromycota*.

gluconeogenesis (gloo″ko-ne″o-jen′e-sis) The synthesis of glucose from noncarbohydrate precursors such as lactate and amino acids.

glutamine synthetase–glutamate synthase (GS-GOGAT) system A mechanism used by many microbes to incorporate ammonia.

glycerol diether lipids Archaeal lipids formed when isoprenoid hydrocarbons are linked to glycerol by ether bonds.

glycocalyx (gli″ko-kal′iks) A network of polysaccharides extending from the surface of bacteria and other cells.

glycogen (gli′ko-jen) A highly branched polysaccharide containing glucose, which is used to store carbon and energy.

glycolysis (gli-kol′ĭ-sis) The conversion of glucose to pyruvic acid by use of the Embden-Meyerhof pathway, pentose phosphate pathway, or Entner-Doudoroff pathway.

glycolytic pathway A pathway that converts glucose to pyruvic acid.

glycomics Analysis of all the carbohydrates produced by a cell under specific circumstances.

glyoxylate cycle A modified tricarboxylic acid cycle in which the decarboxylation reactions are bypassed by the enzymes isocitrate lyase and malate synthase; it is used to convert acetyl-CoA to succinate and other metabolites.

gnotobiotic (no″to-bi-ot′ik) Animals that are microbe-free or have a known microbiota consisting of one or a few microorganisms.

Golgi apparatus (gol′je) A membranous eukaryotic organelle composed of stacks (dictyosomes) of flattened sacs (cisternae) involved in packaging and modifying materials for secretion and many other processes.

gonococci (gon′o-kok′si) Bacteria of the species *Neisseria gonorrhoeae,* the organism causing gonorrhea.

graft-versus-host disease Pathology resulting from attack of host cells by immunocompetent T cells in a transplanted organ or stem cells.

Gram stain A differential staining procedure that divides bacteria into Gram-positive and Gram-negative groups based on their ability to retain crystal violet when decolorized with an organic solvent such as ethanol.

granular sludge In wastewater management, the stable aggregation of bacteria that readily settle, thereby facilitating recovery of the effluent.

granulocyte A type of white blood cell that stores preformed enzymes and antimicrobial proteins in vacuoles near the cell membrane.

granuloma Term applied to nodular inflammatory lesions containing phagocytic cells.

granzyme Enzyme found in the granules of cytotoxic T cells and natural killer cells that causes targets of these cells to undergo apoptosis.

GRAS An acronym for *g*enerally *r*egarded *a*s *s*afe: a category of food additives recognized in the United States and by the United Nations.

great plate count anomaly (GPCA) The discrepancy between the number of viable microbial cells and the number of colonies that can be cultivated from the same natural sample.

green fluorescent protein (GFP) A protein from the jellyfish *Aequorea victoria* that fluoresces when illuminated at a specific wavelength. The gene for GFP can be fused to gene promoters to determine when a gene is expressed (transcriptional fusion). When fused to the coding sequence of a gene so that a chimeric protein is produced, GFP fluorescence reveals the localization of the protein (translational fusion).

greenhouse gases Gases (e.g., CO_2, CH_4) released from Earth's surface through chemical and biological processes that interact with the chemicals in the stratosphere to decrease radiational cooling of Earth.

green nonsulfur bacteria Anoxygenic photosynthetic bacteria that contain bacteriochlorophylls *a* and *c;* usually photoheterotrophic and display gliding motility. Include members of the phylum *Chloroflexi*.

green sulfur bacteria Anoxygenic photosynthetic bacteria that contain bacteriochlorophylls *a,* plus *c, d,* or *e;* photolithoautotrophic; use H_2, H_2S, or S as electron donor. Include members of the phylum *Chlorobi*.

group A streptococcus (GAS) A Gram-positive, coccus-shaped bacterium often found in the throat and on the skin of humans, having the Lancefield group A of surface carbohydrate.

group B streptococcus (GBS) A Gram-positive, coccus-shaped bacterium found occasionally on mucous membranes of humans, having the Lancefield group B surface carbohydrate.

group translocation An active transport process in which a molecule is moved across a membrane by carrier proteins while being chemically altered at the same time (e.g., phosphoenolpyruvate: sugar phosphotransferase system).

growth factors Organic compounds that must be supplied in the diet for growth because they are essential cell components or precursors of such components and cannot be synthesized by the organism.

growth rate constant (*k*) The rate of microbial population growth expressed in terms of the number of generations per unit time.

guanine (gwan′in) A purine derivative, 2-amino-6-oxypurine found in nucleosides, nucleotides, and nucleic acids.

guanosine tetraphosphate (ppGpp) A small nucleotide that functions as a second messenger for the stringent response. *See also* stringent response.

guild A group of microbes defined by the same physiological activity.

gumma (gum′ah) A soft, gummy, benign tumor occurring in tertiary syphilis.

gut-associated lymphoid tissue (GALT) *See* mucosal-associated lymphoid tissue.

H

haloarchaea (extreme halophiles) A group of archaea that depend on high NaCl concentrations for growth and do not survive at a concentration below about 1.5 M NaCl.

halophile A microorganism that requires high levels of sodium chloride for growth.

halotolerant The ability to withstand large changes in salt concentration.

hami Structures extending from the surface of some archaeal cells that terminate in a grappling hooklike apparatus. They are thought to function in attachment to surfaces.

hapten A molecule not immunogenic by itself that, when coupled to a macromolecular carrier, can elicit antibodies directed against itself.

harmful algal bloom (HAB) In aquatic ecosystems, the growth of a single population of phototroph, either a protist (e.g., diatom, dinoflagellate) or a cyanobacterium, that produces a toxin poisonous to other organisms, sometimes including humans. Alternatively, in the absence of toxin production, the concentration of bloom microbe reaches levels that are inherently harmful to other organisms, such as filter-feeding bivalves.

Hartig net The area of nutrient exchange between ectomycorrhizal fungal hyphae and plant host cells.

health-care–associated infection An infection that is acquired during a patient's stay in a hospital or other type of clinical care facility.

heat fixation *See* fixation.

heat-shock proteins Proteins produced when cells are exposed to high temperatures or other stressful conditions. They protect the cells from damage and often aid in the proper folding of proteins.

helical capsid A viral capsid in the form of a helix.

helicases Enzymes that use ATP energy to unwind DNA ahead of the replication fork.

hemagglutination (hem″ah-gloo″tĭ-na′shun) The clumping of red blood cells by antibodies or components of virus capsids. *See also* viral hemagglutination.

hemagglutination assay A testing procedure based on a hemagglutination reaction.

hemagglutinin (HA) (1) Proteins that cause red blood cells to clump together (hemagglutination). (2) One of the envelope spikes of influenza and some other viruses. They are the basis for identifying different influenza virus strains.

hematopoiesis The process by which blood cells develop into specific lineages from stem cells. Red and white blood cells and platelets develop from this process.

hemolysis The disruption of red blood cells and release of their hemoglobin. In α-hemolysis, a greenish zone of incomplete hemolysis forms around a colony grown on blood agar. A clear zone of complete hemolysis without any obvious color change is formed during β-hemolysis.

herd immunity The resistance of a population to infection and spread of an infectious agent due to the immunity of a high percentage of the population.

heterocysts Specialized cells of cyanobacteria that are the sites of nitrogen fixation.

heterokont flagella A pattern of flagellation found in the members of the protist taxon *Stramenopila,* featuring two flagella, one extending anteriorly and the other posteriorly.

heterolactic fermenters Microorganisms that ferment sugars to form lactate and other products such as ethanol and CO_2.

heterologous gene expression The cloning, transcription, and translation of a gene that has been introduced (cloned) into an organism that normally does not possess the gene.

heterotroph An organism that uses reduced, preformed organic molecules as its principal carbon source.

hexose monophosphate pathway *See* pentose phosphate pathway.

Hfr conjugation Conjugation involving an Hfr strain and an F^- strain.

Hfr strain A strain of *Escherichia coli* that donates its chromosomal genes with high frequency to a recipient cell during conjugation because the F factor is integrated into the donor's chromosome.

hierarchical cluster analysis The organization of gene expression data such that induced and repressed genes, or genes of similar function, are grouped separately.

high-efficiency particulate (HEPA) filter Thick, fibrous filter constructed to remove 99.97% of particles that are 0.3 μm or larger.

high phosphate transfer potential A characteristic of a phosphorylated compound such that it readily transfers a phosphoryl group to another molecule concomitant with a large energy release.

high-throughput screening (HTS) A system that combines liquid handling devices, robotics, computers, data processing, and a sensitive detection system to screen thousands of compounds for a single capability.

histatin An antimicrobial peptide composed of 24 to 38 amino acids, heavily enriched with histidine, that targets fungal mitochondria.

histone A small basic protein with large amounts of lysine and arginine that is associated with eukaryotic DNA in chromatin. Related proteins are observed in many archaeal species, where they form archaeal nucleosomes.

holdfast A structure produced by some bacteria (e.g., *Caulobacter*) that attaches them to a solid object.

holoenzyme A complete enzyme consisting of the apoenzyme plus a cofactor. Also refers to a complete enzyme consisting of all protein subunits (e.g., RNA polymerase holoenzyme).

holozoic nutrition Acquisition of nutrients (e.g., bacteria) by endocytosis and the subsequent formation of a food vacuole or phagosome.

homolactic fermenters Organisms that ferment sugars almost completely to lactic acid.

homologous recombination Recombination involving two DNA molecules that are very similar in nucleotide sequence.

hopanoids Lipids found in bacterial membranes that are similar in structure and function to the sterols found in eukaryotic membranes.

hops Dried flowers of the plant *Humulus lupulus* used in the preparation of beer and lager.

horizontal (lateral) gene transfer (HGT/LGT) The process by which genes are transferred from one mature, independent organism to another. In bacteria and archaea, transformation, conjugation, and transduction are the major mechanisms by which HGT can occur.

hormogonia Small motile fragments produced by fragmentation of filamentous cyanobacteria; used for asexual reproduction and dispersal.

hospital-acquired infections *See* health-care-associated infections.

host An organism that harbors another organism.

housekeeping genes Genes that encode proteins that function throughout most of the life cycle of an organism (e.g., enzymes of the Embden-Meyerhof pathway).

human leukocyte antigen complex (HLA) A collection of genes on chromosome 6 that encodes proteins involved in host defenses; also called major histocompatibility complex.

human microbiome The sum of all the microorganisms that live on and in the human body.

humoral (antibody-mediated) immunity The type of immunity that results from the presence of soluble antibodies in blood and lymph.

hydrogen hypothesis A hypothesis that considers the origin of the eukaryotes through the development of the hydrogenosome. It suggests the organelle arose as the result of an endosymbiotic anaerobic bacterium that produced CO_2 and H_2 as the products of fermentation.

hydrogenosome One member of the mitochondrial family of organelles, it is found in some anaerobic protists that produce ATP by fermentation.

hydrophilic A polar substance that has a strong affinity for water (or is readily soluble in water).

hydrophobic A nonpolar substance lacking affinity for water (or which is not readily soluble in water).

3-hydroxypropionate bi-cycle A pathway used by green nonsulfur bacteria to fix CO_2.

hyperthermophile (hi″per-ther′mo-fīl) A microbe that has its growth optimum between 85°C and about 120°C. Hyperthermophiles usually do not grow well below 55°C.

hypha (hi′fah; pl., **hyphae**) The unit of structure of most fungi and some bacteria; a tubular filament.

hypolimnion The colder, bottom layer of water in a stratified lake.

I

icosahedral capsid A viral capsid that has the shape of a regular polyhedron having 20 equilateral triangular faces and 12 corners.

IgA Immunoglobulin A; the class of dimeric immunoglobulins that is present in mucous membranes and in many body secretions.

IgD Immunoglobulin D; the class of immunoglobulins found on the surface of many B lymphocytes, where it serves as an antigen receptor in the stimulation of antibody synthesis.

IgE Immunoglobulin E; the immunoglobulin class that binds to mast cells and basophils, and is responsible for type I or anaphylactic hypersensitivity reactions such as hay fever and asthma. IgE is also involved in resistance to helminth parasites.

IgG Immunoglobulin G; the predominant immunoglobulin class in serum. It serves to neutralize toxins, opsonize bacteria, activate complement, and cross the placenta to protect the fetus and neonate.

IgM Immunoglobulin M; the class of serum antibody produced first upon infection. It is a large, pentameric molecule that agglutinates pathogens and activates complement. The monomeric form is present on the surface of some B lymphocytes.

immobilization The incorporation of a simple, soluble substance into the body of an organism, making it unavailable for use by other organisms.

immune complex The product of antibody binding to antigen; may also contain components of the complement system.

immune system The defensive system in an animal consisting of the innate and adaptive immune responses. It is composed of widely distributed cells, tissues, and organs that recognize foreign substances and microorganisms and acts to neutralize or destroy them.

immunity Refers to the overall general ability of a host to resist a particular disease; the condition of being immune.

immunization The deliberate introduction of foreign materials into a host to stimulate an adaptive immune response. *See also* vaccine.

immunoblotting The electrophoretic transfer of proteins from polyacrylamide gels to filters to demonstrate the presence of specific proteins through reaction with labeled antibodies.

immunodeficiency The inability to produce a normal innate and/or adaptive immune response.

immunodiffusion A technique involving the diffusion of antigen or antibody within a semisolid gel to produce a precipitin reaction.

immunoelectrophoresis (pl., **immuno-electrophoreses**) The electrophoretic separation of protein antigens followed by diffusion and precipitation in gels using antibodies against the separated proteins.

immunofluorescence A technique used to identify particular antigens microscopically in cells or tissues by binding a fluorescent antibody conjugate.

immunoglobulin (Ig) *See* antibody.

immunology The study of host defenses against invading foreign materials, including pathogenic microorganisms, transformed or cancerous cells, and tissue transplants from other sources.

immunoprecipitation A reaction involving soluble antigens reacting with antibodies to form an aggregate that precipitates out of solution.

inactivated vaccines Nonviable infectious agents prepared to stimulate immunity but not cause infectious disease; also known as killed vaccines.

incidence The number of new cases of a disease in a population at risk.

inclusions (1) Granules, crystals, or globules of organic or inorganic material in the cytosol of cells. (2) Clusters of viral proteins or virions within the nucleus or cytoplasm of virus-infected cells.

incubation period The period after pathogen entry into a host and before signs and symptoms appear.

indel A blending of the words *insertion* and *deletion*; these genetic mutations can be taxonomically useful.

index case The first disease case in an outbreak or epidemic.

indicator organism An organism whose presence indicates the condition of a substance or environment, for example, the potential presence of pathogens. Coliforms are used as indicators of fecal pollution.

indirect immunofluorescence Technique for imaging microscopic agents using antibodies to target the agent and a second, fluorochrome-labeled reagent to bind to the antibodies.

induced mutations Mutations caused by exposure to a mutagen.

inducer A small molecule that stimulates the synthesis of an inducible enzyme.

inducible gene A gene whose expression level can be increased by a regulatory molecule.

induction (1) In virology, the events that trigger a virus to switch from a lysogenic mode to a lytic pathway. (2) In genetics, an increase in gene expression.

infection The invasion of a host by a microorganism with subsequent establishment and multiplication of the agent. An infection may or may not lead to overt disease.

infection thread A tubular structure formed during the infection of a root by nitrogen-fixing bacteria. The bacteria enter the root by way of the infection thread and stimulate the formation of the root nodule.

infectious disease Any change from a state of health in which part or all of the host's body cannot carry on its normal functions because of the presence of an infectious agent or its products.

infectious disease cycle (chain of infection) The linked events that must occur for an infectious disease to be expressed in an individual.

infectious dose 50 (ID_{50}) Refers to the number of organisms that infect 50% of an experimental group of hosts within a specified time period.

infectivity Infectiousness; the state or quality of being infectious or communicable.

inflammasomes A complex formed within the cytoplasm of certain immune cells that promotes inflammation; composed of oligomerized NOD-like receptors and formed in response to the capture of microbe-associated molecular patterns and danger-associated molecular patterns.

inflammation A localized protective response to tissue injury or destruction. Acute inflammation is characterized by pain, heat, swelling, and redness in the injured area.

initiation factors Proteins that function during initiation of protein synthesis.

initiator tRNA The tRNA that binds to the start codon during initiation of translation.

innate (natural) immunity Refers to nonspecific defenses that are mounted within minutes to hours after challenge by a microbial or other foreign antigen. Sometimes also called nonspecific immunity.

innate lymphoid cell (ILC) A lymphocyte that functions as a bridge between the innate and adaptive arms of immunity, amplifying and relaying information about infection and tissue damage.

innate resistance mechanisms *See* innate (natural) immunity.

insertion sequence A transposable element that contains genes only for those enzymes, such as transposase, that are required for transposition.

in silico analysis The study of biology through the examination of nucleic acid and amino acid sequence. *See also* bioinformatics.

in situ reverse transcriptase (ISRT)-FISH A method that uses fluorescently labeled probes to identify mRNA transcripts in natural samples. *See also* fluorescent in situ hybridization (FISH).

insulators Sites in eukaryotic DNA that limit the effects of regulatory proteins to only those genes for which they are specified.

integral membrane protein *See* plasma membrane.

integrase An enzyme observed in some viruses; it catalyzes the integration of provirus DNA into the host chromosome.

integrative conjugative elements (ICEs) *See* conjugative transposon.

integrins (in′tə-grinz) Cellular adhesion receptors that mediate cell-cell and cell-substratum interactions, usually by recognizing linear amino acid sequences on protein ligands.

integron A genetic element with an attachment site for site-specific recombination and an integrase gene. It can capture genes and gene cassettes.

inteins Internal intervening sequences of precursor self-splicing proteins that are removed during formation of the final protein.

intercalating agents Molecules that can insert between the stacked bases of a DNA double helix, thereby distorting the DNA and inducing frameshift mutations.

interferon (IFN) A cytokine that stimulates cells to produce antiviral proteins (type 1 IFNs), and regulates growth, differentiation, or function of immune system cells (type 2 IFNs).

interleukin (in″tər-loo′kin) A cytokine that regulates growth and differentiation, particularly of lymphocytes.

intermediate filaments One of the proteinaceous components of the eukaryotic cytoskeleton.

internal transcribed spacer region (ITSR) The region between small subunit rRNA genes found in many microbial genomes that is conserved and transcribed.

interspecies hydrogen transfer The linkage of H_2 production by fermentative microorganisms to the use of H_2 by archaea during methanogenesis.

intoxication A disease that results from the entrance of a specific toxin into the body of a host. The toxin can induce the disease in the absence of the toxin-producing organism.

intraepidermal lymphocytes T cells found in the epidermis of the skin.

intranuclear inclusion body A structure found within cells infected with cytomegalovirus.

intron A noncoding intervening sequence in a gene that codes for pre-mRNA and is removed (spliced) from the final RNA product.

invasiveness The ability of a microorganism to enter a host, grow and reproduce within the host, and spread throughout its body.

iodophor An antimicrobial agent consisting of an organic compound complexed with iodine.

ionizing radiation Radiation of very short wavelength and high energy that causes atoms to lose electrons (i.e., ionize).

iron-sulfur (Fe-S) protein *See* electron transport chain.

isoelectric focusing An electrophoretic technique in which proteins are separated based on their isoelectric point.

isoelectric point The pH value at which a protein or other molecule no longer carries a net charge.

isoenzyme (isozyme) An enzyme that carries out the same catalytic function but differs in terms of its amino acid sequence, regulatory properties, or other characteristics.

isotope fractionation The preferential use of one stable isotope over another by microbes carrying out metabolic processes.

J

joule The SI (International System of Units) unit of measure for energy or work. One calorie is equivalent to 4.1840 joules.

K

kallikrein An enzyme that acts on kininogen, releasing the active bradykinin protein.

keratinocytes (kĕ-rat′ĭ-no-sīt) Cells of the skin that express keratin.

Kirby-Bauer method A disk diffusion test to determine the susceptibility of a microorganism to chemotherapeutic agents.

Koch's postulates A set of rules for proving that a microorganism causes a particular disease.

Koplik's spots White lesions that appear on mucous membranes in the mouth (buccal mucosa) characteristic of measles infection.

Krebs cycle *See* tricarboxylic acid (TCA) cycle.

L

labyrinthulids A subgroup of stramenopiles characterized by having heterokont flagellated zoospores.

lactic acid bacteria (LAB) Strictly fermentative, Gram-positive bacteria that produce lactic acid as the primary fermentation end product; used in the fermentation of dairy products.

lactic acid fermentation A fermentation that produces lactic acid as the sole or primary product.

lactoferrin An iron-sequestering protein released from macrophages and neutrophils into plasma.

lagging strand The strand of DNA synthesized discontinuously during DNA replication.

lag phase A period following the introduction of microorganisms into fresh culture medium when there is no increase in cell numbers or mass during batch culture.

Lancefield system (group) One of the serologically distinguishable groups (e.g., group A and group B) into which streptococci can be divided.

Langerhans cell Cell found in the skin that internalizes antigen and moves in the lymph to lymph nodes, where it differentiates into a dendritic cell.

lateral gene transfer *See* horizontal gene transfer.

leader A sequence in a gene that lies between the promoter and the start codon. It is transcribed, becoming a nontranslated sequence at the 5′ end of mRNA. It often aids in initiation and regulation of transcription and translation.

leading strand The strand of DNA that is synthesized continuously during DNA replication.

lectin complement pathway An antibody independent pathway of complement activation that is initiated by microbial lectins (proteins that bind carbohydrates).

leghemoglobin A heme-containing pigment produced in leguminous plants. It functions to protect the nitrogenase enzyme from oxygen in nodule-forming, nitrogen-fixing bacteria.

leishmanias (lēsh″ma′ne-ăs) Trypanosomal protists of the genus *Leishmania*.

lentic An aquatic system that features slow-moving or still waters.

lethal dose 50 (LD_{50}) Refers to the number of organisms that kills 50% of an experimental group of hosts within a specified time period.

leukocyte (loo′ko-sīt) Any white blood cell.

ligand *See* receptor.

light reactions *See* photosynthesis.

lignin An irregularly branched molecule made of phenylpropene units; an important structural component of woody plants.

limnology The study of the biological, chemical, and physical aspects of freshwater systems.

lipid A The lipid component of a lipopolysaccharide; also called endotoxin.

lipidomics Study of all the lipids produced by an organism under specific circumstances.

lipopolysaccharide (LPS) (lip″o-pol″e-sak′ah-ríd) A molecule containing both lipid and polysaccharide, found in the outer membrane of the typical Gram-negative cell wall. In many bacteria, it consists of three components: lipid A, core polysaccharide, and O antigen.

lithoheterotrophy The metabolic strategy characterized by the use of inorganic chemicals as an electron and energy source and organic carbon as a source of carbon. *See also* chemolithoheterotroph.

lithotroph An organism that uses reduced inorganic compounds as its electron source.

littoral zone The coastal region of a lake, stream, or ocean.

lobopodia Rounded pseudopodia found in some amoeboid protists.

localized anaphylaxis (atopic reaction) Type I hypersensitivity that remains contained in one tissue space (e.g., hay fever).

log phase *See* exponential phase.

long-term stationary phase The phase following the death phase of a growth curve in which the population size remains at a more or less constant low level for an extended period.

lophotrichous (lo-fot′rĭ-kus) A cell with a cluster of flagella at one or both ends.

lotic An aquatic system that features fast-moving, free-running waters.

lymph node A small secondary lymphoid organ that contains lymphocytes, macrophages, and dendritic cells. It serves as a site for (1) filtration and removal of foreign antigens and (2) activation and proliferation of lymphocytes.

lymphocyte A nonphagocytic, mononuclear leukocyte that is an immunologically competent cell, or its precursor. Lymphocytes are present in the blood, lymph, and lymphoid tissues. *See also* B cell and T cell.

lymphokine A glycoprotein cytokine (e.g., IL-1) secreted by activated lymphocytes, especially sensitized T cells.

lysis (*li′sis*) The rupture or physical disintegration of a cell.

lysogenic (li-so-jen′ik) *See* lysogens.

lysogenic conversion A change in the phenotype of a bacterium due to the presence of a prophage.

lysogenic cycle The phase of a temperate virus's life cycle in which it establishes and maintains lysogeny.

lysogens (li′so-jens) Bacterial and archaeal cells that carry a provirus and can produce viruses under the proper conditions.

lysogeny (li-soj′e-ne) The state in which a viral genome remains within a bacterial or archaeal cell after infection and reproduces along with it, rather than taking control of the host cell and destroying it.

lysosome A spherical membranous eukaryotic organelle that contains hydrolytic enzymes and is responsible for the intracellular digestion of substances.

lysozyme An enzyme that degrades peptidoglycan by hydrolyzing the β(1 → 4) bond that joins *N*-acetylmuramic acid and *N*-acetylglucosamine.

lytic cycle (lit′ik) A viral life cycle that results in the lysis of the host cell.

M

macroautophagy Digestion of cytoplasmic components that involves enclosing the material (e.g., an organelle) in a double-membrane structure called an autophagosome. The autophagosome delivers the material to a lysosome for digestion.

macroelement A nutrient that is required in relatively large amounts (e.g., carbon and nitrogen).

macrolide antibiotic An antibiotic containing a macrolide ring—a large lactone ring with multiple keto and hydroxyl groups—linked to one or more sugars.

macromolecule A large molecule that is a polymer of smaller units joined together.

macronucleus The larger of the two nuclei in ciliate protists. It is normally polyploid and directs the routine activities of the cell.

macrophage The name for a large, mononuclear phagocytic antigen-presenting cell, present in blood, lymph, and other tissues.

madurose The sugar derivative 3-*O*-methyl-D-galactose, which is characteristic of several actinomycete genera that are collectively called maduromycetes.

magnetosomes Magnetic greigite or magnetite particles in magnetotactic bacteria that allow the bacteria to orient themselves in magnetic fields.

maintenance energy The energy a cell requires simply to maintain itself or remain alive and functioning properly. It does not include the energy needed for either growth or reproduction.

major histocompatibility complex (MHC) A chromosome locus encoding the histocompatibility antigens and other components of the immune system. Class I MHC molecules are cell surface glycoproteins present on all nucleated cells; class II MHC glycoproteins are on antigen-presenting cells.

malt Grain soaked in water to soften it, induce germination, and activate its enzymes. The malt is then used in brewing and distilling.

mannose-binding protein (MBP) Also known as mannose-binding lectin, a serum protein that binds to mannose residues in microbial cell walls, thereby initiating complement activation.

marine snow Organic matter that sinks out of the photic zone of the ocean. These flocculent particles are composed of fecal pellets, diatom frustules, and other materials that are not rapidly degraded.

mash The soluble materials released from germinated grains and prepared as a microbial growth medium.

mashing The process in which cereals are mixed with water and incubated to degrade their complex carbohydrates (e.g., starch) to more readily usable forms such as simple sugars.

massively parallel nucleotide sequencing *See* next-generation DNA sequencing.

mass spectrometry A type of spectrometry that determines mass-to-charge ratio of ions formed from the molecule being analyzed. The ratio can be used to identify structures and determine sequences of proteins.

mast cell A white blood cell that produces vasoactive molecules (e.g., histamine) and stores them in vacuoles near the cell membrane where they are released upon cell stimulation by external triggers.

maximum containment level goal The number of pathogens permitted in a water supply to prevent adverse health effects and provide a margin of safety.

M cell Specialized cell of the intestinal mucosa and other sites (e.g., urogenital tract) that delivers antigen from its apical face to lymphocytes clustered within the pocket in its basolateral face.

mediator A complex of proteins in eukaryotic cells that is often involved in transcription initiation and regulation.

meiosis (mi-o′sis) The type of cell division by which a diploid cell divides and forms four haploid cells.

melting temperature (T_m) The temperature at which double-stranded DNA separates into individual strands; used to compare genetic similarity in microbial taxonomy.

membrane attack complex (MAC) The complex of complement proteins (C5b–C9) that creates a pore in the plasma membrane of a target cell and leads to cell lysis.

membrane filter Porous material that retains microorganisms as the suspending liquid passes through the pores.

membrane filter technique The use of a thin porous filter to collect microorganisms from water, air, and food.

memory cell An inactive lymphocyte derived from a sensitized B or T cell capable of a rapid response to subsequent antigen exposure.

mesophile A microorganism with a growth optimum around 20 to 45°C, a minimum of 15 to 20°C, and a maximum about 45°C or lower.

messenger RNA (mRNA) Single-stranded RNA synthesized from a nucleic acid template (DNA in cellular organisms, RNA in some viruses) during transcription; mRNA binds to ribosomes and directs the synthesis of protein.

metabolic channeling The localization of metabolites and enzymes in different parts of a cell.

metabolic engineering The use of molecular techniques to develop novel biochemical pathways that either promote product yield or generate new products.

metabolism The total of all chemical reactions in the cell; almost all are enzyme catalyzed.

metabolite flux The rate of turnover of a metabolite.

metabolites Chemical compounds produced by the metabolic activities of organisms.

metabolomics Analysis of all the small metabolites present in a cell under specific circumstances.

metagenomic library A genomic library constructed of DNA (or cDNA derived from mRNA) extracted directly from the environment.

metagenomics The study of genomes recovered from environmental samples (including the human body) without first isolating members of the microbial community and growing them in cultures.

metalimnion In lakes, the region of the water column between the hypolimnion and the epilimnion.

metaproteomics The emerging field of examining all the proteins produced in a given microbial habitat at a specific time.

metatranscriptomics Large-scale sequencing of mRNAs collected from natural environments as a means to assess microbial activities.

methane hydrate Pools of trapped methane that accumulates in latticelike cages of crystalline water 500 m or more below the sediment surface in many regions of the world's oceans.

methanogenesis The production of methane by certain members of the archaeal phylum *Euryarchaeota*.

methanogens (meth′ə-no-jens″) Strictly anaerobic archaea that derive energy by converting CO_2, H_2, formate, acetate, and other compounds to either methane or methane and CO_2.

methanotroph A microbe that has the ability to grow on methane as its sole carbon and energy source.

methylotroph A bacterium that uses reduced one-carbon compounds such as methane and methanol as its sole source of carbon and energy.

metronidazole Antimicrobial chemotherapeutic agent of the nitromidazole family having biological activity on anaerobic bacteria and protozoa.

Michaelis constant (K_m) A value that represents the substrate concentration required for an enzyme to operate at half maximal velocity.

microaerophile (mi″kro-a′er-o-fīl) A microorganism that requires low levels of oxygen for growth, around 2 to 10%, but is damaged by normal atmospheric oxygen levels.

microautoradiography A technique whereby the uptake of a radioactive substrate by single cells is determined.

microbe-associated molecular pattern (MAMP) Conserved molecular structures that occur in patterns on microbial surfaces. The structures and their patterns are unique to particular types of microorganisms and invariant among members of a given microbial group.

microbial ecology The study of microbial populations and communities in natural habitats, such as soils, water, food, etc.

microbial energy conversion The processes by which microbes are used to generate useful forms of energy, such a biofuel (ethanol, H_2, methanol) production, or electricity through microbial fuel cells.

microbial flora (microbiota) *See* microbiota.

microbial fuel cell An apparatus designed to capture electrons produced during microbial respiration and convert these electrons to electricity.

microbial loop The cycling of organic matter synthesized by photosynthetic microorganisms among other microbes, such as bacteria and protozoa. This process "loops" organic nutrients, minerals, and carbon dioxide back for reuse by the primary producers and makes the organic matter unavailable to higher consumers.

microbial mat A firm structure of layered microorganisms with complementary physiological activities that can develop on surfaces in aquatic environments.

microbial transformation *See* biotransformation.

microbiology The study of organisms that are usually too small to be seen with the naked eye.

microbiome The totality of microorganisms and microbial genomes that constitute a host's normal microbiota.

microbiota The microbes found in a habitat.

microcosms Incubation chambers with conditions that mimic those in a natural setting.

microdroplet culture A technique designed to obtain an axenic culture whereby cells from a microbial community are encapsulated in a gel matrix, which when emulsified generates a porous microdroplet that houses a single cell. The microdroplets can be incubated together, thereby allowing the exchange of small molecules. Following incubation, microdroplets containing colonial growth can be separated by flow cytometry.

microelectrode An electrode with a tip that is sufficiently small to perform nondestructive measurements at intervals of less than 1 mm.

microflora *See* microbiota.

micronucleus The smaller of the two nuclei in ciliate protists. Micronuclei are diploid and involved only in genetic recombination and the regeneration of macronuclei.

micronutrients Nutrients required in very small quantities for growth and reproduction. Also called trace elements.

microorganism An organism that is usually too small to be seen clearly with the naked eye and is often unicellular, or if multicellular, does not exhibit a high degree of differentiation.

micro RNAs (miRNAs) Very small RNAs that inhibit translation of a target mRNA.

microsporidia Primitive obligate intracellular fungi; primarily infect vertebrates.

microtubules (mi″kro-tu′buls) One of the proteinaceous components of the eukaryotic cytoskeleton, flagella, and cilia; composed of tubulin proteins.

mineralization The conversion of organic nutrients into inorganic material during microbial growth and metabolism.

mineral soil Soil that contains less than 20% organic carbon.

minimal inhibitory concentration (MIC) The lowest concentration of a drug that will prevent the growth of a particular microorganism.

minimal lethal concentration (MLC) The lowest concentration of a drug that will kill a particular microorganism.

minus (negative) strand A viral single-stranded nucleic acid that is complementary to the viral mRNA.

mismatch repair A type of DNA repair in which a portion of a newly synthesized strand of DNA containing mismatched base pairs is removed and replaced, using the parental strand as a template.

missense mutation A single base substitution in DNA that changes a codon for one amino acid into a codon for another.

mitochondrion (mi″to-kon′dre-on) The eukaryotic organelle that is the site of electron transport, oxidative phosphorylation, and pathways such as the Krebs cycle; it provides most of a nonphotosynthetic cell's energy under aerobic conditions.

mitosis A process that takes place in the nucleus of a eukaryotic cell and results in the formation of two new nuclei, each with the same number of chromosomes as the parent.

mitosome A member of the mitochondria family of organelles found in certain protists that lack mitochondria or hydrogenosomes.

mixed acid fermentation A type of fermentation carried out by members of the family *Enterobacteriaceae* in which ethanol and a complex mixture of organic acids are produced.

mixotrophy A nutritional strategy that includes different types of metabolism (e.g., phototrophy and chemoorganotrophy).

modified atmosphere packaging (MAP) Addition of gases such as nitrogen and carbon dioxide to packaged foods to inhibit the growth of spoilage organisms.

mold Any of a large group of fungi that exist as multicellular filamentous colonies; typically lack macroscopic fruiting bodies.

molecular chaperones *See* chaperone proteins.

monocistronic mRNA An mRNA containing a single coding region.

monoclonal antibody (mAb) An antibody of a single type that is produced by a population of genetically identical plasma cells; typically produced in cell cultures derived from the fusion of a cancer cell and an antibody-producing cell (i.e., hybridoma).

monocyte A mononuclear phagocytic leukocyte; precursor of macrophages and dendritic cells.

monokine A generic term for a cytokine produced by macrophages or monocytes.

monotrichous (mon-ot′rĭ-kus) Having a single flagellum.

morbidity rate Measures the number of individuals who become ill as a result of a particular disease within a susceptible population during a specific time period.

mordant A substance that helps fix dye on or in a cell.

morphovar A variant strain of a microbe characterized by morphological differences.

mortality rate The ratio of the number of deaths from a given disease to the total number of cases of the disease.

most probable number (MPN) Statistical estimation of the size of a population in a liquid by diluting and determining end points for microbial growth.

mucociliary blanket The layer of cilia and mucus that lines certain portions of the respiratory system; it traps microorganisms and then transports them by ciliary action away from the lungs.

mucosal-associated lymphoid tissue (MALT) Organized and diffuse immune tissues found as part of the mucosal epithelium. It can be specialized to the gut (GALT) or the bronchial system or (BALT).

multicloning site (MCS) A region of DNA on a cloning vector that has a number of restriction enzyme recognition sequences to facilitate the cloning of a gene.

multilocus sequence analysis (MLSA) The application of multilocus sequence typing to more than one species.

multilocus sequence typing (MLST) A method for genotypic classification of bacteria or archaea within a single genus using nucleotide differences among five to seven housekeeping genes.

multiple strand displacement A technique used to amplify very low concentrations of DNA; it can yield enough DNA from a single cell to perform DNA sequencing.

murein *See* peptidoglycan.

must The juices of fruits, including grapes, that can be fermented for the production of alcohol.

mutagen (mu′tah-jen) A chemical or physical agent that causes mutations.

mutation A heritable change in the genetic material.

mutualism A type of symbiosis in which both partners gain from the association and are dependent on each other.

mutualist An organism associated with another in an obligatory relationship that is beneficial to both.

mycelium (mi-se′le-um) A mass of branching hyphae found in fungi and some bacteria.

Myc factor A lipochitooligosaccharide produced by some mycorrhizal fungi that prompts their uptake by the roots of host plants.

mycobiont The fungal partner in a lichen.

mycolic acids Complex 60 to 90 carbon fatty acids with a hydroxyl on the β-carbon and an aliphatic chain on the α-carbon; found in the cell walls of mycobacteria.

mycologist A person specializing in mycology; a student of mycology.

mycology The science and study of fungi.

mycoplasmas Common name for bacteria that are members of the class *Mollicutes,* phylum *Tenericutes*. They lack cell walls and cannot synthesize peptidoglycan precursors.

mycorrhizal fungi Fungi that form stable, mutualistic relationships on (ectomycorrhizal) or in (endomycorrhizal) the roots of vascular plants.

mycosis (mi-ko′sis; pl., **mycoses**) Any disease caused by a fungus.

mycotoxicology (mi-ko′tok″si-kol′o-je) The study of fungal toxins and their effects on various organisms.

myositis (mi″o-si′tis) Inflammation of a striated or voluntary muscle.

myxobacteria A group of Gram-negative, aerobic soil bacteria characterized by gliding motility, a complex life cycle with the production of fruiting bodies, and the formation of myxospores.

myxospores (mik′so-spōrs) Special dormant spores formed by myxobacteria.

N

naked amoeba An amoeboid protist that lacks a cell wall or other supporting structures.

naked viruses *See* nonenveloped virus.

nanowires Threadlike extensions of plasma membrane that transfer electrons from the terminal point in the electron transport chain to an external metal surface.

narrow-spectrum drugs Chemotherapeutic agents effective only against a limited variety of microorganisms.

natural classification A classification system that arranges organisms into groups whose members share many characteristics and reflect as much as possible the biological nature of organisms.

natural immunity *See* innate immunity.

natural killer (NK) cell A type of white blood cell that destroys host cells infected with intracellular pathogens and tumor cells.

naturally acquired active immunity The type of active immunity that develops when an individual's immune system encounters an appropriate antigen during the course of normal activities; it often arises as the result of recovering from an infection and lasts a long time.

naturally acquired passive immunity The type of temporary immunity that involves the transfer of antibodies from one individual to another.

natural products Industrially important compounds, such as antibiotics, produced by microbes.

negative selection In immunology, the process by which lymphocytes that recognize host (self) antigens undergo apoptosis or become anergic (inactive).

negative staining A staining procedure in which a dye is used to make the background dark while the specimen is unstained.

negative-strand DNA *See* minus strand.

negative-strand RNA *See* minus strand.

negative transcriptional control Regulation of transcription by a repressor protein. When bound to the repressor-binding site, transcription is inhibited.

neoplasia Abnormal cell growth and reproduction due to a loss of regulation of the cell cycle; produces a tumor in solid tissues.

neuraminidase An enzyme that cleaves the chemical bond linking neuraminic acids to the sugars present on the surface of animal cells; in virology, one type of envelope spike on influenza viruses has neuraminidase activity and is used to identify different strains.

neutralization Binding of specific immunoglobulins to toxins or viruses, inhibiting their biological activity.

neutral mutation A missense mutation that does not affect the function of the protein (e.g., a polar amino acid is substituted for a polar amino acid).

neutrophil A mature white blood cell in the granulocyte lineage. It has a nucleus with three to five lobes and is very phagocytic.

neutrophile A microorganism that grows best at a neutral pH range between pH 5.5 and 8.0.

next-generation nucleotide sequencing Methodologies that allow rapid genome sequencing without the prior construction of a genomic library. Instead, fragments of genomic DNA are tethered to a solid substrate, and each fragment is sequenced simultaneously or in a massively parallel fashion.

nicotinamide adenine dinucleotide (NAD^+) (nik″o-tin′ah-mıd) An electron-carrying coenzyme; it is particularly important in catabolic processes and usually transfers electrons from an electron source to an electron transport chain.

nicotinamide adenine dinucleotide phosphate ($NADP^+$) An electron-carrying coenzyme that most often participates as an electron carrier in biosynthetic metabolism.

nitrification The oxidation of ammonia to nitrate.

nitrifying archaea Mesophilic archaea (thaumarchaeotes) capable of oxidizing ammonium to nitrite.

nitrifying bacteria Chemolithotrophic, Gram-negative bacteria that are members of several families within the phylum *Proteobacteria* that either oxidize ammonia to nitrite or nitrite to nitrate.

nitrogenase (ni′tro-jen-ās) The enzyme that catalyzes biological nitrogen fixation.

nitrogen fixation The metabolic process in which atmospheric molecular nitrogen (N_2) is reduced to ammonia; carried out by nitrogen-fixing bacteria and archaea.

nocardioforms Bacteria that resemble members of the genus *Nocardia;* they develop a substrate mycelium that readily breaks up into rods and coccoid elements (a quality called fugacity).

Nod factors Signaling compounds that alter gene expression in the plant host of a rhizobium.

NOD-like receptors (NLRs) Receptors similar to nucleotide-binding and oligomerization

domain (NOD) receptors that sense endogenous metabolites and regulate the production of inflammatory cytokines in response to microbe-associated molecular patterns and danger-associated molecular patterns.

nomenclature The branch of taxonomy concerned with the assignment of names to taxonomic groups in agreement with published rules.

noncompetitive inhibitor A chemical that inhibits enzyme activity by a mechanism that does not involve binding the active site of the enzyme.

noncyclic photophosphorylation The process in which light energy is used to make ATP when electrons are moved from water to $NADP^+$during oxygenic photosynthesis; both photosystem I and photosystem II are involved.

nonenveloped (naked) virus A virus having virions composed only of a nucleocapsid (i.e., lacking an envelope).

nonheme iron protein *See* electron transport chain.

nonsense (stop) codon A codon that does not code for an amino acid but is a signal to terminate protein synthesis.

nonsense mutation A mutation that converts a sense codon to a nonsense (stop) codon.

nonspecific immune response *See* innate (natural) immunity.

nonspecific resistance *See* innate (natural) immunity.

normal microbiota *See* microbiota.

nosocomial infection (nos″o-ko′me-al) *See* health-care–associated infection.

nuclear envelope The complex double-membrane structure forming the outer boundary of the eukaryotic nucleus. It is covered by nuclear pores through which substances enter and leave the nucleus.

nuclear pore complex The nuclear pore plus about 30 proteins that form the pore and are involved in moving materials across the nuclear envelope.

nucleocapsid (nu″kle-o-kap′sid) The viral nucleic acid and its surrounding capsid; the basic unit of virion structure.

nucleoid An irregularly shaped region in a bacterial or archaeal cell containing genetic material.

nucleoid occlusion A mechanism used by many bacteria to prevent premature formation of a septum during binary fission.

nucleolus (nu-kle′o-lus) The organelle, located within the nucleus and not bounded by a membrane, that is the location of ribosomal RNA synthesis and the assembly of ribosomal subunits.

nucleoside (nu′kle-o-sīd″) A combination of ribose or deoxyribose with a purine or pyrimidine base but lacking phosphate.

nucleosome (nu′kle-o-sōm″) A complex of histones and DNA found in eukaryotic chromatin and some archaea; the DNA is wrapped around the surface of the beadlike histone complex.

nucleotide (nu′kle-o-tīd) A combination of ribose or deoxyribose with phosphate and a purine or pyrimidine base; a nucleoside plus one or more phosphates.

nucleotide excision repair *See* excision repair.

nucleus The eukaryotic organelle enclosed by a double-membrane envelope that contains the cell's chromosomes.

numerical aperture The property of a microscope lens that determines how much light can enter and how great a resolution the lens can provide.

O

O antigen The terminal polysaccharide of the lipopolysaccharide found on some Gram-negative bacterial cell walls.

obligate aerobes Organisms that grow only in the presence of oxygen.

obligate anaerobes Microorganisms that cannot tolerate oxygen and die when exposed to it.

ocean acidification The decline in pH in ocean waters as a result of changes to the carbonate equilibrium system.

oceanography The study of the biological, chemical, and physical aspects of the oceans.

Okazaki fragments Short stretches of polynucleotides produced during discontinuous DNA replication.

oligonucleotide A short fragment of DNA or RNA, usually artificially synthesized, used in a number of molecular genetic techniques such as DNA sequencing and polymerase chain reaction.

oligonucleotide signature sequence Short, conserved nucleotide sequences that are specific for a phylogenetically defined group of organisms. The signature sequences found in small subunit rRNA molecules are most commonly used.

oligotrophic environment (ol″ĭ-go-trof′ik) An environment containing low levels of nutrients that support microbial growth.

oncogene (ong″ko-jēn) A gene whose activity is associated with the conversion of normal cells to cancer cells.

oncovirus A virus known to be associated with the development of cancer.

oocyst (o′o-sist) Cyst formed around a zygote of certain protozoa.

öomycetes (o″o-mi-se′tēz) A collective name for protists also known as water molds. Formerly thought to be fungi.

open reading frame (ORF) A sequence of DNA thought to encode a protein because it is not interrupted by a stop codon and has an apparent promoter and ribosome-binding site at the 5′ end and a terminator at the 3′ end.

operational taxonomic unit (OTU) A term that includes all sources of data used to construct phylogenetic trees; that is, it includes species, strains, and genomic sequences from organisms not yet grown in culture.

operator The segment of DNA in an operon to which the repressor protein binds; it controls the expression of the genes adjacent to it.

operon In bacteria, the sequence of bases in DNA that contains a promoter and one or more structural genes and often an operator or activator-binding site that controls their expression.

opportunistic microorganism or pathogen A microorganism that is usually free living or a part of the host's normal microbiota but may become pathogenic under certain circumstances, such as when the immune system is compromised.

opsonization (op″so-ni-za′shun) The coating of foreign substances by antibody, complement proteins, or fibronectin to make the substances more readily recognized by phagocytic cells.

optical tweezer A focused laser beam that can drag and isolate an individual microorganism from a complex microbial mixture.

organelle A structure within or on a cell that performs specific functions and is related to the cell in a way similar to that of an organ to the body of a multicellular organism.

organic soil A soil that contains at least 20% organic carbon.

organotrophs Organisms that use reduced organic compounds as their electron source.

origin of replication A site on a chromosome or plasmid where DNA replication is initiated.

origin recognition complex (ORC) A complex of six proteins that "marks" the origins of replication in eukaryotic chromosomes.

orthologue A gene found in the genomes of two or more different organisms that share a common ancestry. The products of orthologous genes are presumed to have similar functions.

osmophiles Microorganisms that grow best in or on media of high solute concentration.

osmotolerant Organisms that grow over a fairly wide range of water activity or solute concentration.

osmotrophy A form of nutrition in which soluble nutrients are absorbed through the cytoplasmic membrane; found in bacteria, archaea, fungi, and some protists.

Öuchterlony technique *See* double diffusion agar assay.

outbreak The sudden, unexpected occurrence of a disease in a given population.

outer membrane A membrane located outside the peptidoglycan layer in the cell walls of typical Gram-negative bacteria.

oxidation-reduction (redox) reactions Reactions involving electron transfers; the electron donor (reductant) gives electrons to an electron acceptor (oxidant).

oxidative burst *See* respiratory burst.

oxidative phosphorylation (fos″for-ĭ-la′-shun) The synthesis of ATP from ADP using energy made available during electron transport initiated by the oxidation of a chemical energy source.

oxygenic photosynthesis Photosynthesis that oxidizes water to form oxygen; the form of photosynthesis characteristic of plants, protists, and cyanobacteria.

P

palisade arrangement Angular arrangements of bacteria whereby cells remain partially attached after snapping division.

pandemic An increase in the occurrence of a disease within a large and geographically

widespread population (often refers to a worldwide epidemic).

Paneth cell (pah′net) A specialized epithelial cell of the intestine that secretes hydrolytic enzymes and antimicrobial proteins and peptides.

pangenome The collection of genes found in all strains that belong to a single species or other taxonomic group.

paralogue Two or more genes in the genome of a single organism that arose through duplication of a common ancestral gene. The products of paralogous genes may have slightly different functions.

parasite An organism that lives on or within another organism (the host) and benefits from the association while harming its host. Often the parasite obtains nutrients from the host.

parasitism A type of symbiosis in which one organism benefits from the other and the host is usually harmed.

parasporal body An intracellular, solid protein crystal made by the bacterium *Bacillus thuringiensis*. It is the basis of the bacterial insecticide Bt.

parfocal A microscope that retains proper focus when the objectives are changed.

particulate organic matter (POM) Nutrients that are not dissolved or soluble, generally referring to aquatic ecosystems. This includes microorganisms and their cellular debris after senescence or viral lysis.

passive diffusion The movement of molecules from a region of higher concentration to one of lower concentration as a result of random thermal agitation.

pasteurization The process of heating liquids to destroy microorganisms that can cause spoilage or disease.

pathogen (path′o-jən) Any organism that causes disease.

pathogenicity (path″o-je-nis′ĭ-te) The condition or quality of being pathogenic, or the ability to cause disease.

pathogenicity island A segment of DNA in some pathogens that contains genes responsible for virulence; often codes for a type III secretion system that allows the pathogen to secrete virulence proteins and damage host cells.

pattern recognition molecule (PRM) A receptor found on macrophages and other phagocytic cells that binds to microbe-associated molecular patterns on microbial surfaces.

PCR bias Artifactual or misleading results obtained when microbial populations are assessed by amplifying genes or genomes by the polymerase chain reaction (PCR); occurs because not all DNA or RNA is amplified at the same rate.

pelagic zone The central region of a lake or ocean not influenced by events or nutrients found in the coastal regions.

pellicle (pel′ĭ-k′l) A relatively rigid layer of proteinaceous elements just beneath the plasma membrane in many protists. The plasma membrane is sometimes considered part of the pellicle.

penicillin A β-lactam antibiotic. The first true antibiotic to be discovered and used clinically.

penicillinase A β-lactamase enzyme that digests the active moiety of penicillin.

pentose phosphate (hexose monophosphate) pathway A glycolytic pathway that oxidizes glucose 6-phosphate to ribulose 5-phosphate and then converts it to a variety of three to seven carbon sugars.

peplomer (spike) (pep′lo-mer) A protein or protein complex that extends from the viral envelope and often is important in virion attachment to the host cell surface.

peptide interbridge A short peptide chain that connects the tetrapeptide chains in the peptidoglycan of some bacteria.

peptidoglycan (pep″tĭ-do-gli′kan) A large polymer composed of long chains of alternating *N*-acetylglucosamine and *N*-acetylmuramic acid residues. The polysaccharide chains are linked to each other through connections between tetrapeptide chains attached to the *N*-acetylmuramic acids. It provides much of the strength and rigidity possessed by bacterial cell walls; also called murein.

peptidyl or donor site (P site) The site on the ribosome that contains the peptidyl-tRNA at the beginning of the elongation cycle during protein synthesis.

peptidyl transferase The ribozyme that catalyzes the transpeptidation reaction in protein synthesis; in this reaction, an amino acid is added to the growing peptide chain.

perforin Pore-forming proteins secreted along with granzymes by cytotoxic T lymphocytes and NK cells.

peripheral membrane protein *See* plasma membrane.

peripheral tolerance The process by which self-reactive B and T cells are inhibited in body tissues other than bone marrow and thymus, respectively.

periplasm (per′ĭ-plaz-əm) The substance that fills the periplasmic space.

periplasmic flagella The flagella that lie under the outer sheath and extend from both ends of a spirochete cell to overlap in the middle and form the axial filament. Also called axial fibrils, axial filaments, and endoflagella.

periplasmic space The space between the plasma membrane and the outer membrane in typical Gram-negative bacteria, and between the plasma membrane and the cell wall in typical Gram-positive bacteria. A similar space is sometimes observed between the plasma membrane and the cell wall of some archaea.

peristalsis The muscular contractions of the gut that propel digested foods and waste through the intestinal tract.

peritrichous (pĕ-rit′rĭ-kus) A cell with flagella distributed over its surface.

peronosporomycetes Name for öomycetes, a subgroup of *Stramenopila,* distinguished by the formation of large egg cells when they reproduce.

persisters Variants of microbial cells in a population that are resistant to antibiotics.

phage (fāj) *See* bacteriophage.

phagocytic vacuole A membrane-delimited vacuole produced by cells carrying out phagocytosis. It is formed by the invagination of the plasma membrane and contains solid material.

phagocytosis The endocytotic process in which a cell encloses large particles in a phagocytic vacuole (phagosome) and engulfs them.

phagolysosome The vacuole that results from the fusion of a phagosome with a lysosome.

phagosome A membrane-enclosed vacuole formed by the invagination of the cell membrane during endocytosis.

phase-contrast microscope A microscope that converts slight differences in refractive index and cell density into easily observed differences in light intensity.

phenetic system A classification system that groups organisms together based on the similarity of their observable characteristics.

phenol coefficient test A measurement of the effectiveness of disinfectants that compares their activity against test bacteria with that of phenol.

phenotype Observable characteristics of an organism.

phenotypic rescue The identification of a cloned gene based on its ability to complement a genetic deficiency in the host cell.

phosphatase (fos′fah-tās″) An enzyme that catalyzes the hydrolytic removal of phosphate from molecules.

phosphoenolpyruvate:sugar phosphotransferase system (PTS) A group translocation system used by many bacteria. As a sugar is transported into the cell, the hydrolysis of a high-energy phosphate bond fuels its import, and the sugar is modified by the covalent attachment of the phosphoryl group.

phosphorelay system A set of proteins involved in the transfer of phosphate from one protein in the set to another. It is often used to regulate protein activity or transcription.

photic zone The illuminated area of an aquatic habitat from the surface to the depth to which the rate of photosynthesis equals that of respiration.

photoautotroph *See* photolithoautotroph.

photolithoautotroph An organism that uses light energy, an inorganic electron source (e.g., H_2O, H_2, H_2S), and CO_2 as its carbon source. Also called photolithotrophic autotroph or a photoautotroph.

photoorganoheterotroph A microorganism that uses light energy, organic electron sources, and organic molecules as a carbon source. Also called photoorganotrophic heterotroph.

photophosphorylation The synthesis of ATP from ADP using energy made available by the absorption of light.

photoreactivation The process in which blue light is used by an enzyme to repair thymine dimers in DNA.

photosynthate Nutrient material released from phototrophic organisms and contributes to the pool of dissolved organic matter.

photosynthesis The trapping of light energy and its conversion to chemical energy (light reactions), which is then used to reduce CO_2 and incorporate it into organic molecules (dark reactions).

photosystem I The photosystem in eukaryotic cells and cyanobacteria that absorbs longer wavelength light, usually greater than about 680 nm, and transfers the energy to chlorophyll P700 during photosynthesis; it is involved in both cyclic and noncyclic photophosphorylation.

photosystem II The photosystem in eukaryotic cells and cyanobacteria that absorbs shorter wavelength light, usually less than 680 nm, and transfers the energy to chlorophyll P680 during photosynthesis; it participates in noncyclic photophosphorylation.

phototaxis The ability of certain phototrophic organisms to move in response to a light source.

phototrophs Organisms that use light as their energy source.

phycobiliproteins Photosynthetic pigments found in cyanobacteria that are composed of proteins with attached tetrapyrroles.

phycobilisomes Particles on the membranes of cyanobacteria that contain photosynthetic pigments.

phycobiont (fi″ko-bi′ont) The photosynthetic protist or cyanobacterial partner in a lichen.

phycocyanin (fi″ko-si′an-in) A blue phycobiliprotein pigment used to trap light energy during photosynthesis.

phycoerythrin (fi″ko-er′i-thrin) A red photosynthetic phycobiliprotein pigment used to trap light energy.

phycology (fi-kol′o-je) The study of algae.

phyletic classification system *See* phylogenetic classification system.

phyllosphere The surface of plant leaves.

phylochip *See* phylogenetic oligonucleotide arrays.

phylogenetic classification system A classification system based on evolutionary relationships, rather than the general similarity of characteristics.

phylogenetic oligonucleotide arrays Microarrays that contain rRNA sequences as probes and are used as a means to detect complementary rRNA sequences from the environment.

phylogenetic tree A graph made of nodes and branches, much like a tree in shape, that shows phylogenetic relationships between groups of organisms and sometimes also indicates the evolutionary development of groups.

phylogeny The evolutionary development of a species.

phylotype A taxon that is characterized only by its nucleic acid sequence; generally discovered during metagenomic analysis.

physical map In genomics, this refers to a diagram of a chromosome, gene, or other genetic element that shows restriction endonuclease recognition sites. Specific genes and other genetic elements (e.g., origin of replication) may also be noted.

phytoplankton A community of floating photosynthetic organisms, composed of photosynthetic protists and cyanobacteria.

picoplankton Planktonic microbes between 0.2 and 2.0 μm in size, including the cyanobacterial genera *Prochlorococcus* and *Synechococcus*.

piezophilic (pi-e-zo-fil′ic) Describing organisms that prefer or require high pressures for growth and reproduction.

pili (s., pilus) *See* fimbria.

pitching Pertaining to inoculation of a nutrient medium with yeast, for example, in beer brewing.

plaque A clear area in a lawn of host cells that results from their lysis by viruses.

plaque assay A method used to determine the number of infectious virions.

plaque-forming unit The unit of measure of a plaque assay. It usually represents a single infectious virion.

plasma cell A mature, differentiated B lymphocyte that synthesizes and secretes antibody.

plasmalemma The plasma membrane in protists.

plasma membrane The selectively permeable membrane surrounding the cell's cytoplasm; also called the cell membrane, plasmalemma, or cytoplasmic membrane. For most cells it is a lipid bilayer (some archaea have a lipid monolayer) with proteins embedded in it (integral membrane proteins) and associated with the surface (peripheral membrane proteins).

plasmid A double-stranded DNA molecule that can exist and replicate independently of the chromosome. A plasmid is stably inherited but is not required for the host cell's growth and reproduction.

plasmid fingerprinting A technique used to identify microbial isolates as belonging to the same strain because they contain the same number of plasmids with the identical molecular weights and similar phenotypes.

plasmodial (acellular) slime mold A member of the protist division *Amoebozoa (Myxogastria)* that exists as a thin, streaming, multinucleate mass of protoplasm (plasmodium) for some portion of its life cycle.

plasmolysis (plaz-mol′i-sis) The process in which water osmotically leaves a cell, which causes the cytoplasm to shrivel up and pull the plasma membrane away from the cell wall.

plastid A cytoplasmic organelle of algae and higher plants that contains pigments such as chlorophyll, stores food reserves, and often carries out processes such as photosynthesis.

pleomorphic (ple″o-mor′fik) Refers to cells or viruses that are variable in shape and lack a single, characteristic form.

plus (positive) strand A viral nucleic acid strand that is equivalent in base sequence to the viral mRNA.

point mutation A mutation that affects only a single base pair.

polar flagellum A flagellum located at one end of an elongated cell.

3′ poly-A tail *See* pre-mRNA.

poly-β-hydroxybutyrate (PHB) A linear polymer of β-hydroxybutyrate used as a reserve of carbon and energy by many bacteria.

polycistronic mRNA An mRNA that has more than one coding region; formed when an operon is transcribed.

polyhistidine tagging (His-tagging) A method by which a protein is fused to six histidine residues, thereby facilitating the protein's purification through affinity chromatography.

polymerase chain reaction (PCR) An in vitro technique used to synthesize large quantities of specific nucleotide sequences from small amounts of DNA. It employs oligonucleotide primers complementary to specific sequences in the target gene and special heat-stable DNA polymerases (e.g., Taq polymerase).

polymorphonuclear leukocyte (pol″e-mor″fo-noo′kle-ər) A leukocyte that has a variety of nuclear forms.

polyphasic taxonomy An approach in which taxonomic schemes are developed using a wide range of phenotypic and genotypic information.

polyprotein A large polypeptide that contains several proteins, which are released when the polyprotein is cut by proteases. Polyproteins are often produced by viruses having positive-strand RNA genomes.

polyribosome (pol″e-ri′bo-sōm) A complex of several ribosomes translating a single messenger RNA.

population An assemblage of organisms of the same type.

porin proteins Proteins that form channels across the outer membrane of typical Gram-negative bacterial cell walls through which small molecules enter the periplasm.

portal of entry Body surface that is the initial site of pathogen access to the host.

positive transcriptional control Control of transcription by an activator protein. When the activator is bound to the activator-binding site, the level of transcription increases.

postherpetic neuralgia The severe pain after a herpes infection.

posttranslational regulation Alteration of the activity of a protein after it has been synthesized by a structural modification, such as phosphorylation or a conformational change. *See also* allosteric enzyme and reversible covalent modification.

pour plate A Petri dish of solid culture medium with isolated microbial colonies growing both on its surface and within the medium that has been prepared by mixing microorganisms with cooled, still-liquid medium and then allowing the medium to harden.

precipitation (precipitin) reaction The reaction of an antibody with a soluble antigen to form an insoluble precipitate.

precipitin The antibody responsible for a precipitation reaction.

precursor metabolites Intermediates of glycolytic pathways, TCA cycle, and other pathways that serve as starting molecules for biosynthetic pathways that generate monomers and other building blocks needed for synthesis of macromolecules.

pre-mRNA In eukaryotes, the RNA transcript of DNA made by RNA polymerase II prior to processing to form mRNA by the addition of the 5′ cap and 3′ poly-A tail, and the removal of introns.

presence-absence (P-A) test An assay designed to detect the presence of coliforms in water; a positive result must be confirmed by a different assay.

prevalence rate Refers to the total number of individuals infected at any one time in a given population regardless of when the disease began.

Pribnow box A base sequence in bacterial promoters that is recognized by RNA polymerase and is the site of initial polymerase binding.

primary active transport *See* active transport.

primary metabolites Microbial metabolites produced during active growth of an organism.

primary mRNA *See* pre-mRNA.

primary producer Photoautotrophic and chemoautotrophic organisms that incorporate carbon dioxide into organic carbon and thus provide new biomass for the ecosystem.

primary production The incorporation of carbon dioxide into organic matter by photosynthetic organisms and chemoautotrophic organisms.

primary treatment The first step of sewage treatment, in which physical settling and screening are used to remove particulate materials.

primase *See* primosome.

primers *See* polymerase chain reaction and primosome.

primosome In bacteria, a complex of proteins that includes the enzyme primase, responsible for synthesizing the RNA primers needed for DNA replication.

prion (pre′on) An infectious agent consisting only of protein; prions cause a variety of spongiform encephalopathies such as scrapie in sheep.

probe A short, labeled nucleic acid segment complementary in base sequence to part of another nucleic acid that is used to identify or isolate the particular nucleic acid from a mixture through its ability to bind specifically with the target nucleic acid.

probiotic A living microorganism that may provide health benefits beyond its nutritional value when ingested.

prochlorophytes A group of cyanobacteria having both chlorophyll *a* and *b* but lacking phycobilins.

prodromal stage (pro-dro′məl) The period during the course of a disease when signs and symptoms are present, but they are not yet distinctive enough for an accurate diagnosis.

production strains Microbial strains used in industrial processes that have been engineered to generate a high yield of the desired product.

programmed cell death (1) In eukaryotes, apoptosis. (2) In some bacteria, a mechanism proposed to account for the decline in cell numbers during the death phase of a growth curve. *See also* apoptosis.

prokaryotic cells (pro″kar-e-ot′ik) Cells having a type of structure characterized by the lack of a true, membrane-enclosed nucleus. All known members of *Archaea* and most members of *Bacteria* exhibit this type of cell structure; some members of the bacterial phylum *Planctomycetes* have a membrane surrounding their genetic material.

promoter The region on DNA at the start of a gene that RNA polymerase binds to before beginning transcription.

proofreading The ability of enzymes to check their products to ensure that the correct product is made. For instance, DNA polymerase checks newly synthesized DNA and replaces an incorrect nucleotide with the correct one prior further synthesis.

propagated epidemic An epidemic that is characterized by a relatively slow and prolonged rise and then a gradual decline in the number of individuals infected. It usually results from the introduction of an infected individual into a susceptible population and transmission of the pathogen from person to person.

prophage (pro′fāj) **(provirus)** (1) The latent form of a temperate bacterial or archaeal virus that remains within the lysogen, usually integrated into the host chromosome. (2) The form of a eukaryotic virus that remains within the host cell during a latent infection. Also refers to a retroviral genome after it has been integrated into the host's chromosome.

prostheca (pros-the′kah) An extension of a bacterial cell, including the plasma membrane and cell wall, that is narrower than the mature cell.

prosthetic group A tightly bound cofactor that remains at the active site of an enzyme during its catalytic activity.

protease (pro′te-ās) An enzyme that hydrolyzes proteins. Also called a proteinase.

proteasome A large, cylindrical protein complex observed in eukaryotic cells that degrades ubiquitin-labeled proteins to peptides in an ATP-dependent process. Also called 26S proteasome. Similar protein-degrading machinery has been observed in some archaea and bacteria.

protein modeling The process by which the amino acid sequence of a protein is analyzed using software designed to predict the protein's three-dimensional structure.

protein splicing The posttranslational process in which part of a precursor polypeptide is removed before the mature polypeptide folds into its final shape; it is carried out by self-splicing proteins that remove inteins and join the remaining exteins.

proteome The complete collection of proteins that an organism produces.

proteomics The study of the structure and function of cellular proteins.

proteorhodopsin A rhodopsin molecule first identified in marine proteobacteria but since found in a variety of microbes. It enables rhodopsin-based phototrophy. *See also* archaerhodopsin.

protist Unicellular and sometimes colonial eukaryotic organisms that lack cellular differentiation into tissues. Many chemoorganotrophic protists are referred to as protozoa; many phototrophic protists are referred to as algae.

protistology The study of protists.

protomer An individual protein of a viral capsid; a capsomer is made of protomers.

proton motive force (PMF) The potential energy arising from a gradient of protons and a membrane potential that powers ATP synthesis and other processes.

proto-oncogene Normal cellular gene that when mutated or overexpressed contributes to malignant transformation of a cell.

protoplast (1) The plasma membrane and everything within it. (2) A bacterial, archaeal, or fungal cell with its cell wall completely removed. It is spherical in shape and osmotically sensitive.

protoplast fusion The joining of cells that have had their walls weakened or completely removed.

prototroph A microorganism that requires the same nutrients as the majority of naturally occurring members of its species.

protozoa (pro″to-zo′a) A common term for a group of unrelated unicellular, chemoorganotrophic protists.

protozoology The study of protozoa.

provirus *See* prophage.

pseudogene A degraded, nonfunctional gene.

pseudomurein A complex polysaccharide observed in the cell walls of some archaea; it resembles peptidoglycan (murein) in structure and chemical make-up; also called pseudopeptidoglycan.

pseudopodium or pseudopod (soo″do-po′de-um) A nonpermanent cytoplasmic extension of the cell by which amoeboid protists move and feed.

psychrophile (si′kro-fīl) A microorganism that has an optimum growth temperature of 15°C or lower and a temperature maximum around 20°C.

psychrotolerant (psychrotroph) A microorganism that has a growth optimum between 20 and 30°C and a maximum of about 35°C.

PulseNet A program developed and overseen by the Centers for Disease Control and Prevention in which pulse-field gel electrophoresis is used to characterize pathogens found to contaminate food in an effort to detect and track these microbes.

punctuated equilibria The observation based on the fossil record that evolution does not proceed at a slow and linear pace but rather is periodically interrupted by rapid bursts of speciation and extinction driven by abrupt changes in environmental conditions.

pure (axenic) culture A population of cells that are identical because they arise from a single cell.

purine (pu′rēn) A heterocyclic, nitrogen-containing molecule with two joined rings that occurs in nucleic acids and other cell constituents (e.g., adenine and guanine).

purple membrane An area of the plasma membrane of *Halobacterium* that contains archaerhodopsin and is active in trapping light energy.

purple nonsulfur bacteria Anoxygenic photosynthetic α- and β-proteobacteria.

purple sulfur bacteria Anoxygenic photosynthetic γ-proteobacteria.

putrefaction The microbial decomposition of organic matter, especially the anaerobic breakdown of proteins, with the production of foul-smelling compounds such as hydrogen sulfide and amines.

pyogenic Pus-producing.

pyrenoid (pi′rĕ-noid) The differentiated region of the chloroplast that is a center of starch formation in some photosynthetic protists.

pyrimidine (pi-rim′i-dēn) A nitrogen-containing molecule with one ring that occurs in nucleic acids and other cell constituents; the most important pyrimidines are cytosine, thymine, and uracil.

pyruvate formate-lyase (PFL) An enzyme system that cleaves pyruvate into formic acid and acetyl-CoA. It is used by enteric bacteria that perform mixed acid fermentation.

Q

Q cycle The process associated with proton movement across the membrane at complex III of an electron transport chain.

Quellung reaction The increase in visibility or the swelling of the capsule of a microorganism in the presence of antibodies against capsular antigens.

quinine drugs Antimicrobial chemotherapeutic agents derived from the bark of the cinchona tree and used to treat malaria.

quinolones A class of broad-spectrum, bacteriocidal antibiotics, derived from nalidixic acid, that bind to DNA gyrase, inhibiting DNA replication.

quorum sensing The process in which bacteria monitor their own population density or the presence of other species of bacteria by sensing the levels of signal molecules (e.g., *N*-acylhomoserine lactone) released by the microorganisms. When these signal molecules reach a threshold concentration, quorum-dependent genes are expressed.

R

racking The removal of sediments from wine bottles.

radappertization The use of gamma rays from a cobalt source for control of microorganisms in foods.

radioimmunoassay (RIA) (ra″de-o-im″u-no-as′a) A sensitive assay in which a purified radioisotope-labeled antigen or antibody competes for antibody or antigen with unlabeled standard antigen or test antigen in experimental samples to determine the concentration of a substance in the samples.

rapid plasmid reagin A rapid diagnostic test for syphilis.

rapid sand filters A step in drinking water purification that removes particulates by passage over sand.

reaction-center chlorophyll pair The two chlorophyll molecules in a photosystem that are energized by the absorption of light and release electrons to an associated electron transport chain, thus initiating energy conservation by photophosphorylation.

reactive nitrogen intermediate (RNI) Charged nitrogen radicals.

reactive oxygen intermediate (ROI) *See* reactive oxygen species (ROS).

reactive oxygen species (ROS) Superoxide radical (O_2^-.), hydrogen peroxide (H_2O_2), singlet oxygen ($^1O_2$), and hydroxyl radical (OH^-) derivatives of oxygen.

reading frame The way in which nucleotides in DNA and mRNA are grouped into codons for reading the message contained in the nucleotide sequence.

readthrough A phenomenon in which a ribosome ignores a stop codon and continues protein synthesis. This generates a different protein than that produced if the ribosome had stopped at the stop codon.

reagin (re′ah-jin) Antibody that mediates immediate hypersensitivity reactions. IgE is the major reagin in humans.

real-time PCR A type of polymerase chain reaction (PCR) that quantitatively measures the amount of template in a sample as the amount of fluorescently labeled amplified product.

RecA A protein that functions in DNA repair and recombination processes. Homologues of RecA have been found in all three domains of life.

receptor-mediated endocytosis *See* endocytosis.

receptors Proteins that bind signaling molecules (ligands), thereby initiating cellular responses.

recognition sites Specific nucleotide sequences to which DNA-binding proteins (e.g., regulatory proteins, sigma factors, restriction enzymes) bind.

recombinant DNA technology The techniques used in carrying out genetic engineering.

recombinants Organisms produced following a recombination event.

recombinant-vector vaccine A vaccine produced by the introduction of one or more of a pathogen's genes into attenuated viruses or bacteria, which serves as a vector, replicating within the vertebrate host and expressing the gene(s) of the pathogen. The pathogen's antigens induce an immune response.

recombinases Enzymes that catalyze integration and excision of DNA segments during site-specific recombination.

recombination The process in which a new recombinant chromosome is formed by combining genetic material from two different nucleic acids. In some cases, the nucleic acids are from two different organisms.

recombinational repair A DNA repair process that repairs damaged DNA when there is no remaining template; a piece of DNA from a sister molecule is used.

red tides Population blooms of dinoflagellates that release red pigments and toxins, which can lead to paralytic shellfish poisoning. *See also* harmful algal blooms.

redox potential The tendency of a chemical compound or system to accept electrons; more formally called oxidation-reduction potential.

reducing power Molecules such as NADH and NADPH that temporarily store electrons. The stored electrons are used in anabolic reactions such as CO_2 fixation and the synthesis of monomers (e.g., amino acids).

reductive amination pathway A mechanism used by many microbes to incorporate ammonia.

reductive dehalogenation The cleavage of carbon-halogen bonds by anaerobic bacteria that creates a strong electron-donating environment.

reductive TCA cycle A pathway used by some chemolithotrophs and some anoxygenic phototrophs to fix CO_2. It involves the TCA cycle running in the reverse direction; also called reverse citric acid cycle.

refractive index A measure of how much a substance deflects a light ray from a straight path as it passes from one medium (e.g., glass) to another (e.g., air). It is calculated as the ratio of the velocity of light passing through the first medium to that of light passing through the second medium.

regulatory site *See* allosteric enzyme.

regulatory T cells (Tregs) T cells that control the development of effector T cells and B cells.

regulon A collection of genes or operons that is controlled by a common regulatory protein.

remote sensing The gathering of data and transformation of data into maps.

replica plating A technique for isolating mutants by transferring cells from an agar plate with nonselective medium to a piece of velvet and then onto plates with selective media or environmental conditions.

replicase An RNA-dependent RNA polymerase used to replicate the genome of an RNA virus.

replication The process in which an exact copy of parental DNA (or viral RNA) is made with the parental molecule serving as a template.

replication fork The Y-shaped structure where DNA is replicated.

replicative form (RF) A double-stranded nucleic acid that is formed from a single-stranded viral genome and used to synthesize mRNA and new copies of the genome.

replicative transposition A transposition event in which a replicate of the transposon remains in its original site.

replicon A unit of the genome that contains an origin of replication and in which DNA is replicated.

replisome A large protein complex that copies the DNA double helix to form two daughter chromosomes.

repressible gene A gene that encodes a protein whose level drops in the presence of a small molecule. If the gene product is a biosynthetic enzyme, the small molecule is often an end product of the metabolic pathway in which it functions.

repressor protein A protein that can bind to a repressor-binding site and inhibit transcription.

reservoir A site, alternate host, or carrier that normally harbors pathogenic organisms and serves as a source from which other individuals can be infected.

reservoir host An organism other than a human infected with a pathogen that can also infect humans.

residual body A lysosome after digestion of its contents has occurred. It contains undigested material.

resolution The ability of a microscope to distinguish between small objects that are close together.

respiration An energy-yielding process in which the energy substrate is oxidized using an exogenous or externally derived electron acceptor.

respiratory burst An increase in oxygen consumption by an activated phagocytic cell to generate highly toxic oxygen products such as

singlet oxygen, superoxide radical, hydrogen peroxide, hydroxyl radical, and hypochlorite within the phagolysosome.

response regulator *See* two-component signal transduction system.

restriction A process used by bacteria to defend the cell against viral infection; accomplished by enzymes that cleave the viral DNA; also called host restriction.

restriction enzymes Enzymes produced by bacterial cells that cleave DNA at specific nucleotide sequences. They evolved to protect bacteria from viral infection and are used in genetic engineering.

restriction fragment length polymorphism (RFLP) Fragments of DNA of different sizes following endonuclease cleavage. The differences can be used to determine genetic similarity among organisms.

reticulate body (RB) The cellular form in the chlamydial life cycle that grows and reproduces within the host cell.

reticulopodia Netlike pseudopodia found in certain amoeboid protists.

retroviruses A group of viruses with RNA genomes that carry the enzyme reverse transcriptase and form a DNA copy of their genome during their life cycle.

reverse electron flow An energy-consuming process used by some chemolithotrophs and phototrophs to generate reducing power.

reverse transcriptase (RT) A multifunctional enzyme used by retroviruses and reverse transcribing DNA viruses during their life cycles. It has RNA-dependent DNA polymerase, DNA-dependent DNA polymerase, and RNAase activity. It synthesizes double-stranded DNA from single-stranded RNA.

reverse vaccinology The use of genomics to identify candidate target molecules on a pathogen for vaccine development.

reversible chain termination sequencing A next-generation DNA sequencing technique that incorporates fluorescently labeled nucleotides that bear a small molecule on the 3′ OH to block addition of the next nucleotide triphosphate. Once the incorporation of the modified base is recorded, the blocking molecule is removed, leaving an unmodified 3′ OH so the next labeled, modified base can be incorporated and recorded; the process continues in an iterative fashion.

reversible covalent modification A mechanism of enzyme regulation in which the enzyme's activity is either increased or decreased by the reversible covalent addition of a group such as phosphate or AMP to the protein.

reversion mutation A mutation in a mutant organism that changes its phenotype back to the wild type; the second mutation is at the same site as the initial mutation.

rhizobia Any one of a number of α- and β-proteobacteria that form symbiotic nitrogen-fixing nodules on the roots of leguminous plants.

rhizomorph A macroscopic, densely packed thread consisting of individual cells formed by some fungi. A rhizomorph can remain dormant or serve as a means of fungal dissemination.

rhizoplane The surface of a plant root.

rhizosphere A region around the plant root where materials released from the root increase the microbial population and its activities.

ribonucleic acid (RNA) A polynucleotide composed of ribonucleotides joined by phosphodiester bonds.

ribosomal frameshifting A phenomenon in which a ribosome shifts the reading frame of the message, thus generating a different protein than it would have if it had stopped at the stop codon.

ribosomal RNA (rRNA) The RNA present in ribosomes; contributes to ribosome structure and also directly involved in the mechanism of protein synthesis.

ribosome The organelle where protein synthesis occurs; the message encoded in mRNA is translated here.

ribosome-binding site (RBS) Nucleotide sequences on mRNA recognized by a ribosome, so that it orients properly on the mRNA and begins translation at the appropriate codon.

riboswitch A site in the leader of an mRNA molecule that interacts with a metabolite or other small molecule, causing the leader to change its folding pattern. In some riboswitches, this change can alter transcription; in others, it affects translation.

ribotyping The use of conserved rRNA sequences to probe chromosomal DNA for classifying bacterial strains.

ribozyme An RNA molecule with catalytic activity.

ribulose 1,5-bisphosphate carboxylase/oxygenase (RubisCO) The enzyme that catalyzes incorporation of CO_2 in the Calvin-Benson cycle.

RNA-dependent DNA polymerase An enzyme that synthesizes DNA using an RNA template; also called reverse transcriptase.

RNA-dependent RNA polymerase An enzyme that synthesizes RNA using an RNA template.

RNA polymerase An enzyme that catalyzes the synthesis of RNA.

RNA polymerase core enzyme The portion of bacterial RNA polymerase that synthesizes RNA. It consists of all subunits except sigma factor.

RNA polymerase holoenzyme Bacterial RNA polymerase core enzyme plus sigma factor.

RNA-seq Direct sequencing of total cellular mRNA.

RNA silencing A response made by eukaryotic cells that protects them from infections caused by double-stranded RNA viruses.

RNA world The theory that posits that the first self-replicating molecule was RNA and this led to the evolution of the first primitive cell.

rolling-circle replication A mode of DNA replication in which the replication fork moves around a circular DNA molecule, displacing a strand to give a 5′ tail that is also copied to produce new double-stranded DNA.

root nodule Gall-like structures on roots that contain endosymbiotic nitrogen-fixing bacteria.

rough endoplasmic reticulum (RER) *See* endoplasmic reticulum.

R plasmids (R factors) Plasmids bearing one or more drug-resistance genes.

S

sac fungi Common name for the *Ascomycota*.

sanitization Reduction of the microbial population on an inanimate object to levels judged safe by public health standards.

saprophyte (sap′ro-fīt) An organism that takes up nonliving organic nutrients in dissolved form and usually grows on decomposing organic matter.

SAR11 The most abundant group of microbes on Earth, this lineage of α-proteobacteria has been found in almost all marine ecosystems studied.

satellites Subviral infectious agents composed of DNA or RNA encapsidated with the aid of an unrelated helper virus.

scale-up The process of increasing the volume of a culture from a small, experimental system to a large-volume system for the production of an industrially important compound.

scanning electron microscope (SEM) An electron microscope that passes a beam of electrons over the surface of a specimen; an image is formed from the electrons that are emitted by the specimen.

scanning probe microscope A microscope used to study surface features by moving a sharp probe over the object's surface (e.g., atomic force and scanning tunneling microscopes).

scanning tunneling microscope *See* scanning probe microscope.

sclerotia (sklĕ-ro′she-ə) Compact masses of hyphae produced by some filamentous fungi that permit overwintering. In the spring, they germinate to produce either additional hyphae or conidia.

Sec system A system found in all domains of life that transports a protein through or inserts it into a membrane.

secondary active transport *See* active transport.

secondary metabolites Products of metabolism that are synthesized after growth has been completed. Antibiotics are considered secondary metabolites.

secondary treatment The biological degradation of dissolved organic matter in the process of sewage treatment; the organic material is either mineralized or changed to settleable solids.

second law of thermodynamics Physical and chemical processes proceed in such a way that the entropy of the universe (the system and its surroundings) increases to the maximum possible.

second messengers Small molecules that are made in response to an extracellular signal (the first messenger). They "pass" the message to effector molecules that bring about the appropriate response to the signal.

secretory IgA (sIgA) The class of immunoglobulin associated with mucous membranes. *See also* IgA.

secretory pathway The process used by eukaryotic cells to synthesize proteins and lipids,

followed by secretion or delivery to organelles or the plasma membrane.

sedimentation basin A containment vessel used during surface water purification. Following the addition of material to facilitate the formation of coagulated impurities, water is left until such material has precipitated, forming sediment at the bottom of the basin.

segmented genome A viral genome that is divided into several parts or fragments, each usually coding for a single polypeptide.

selectable marker A gene conferring a wild-type or mutant phenotype that can be determined by growth on specific media.

selectins A family of cell adhesion molecules displayed on activated endothelial cells; mediate leukocyte binding to the vascular endothelium.

selective media Culture media that favor the growth of specific microorganisms; this may be accomplished by inhibiting the growth of undesired microorganisms.

selective toxicity The ability of a chemotherapeutic agent to kill or inhibit a microbial pathogen while damaging the host as little as possible.

self-assembly The spontaneous formation of a complex structure from its component molecules without the aid of special enzymes or factors.

sense codon A codon that specifies an amino acid.

sensor kinase *See* two-component signal transduction system.

sensory rhodopsin Microbial rhodopsin that senses the spectral quality of light. *See also* archaerhodopsin.

sepsis Systemic response to infection manifested by two or more of the following conditions: temperature >38°C or <36°C; heart rate >90 beats per min; respiratory rate >20 breaths per min, or pCO_2 <32 mm Hg; leukocyte count >12,000 cells per ml^3 or >10% immature (band) forms. Sepsis also has been defined as the presence of pathogens or their toxins in blood and other tissues.

septate hyphae Fungal hyphae (filaments) having cross walls.

septation The process of forming a cross wall between two daughter cells during cell division.

septicemia (sep″tĭ-se′me-ah) A disease associated with the presence in the blood of pathogens or bacterial toxins.

septic shock Sepsis associated with severe hypotension despite adequate fluid resuscitation, along with the presence of perfusion abnormalities that may include but are not limited to lactic acidosis, oliguria, or an acute alteration in mental status.

septic tank A tank used to process domestic sewage. Solid material settles out and is partially degraded by anaerobic bacteria as sewage slowly flows through the tank. The outflow is further treated or dispersed in oxic soil.

septum (pl., **septa**) A partition that is used to separate cellular material. Septa are formed during cell division to divide the two daughter cells. They also separate cells in filamentous organisms and a developing endospore from its mother cell.

sequencing by synthesis Any DNA sequencing technology that determines the nucleotide sequence as labeled nucleotides are incorporated.

serology The branch of immunology that is concerned with in vitro reactions involving one or more serum constituents (e.g., antibodies and complement).

serotyping A technique or serological procedure used to differentiate between strains (serovars or serotypes) of microorganisms that have differences in the antigenic composition of a structure or product.

serovar A variant strain of a microbe that has distinctive antigenic properties.

settling basin A basin used during water purification to chemically precipitate fine particles, microorganisms, and organic material by coagulation or flocculation.

sex pilus (pĭ′lus) A thin protein appendage required for bacterial conjugation. The cell with sex pili donates DNA to recipient cells.

sheath A hollow, tubelike structure surrounding a cell; present in some genera of bacteria.

Shine-Dalgarno sequence A segment in the leader of bacterial mRNA and some archaeal mRNA that binds to a sequence on the 16S rRNA of the small ribosomal subunit. This helps properly orient the mRNA on the ribosome.

shuttle vector A DNA vector (e.g., plasmid, cosmid) that has two origins of replication, each recognized by a different microorganism. Thus the vector can replicate in both microbes.

siderophore (sid′er-o-for″) A small molecule that complexes with ferric iron and supplies it to a cell by aiding in its transport across the plasma membrane.

sigma factor A protein that helps bacterial RNA polymerase core enzyme recognize the promoter at the start of a gene. Thus, it is a transcription factor.

sign An objective change in a diseased body that can be directly observed (e.g., a fever or rash).

signal 1 Primary lymphocyte activation that occurs when antigen is presented to the lymphocyte by its appropriate MHC molecule on the presenting cell.

signal 2 Confirmatory event causing lymphocytes stimulated by signal 1 to complete activation and thus become effector cells.

signal peptide The amino terminal sequence on a protein destined for transport through or into a membrane. It delays protein folding and is recognized by the Sec system.

signal recognition particle A complex of a small RNA and a protein that directs a polypeptide and its translating ribosome to the Sec system during cotranslational translocation.

silage Fermented plant material with increased palatability and nutritional value for animals, which can be stored for extended periods.

silencers Sites on eukaryotic chromosomes to which repressor proteins bind.

silent mutation A mutation that does not change an organism's proteins or phenotype even though the DNA base sequence has been changed.

simple (cut-and-paste) transposition A transposition event in which the transposable element is cut out of one site and ligated into a new site.

single-cell genomic sequencing A method whereby the genome of a single microbial cell is copied many times by the multiple displacement amplification (MDA) technique. The genome is then sequenced by a next-generation technique.

single nucleotide polymorphism (SNP) Difference of one base in genes or genetic elements that are otherwise highly conserved among members of a given taxon.

single radial immunodiffusion (RID) assay An immunodiffusion technique that quantitates antigens by following their diffusion through a gel containing antibodies directed against the test antigens.

site-directed mutagenesis The in vitro process by which a specific nucleotide change is made to a particular gene.

site-specific recombination Recombination between two DNA molecules that does not involve extensive areas of homology between the two molecules. It is catalyzed by enzymes called recombinases distinct from RecA, and it is the mechanism by which transposition occurs.

skin-associated lymphoid tissue (SALT) The lymphoid tissue in the skin that forms a first-line defense as a part of innate immunity.

S-layer A regularly structured layer composed of protein or glycoprotein that lies on the surface of many bacteria and archaea.

slime The viscous extracellular glycoproteins or glycolipids produced by some bacteria. *See also* slime layer.

slime layer A layer of diffuse, unorganized, easily removed material lying outside an archaeal or bacterial cell wall.

slime mold A common term for members of the protist taxa *Myxogastria* and *Dictyostelia*.

slow sand filter A bed of sand through which water slowly flows; the gelatinous microbial layer on the sand grain surface removes waterborne microorganisms, particularly *Giardia*.

sludge A general term for the precipitated solid matter produced during water and sewage treatment; solid particles composed of organic matter and microorganisms that are involved in aerobic sewage treatment (activated sludge).

small interfering RNAs (siRNAs) Small RNA molecules that affect either transcription of target genes or translation of target mRNAs.

small RNAs (sRNAs) Small regulatory RNA molecules that do not function as messenger, ribosomal, or transfer RNAs.

small subunit rRNA (SSU rRNA) The rRNA associated with the small ribosomal subunit: 16S rRNA in bacterial and archaeal cells and 18S rRNA in eukaryotes.

smooth endoplasmic reticulum *See* endoplasmic reticulum.

snapping division A distinctive type of binary fission resulting in an angular or a palisade arrangement of cells; characteristic of members of the genera *Arthrobacter* and *Corynebacterium*.

soil organic matter (SOM) The organic material within a soil; organic material is important because it helps to retain nutrients, maintain soil structure, and hold water for plant use.

SOS response A complex, inducible process that allows bacterial cells with extensive DNA damage to survive, although often in a mutated form; it involves cessation of cell division, upregulation of several DNA repair systems, and induction of translesion DNA synthesis.

sour mash Liquid mixture of fermented grain that is reserved from one batch of distilled spirits to start the fermentation of a new batch; used in the production of whiskey and bourbon.

Southern blotting technique A procedure used to isolate and identify DNA fragments from a complex mixture. The isolated, denatured fragments are transferred from an agarose gel to a nylon filter and identified by hybridization with oligonucleotide probes.

specialized transduction A transduction process in which only a specific set of bacterial or archaeal genes is carried to a recipient cell by a temperate virus; the cell's genes are acquired because of a mistake in the excision of a provirus during the lysogenic life cycle.

species Species of higher organisms are groups of interbreeding or potentially interbreeding natural populations that are reproductively isolated. Archaeal and bacterial species are often defined as collections of strains that have many stable properties in common and differ significantly from other strains. However, there is currently considerable debate about the best definition of archaeal and bacterial species.

specific immune response *See* adaptive immunity.

specific immunity *See* adaptive immunity.

spheroplast (sfēr′o-plast) A spherical cell formed by the weakening or partial removal of the rigid cell wall component.

spike *See* peplomer.

spirillum (spi-ril′um) A rigid, spiral-shaped bacterium.

spirochete (spi′ro-kēt) A flexible, spiral-shaped bacterium with periplasmic flagella.

spleen A secondary lymphoid organ where old erythrocytes are destroyed and blood-borne antigens are trapped and presented to lymphocytes.

spliceosome A complex of proteins and small RNAs that carries out RNA splicing in eukaryotes.

spontaneous generation An early belief that living organisms could develop from nonliving matter.

spontaneous mutations Mutations that occur due to errors in replication or the occurrence of lesions in the DNA (e.g., apurinic sites).

sporangiospore (spo-ran′je-o-spōr) A spore borne within a sporangium.

sporangium (spo-ran′je-um; pl., **sporangia**) A saclike structure or cell, the contents of which are converted into one or more spores.

spore A differentiated, specialized cell that can be used for dissemination, for survival in adverse conditions because of its heat and dessication resistance, and/or for reproduction. Spores are usually unicellular and may develop into vegetative organisms or gametes. They may be produced asexually or sexually.

sporozoite The motile, infective stage of apicomplexan protists.

sporulation The process of spore formation.

spread plate A Petri dish of solid culture medium with isolated microbial colonies growing on its surface that has been prepared by spreading a dilute microbial suspension evenly over the agar surface.

stable isotope analysis The use of stable (nonradioactive) isotopes to determine the fate of a given nutrient or compound in the environment.

stable isotope probing A technique that uses stable isotopes to examine nutrient cycling and identify the microbes involved.

stalk A bacterial appendage produced by the cell and extending from it.

standard free energy change The free energy change of a reaction at 1 atmosphere pressure when all reactants and products are present in their standard states; usually the temperature is 25°C.

standard plate counts *See* viable counting methods.

standard reduction potential A measure of the tendency of an electron donor to lose electrons in an oxidation-reduction (redox) reaction. The more negative the reduction potential of a compound, the better electron donor it is.

start codon The first codon in an mRNA that is translated; it signifies the translation start site.

starter culture An inoculum, consisting of a mixture of microorganisms, used to start a commercial fermentation.

static Inhibiting or retarding growth.

stationary phase The phase of microbial growth in a batch culture when population growth ceases and the growth curve levels off.

stem-nodulating rhizobia Rhizobia that produce nitrogen-fixing structures above the soil surface on plant stems.

sterilization The process by which all living cells, spores, viruses, and viroids are either destroyed or removed from an object or habitat.

Stickland reaction A type of fermentation in which an amino acid serves as the energy source and another amino acid serves as the electron acceptor.

sticky ends The complementary single-stranded ends of double-stranded DNA that result from cleavage with certain restriction endonuclease enzymes. These single-stranded ends can be used to introduce new fragments of DNA to generate a recombinant molecule.

stigma A photosensitive region on the surface of certain protists that is used in phototaxis.

stop codon *See* nonsense codon.

strain A population of organisms that descends from a single organism or pure culture isolate.

streak plate A Petri dish of solid culture medium with isolated microbial colonies growing on its surface that has been prepared by spreading a microbial mixture over the agar surface, using an inoculating loop.

streptomycete Any high G + C Gram-positive bacterium of the genera *Kitasatospora, Streptomyces,* and *Streptoverticillium.*

strict anaerobes *See* obligate anaerobes.

stringent response A decrease in tRNA and rRNA, and an increase in specific amino acid biosynthetic enzymes in response to amino acid starvation.

structural gene A gene that codes for the synthesis of a polypeptide or polynucleotide (i.e., rRNA, tRNA) with a nonregulatory function.

structural proteomics Analysis of the three-dimensional structure of many proteins to predict the structure of other proteins and protein complexes.

subgenomic mRNA Viral mRNA that is smaller than the genomic RNA of an RNA virus.

substrate (1) A reacting molecule in a chemical reaction that is bound by an enzyme. (2) The first molecule of a biochemical pathway. (3) A surface upon which microbes grow.

substrate-level phosphorylation The synthesis of ATP from ADP by phosphorylation coupled with the exergonic breakdown of a high-energy organic substrate molecule.

substrate mycelium In actinobacteria and fungi, a mat of hyphae that penetrates the surface into which the microbes are growing.

subsurface biosphere The region below the plant root zone where microbial populations grow.

subunit vaccines Immunogenic materials derived from whole infectious agents; e.g., bacterial capsular polysaccharide.

sulfate- or sulfur-reducing bacteria (SRB) Anaerobic bacteria that use sulfate or sulfur or both as a terminal electron acceptor during respiration, thereby performing dissimilatory sulfate reduction.

sulfate reduction The use of sulfate as an electron acceptor, which results in the accumulation of reduced forms of sulfur such as sulfide or incorporation of sulfur into organic molecules, usually as sulfhydryl groups.

superantigens Toxic bacterial proteins that overstimulate the immune system.

superoxide dismutase (SOD) (dis-mu′tās) An enzyme found in all aerobes, facultative anaerobes, and microaerophiles that catalyzes the conversion of the radical oxygen species superoxide to hydrogen peroxide and molecular oxygen (O_2).

superphylum A classification of organisms below the level of domain but above phylum; includes several phyla that are united by one or more distinct characteristics.

supportive media Culture media that are able to sustain the growth of many different kinds of microorganisms.

suppressor mutation A mutation at a different site that overcomes the effect of a forward mutation and produces the normal phenotype. The different site can be within the same gene (intragenic suppressor) or different gene (extragenic suppressor) as the forward mutation.

Svedberg unit (sfed′berg) The unit used in expressing the sedimentation coefficient; the greater a particle's Svedberg value, the faster it travels in a centrifuge.

symbiont Any organism that has a specific relationship with another that can be characterized as mutualism, cooperation, commensalism, predation, parasitism, amensalism, or commensalism.

symbiosis The living together or close association of two dissimilar organisms, each of these organisms being known as a symbiont.

symbiosome The organelle-like compartment that houses bacteroids that fix nitrogen during rhizobium nodulation.

symport Linked transport of two substances across a plasma membrane in the same direction.

symptom A change during a disease that a person subjectively experiences (e.g., pain, fatigue, or loss of appetite). Sometimes the term symptom is used more broadly to include any observed signs.

syndrome *See* disease syndrome.

syngamy The fusion of haploid gametes.

synteny Partial or complete conservation of gene order observed when the genomes of two closely related organisms are compared.

synthetic medium *See* defined medium.

syntrophism (sin′trōf-izəm) The association in which the growth of one organism either depends on, or is improved by, the provision of one or more growth factors or nutrients by a neighboring organism. Sometimes both organisms benefit.

systematic epidemiology The field of epidemiology that focuses on the ecological and social factors that influence the development of emerging and reemerging infectious diseases.

systematics The scientific study of organisms with the ultimate objective of characterizing and arranging them in an orderly manner; often considered synonymous with taxonomy.

systemic anaphylaxis Type 1 (immediate) hypersensitivity that involves multiple tissue sites and results in shock. It is often fatal if not treated.

T

tandem mass spectrometry The analysis of molecules using two mass spectrometers sequentially.

Taq polymerase A thermostable DNA polymerase used in the polymerase chain reaction.

Tat system A system used to transport folded proteins across the plasma membrane in bacteria and some archaea; some eukaryotes have homologues of the Tat system in their chloroplasts and mitochondria.

taxon A group into which related organisms are classified.

taxonomy The science of biological classification; it consists of three parts: classification, nomenclature, and identification.

T cell (T lymphocyte) A type of lymphocyte that matures into an immunologically competent cell within the thymus.

T-cell antigen receptor (TCR) The receptor on the T-cell surface consisting of two antigen-binding peptide chains and associated with a several other glycoproteins. Binding of antigen to the TCR in association with MHC activates the T cell.

T-cell receptor complexes *See* T-cell antigen receptor.

T-dependent antigen An antigen that activates B-cell response only with the aid of T-helper cells.

T DNA A portion of the *Agrobacterium tumefaciens* Ti plasmid integrated into the host plant's chromosome.

teichoic acids (ti-ko′ik) Polymers of glycerol or ribitol joined by phosphates; found in the cell walls of most Gram-positive bacteria.

teichoplanin Antibacterial agent that interferes with cell wall synthesis.

teliospores Diploid spores formed by fungi of *Ustilaginomycota.*

telomerase An enzyme in eukaryotes that replicates the ends of chromosomes.

telomeres Complexes of DNA and proteins at the ends of eukaryotic chromosomes.

temperate bacteriophages (viruses) Bacterial and archaeal viruses that can establish a lysogenic relationship, rather than immediately lysing their hosts.

template strand A DNA or RNA strand that specifies the base sequence of a new complementary strand of DNA or RNA.

terminator A sequence that marks the end of a gene and stops transcription.

tertiary treatment The removal from sewage of inorganic nutrients, heavy metals, viruses, and other small or dissolved contaminants by chemical and biological means after microbes have degraded dissolved organic material during secondary sewage treatment.

testate amoeba An amoeba with a covering (test) made either by the protist or from materials collected from the environment.

tetanolysin (tet″ah-nol′ĭ-sin) A hemolysin that aids in tissue destruction; produced by *Clostridium tetani*.

tetanospasmin (tet″ah-no-spaz′min) The neurotoxic component of the tetanus toxin, which causes the muscle spasms of tetanus.

tetracyclines (tet″rah-si′klēns) A family of antibiotics with a common four-ring structure that are isolated from the genus *Streptomyces* or produced semisynthetically.

T_H 0 cell Precursor to T_H1, T_H17, and T_H2 cells.

T_H 1 cell A $CD4^+$ T-helper cell that secretes interferon-gamma, interleukin-2, and tumor necrosis factor.

T_H 2 cell A $CD4^+$ T-helper cell that secretes interleukin (IL)-4, IL-5, IL-6, IL-9, IL-10, and IL-13, influencing growth and differentiation of B cells.

T_H 9 cells T_H2 cells that halt their characteristic T_H2 profile upon exposure to TGF-β and subsequently produce IL-9.

T_H 17 cells T_H cells found predominantly in the skin and intestinal epithelia, where their release of IL-17 and IL-22 stimulates neutrophils in response to bacterial invasion.

thallus (thal′us) A type of body that is devoid of root, stem, or leaf; characteristic of fungi.

thaumarchaeol Cyclopentane ring-containing lipids unique to members of *Thaumarchaeota*.

T-helper (T_H) cell A T lymphocyte that bears the CD4 co-receptor. Subtypes amplify innate immune responses and promote cell-mediated and antibody-mediated immune responses.

therapeutic index The ratio between the toxic dose and the therapeutic dose of a drug, used as a measure of the drug's relative safety.

thermoacidophiles Microbes that grow best at acidic pHs and temperatures 55°C or higher.

thermocline A water column characterized by a steep temperature gradient.

thermodynamics A science that analyzes energy changes in a system.

thermophile (ther′mo-fīl) A microorganism that can grow at temperatures of 55°C or higher; the minimum is usually around 45°C.

thylakoid (thi′lah-koid) A flattened sac in the chloroplast stroma that contains photosynthetic pigments and the photosynthetic electron transport chain. Similar structures are observed in the cytoplasm of cyanobacteria.

thymic selection A process occurring in the thymus in which T-cell precursors are evaluated for functionality.

thymine (thi′min) The pyrimidine 5-methyluracil found in nucleosides, nucleotides, and DNA.

thymus (thi′məs) A primary lymphoid organ in the chest that is necessary in early life for the development of immunological functions, including T-cell maturation.

T-independent antigen An antigen that triggers a B cell to produce immunoglobulin without T-cell cooperation.

Ti plasmid Tumor-inducing plasmid found in plant pathogenic species of the bacterial genus *Agrobacterium*.

T lymphocyte *See* T cell.

toll-like receptor (TLR) A type of pattern recognition molecule (PRM) on phagocytes and other cells that when bound to a microbial ligand, triggers the production of transcription factor NFκB, which stimulates formation of cytokines, chemokines, and other defense molecules.

topoisomerases Enzymes that change the topology of DNA molecules by transiently breaking one or both strands. They play an important role in DNA replication.

toxemia (tok-se′me-ah) The condition caused by toxins in the blood of the host.

toxigenicity (tok″sĭ-jĕ-nis′i-tē) The capacity of an organism to produce a toxin.

toxin neutralization *See* neutralization.

toxoid A bacterial exotoxin that has been inactivated but still stimulates antitoxin formation when injected into a person or animal.

trace elements *See* micronutrients.

trailer That portion of a gene downstream of the coding region. It is transcribed but not translated.

transaminase An enzyme that catalyzes a transamination reaction.

transamination The transfer of an amino group from an amino acid to an α-keto acid acceptor. Transamination is used both for degradation of amino acids and in their synthesis.

transcriptase (trans-krip′tās) An enzyme that catalyzes transcription.

transcription The process in which RNA with a base sequence complementary to the template strand of DNA or RNA is synthesized.

transcriptome All the messenger RNA transcribed from the genome of an organism under a given set of circumstances.

transcriptomics The study of all the mRNA expressed by a cell at the time of sampling.

transduction The transfer of genes between bacterial or archaeal cells by viruses.

transfer RNA (tRNA) A small RNA that binds an amino acid and delivers it to the ribosome for incorporation into a polypeptide chain during protein synthesis.

transformation (1) A mode of gene transfer in bacteria and archaea in which a piece of free DNA is taken up by a cell and integrated into its genome. (2) In recombinant DNA technology, the uptake of free DNA by a cell. (3) The conversion of a cell into a malignant, cancerous cell.

transition mutations Mutations that involve the substitution of a different purine base for the purine present at the site of the mutation or the substitution of a different pyrimidine for the normal pyrimidine.

translation Protein synthesis; the process by which the genetic message carried by mRNA directs the synthesis of polypeptides with the aid of ribosomes and other cell constituents.

translesion DNA synthesis A type of DNA synthesis that occurs during the SOS response. DNA synthesis occurs without an intact template and generates mutations as a result.

translocation (1) During the elongation cycle of protein synthesis, the movement of the ribosome relative to the mRNA that repositions the A site of the ribosome over the next codon to be translated; (2) the movement of a protein across or into a membrane.

transmissible spongiform encephalopathies Degenerative central nervous system diseases in which the brain has a spongy appearance; due to prions.

transmission electron microscope (TEM) A microscope in which an image is formed by passing an electron beam through a specimen and focusing the scattered electrons with magnetic lenses.

transpeptidation (1) The reaction that forms the peptide cross-links during peptidoglycan synthesis. (2) The reaction that forms a peptide bond during the elongation cycle of protein synthesis.

transposable element A small DNA molecule that carries the genes for transposition and thus can move around the genome.

transposase An enzyme that catalyzes the movement of a mobile genetic element.

transposition The movement of a piece of DNA around the chromosome.

transposon (tranz-po′zon) A mobile genetic element that encodes recombinase, which is needed for transposition, and contains other genes that are not required for transposition.

transversion mutations Mutations that result from the substitution of a purine base for the normal pyrimidine or vice versa.

tricarboxylic acid (TCA) cycle The cycle that oxidizes acetyl coenzyme A to CO_2 and generates NADH and $FADH_2$ for oxidation in an electron transport chain; also supplies precursor metabolites for biosynthesis. Also called citric acid cycle and Krebs cycle.

trichocyst A small organelle beneath the pellicle of some protists. It can be extruded to function as either an anchoring device or as a form of defense.

trichome (tri′kōm) A filament of microbial cells that are in close contact with one another over a large area.

trickling filter A bed of rocks covered with a microbial film that aerobically degrades organic waste during secondary sewage treatment.

trimethoprim A synthetic antibiotic that inhibits production of folic acid by binding to dihydrofolate reductase. Trimethoprim has a wide spectrum of activity and is bacteriostatic.

trophozoite (trof″o-zo′īt) The active, motile feeding stage of a protozoan organism.

tropism (1) The movement of living organisms toward or away from a focus of heat, light, or other stimulus. (2) The selective infection of certain organisms or host tissues by a virus due to the presence of the specific receptor to which the virus binds.

trypanosome (tri-pan′o-sōm) A flagellated protozoan of the genus *Trypanosoma;* often live in the blood of humans and other vertebrates and are transmitted by insect bites.

tubercle (too′ber-k′l) A small, rounded nodular lesion produced by *Mycobacterium tuberculosis*.

tuberculous cavity An air-filled cavity that results from a tubercle lesion caused by *M. tuberculosis*.

tumble Random turning or tumbling movements made by flagellated bacteria when they stop swimming in a straight line (a run).

tumor suppressor genes Genes encoding tumor suppressor proteins.

tumor suppressor proteins Proteins that regulate cell cycling or repair DNA. Their inactivation can contribute to the development of cancer.

turbidostat A continuous culture system equipped with a photocell that adjusts the flow of medium through the culture vessel to maintain a constant cell density or turbidity.

twitching motility A type of bacterial motility characterized by short, intermittent jerky motions due to extension and retraction of type IV pili.

two-component signal transduction system A regulatory system that uses the transfer of phosphoryl groups to control gene transcription and protein activity. It has two major components: a sensor kinase and a response regulator protein.

two-dimensional gel electrophoresis An electrophoretic procedure that separates proteins using two procedures: isoelectric focusing and SDS-PAGE.

tyndallization The process of repeated heating and incubation to destroy bacterial spores.

type I hypersensitivity A form of immediate hypersensitivity arising from the binding of antigen to IgE attached to mast cells, which then release anaphylaxis mediators such as histamine. Examples: hay fever, asthma, and food allergies.

type II hypersensitivity A form of immediate hypersensitivity involving the binding of antibodies to antigens on cell surfaces followed by destruction of the target cells (e.g., through complement attack, phagocytosis, or agglutination).

type III hypersensitivity A form of immediate hypersensitivity resulting from the exposure to excessive amounts of antigens to which antibodies bind. These antibody-antigen complexes activate complement and trigger an acute inflammatory response with subsequent tissue damage.

type IV hypersensitivity A delayed hypersensitivity response that results from the binding of antigen to activated T lymphocytes, which then release cytokines to trigger inflammation that damages tissue. Type IV hypersensitivity is seen in contact dermatitis from poison ivy, leprosy, and tertiary syphilis.

type I secretion system *See* ABC protein secretion pathway.

type III secretion system A system in Gram-negative bacteria that secretes virulence factors and injects them into host cells.

type IV secretion system A system in Gram-negative bacteria that secretes proteins; some Gram-negative and Gram-positive bacteria use this secretion system to transfer DNA during bacterial conjugation.

type V secretion system A pathway in Gram-negative bacteria that translocates proteins across the outer membrane after they have been translocated across the plasma membrane by the Sec system.

type VI secretion system A protein secretion system in Gram-negative bacteria that is similar in structure to the machinery used by some bacteriophages to insert their DNA into host cells.

type strain The microbial strain that is the nomenclatural type or holder of the species name. A type strain will remain within that species should nomenclature changes occur.

U

ubiquinone *See* electron transport chain.

ultraviolet (UV) radiation High-energy radiation of short wavelength, about 10 to 400 nm.

uniporters Carrier proteins that move a single solute across a membrane.

universal phylogenetic tree A phylogenetic tree that considers the evolutionary relationships among organisms from all three domains of life: *Bacteria, Archaea,* and *Eukarya*.

upstream activating sequences (UASs) Sequences near eukaryotic genes where activator proteins bind.

uracil (u′rah-sil) The pyrimidine 2,4-dioxy-pyrimidine, which is found in nucleosides, nucleotides, and RNA.

use dilution test Method of evaluating disinfectant effectiveness at a recommended dilution.

V

vaccine A preparation of antigens and adjuvant administered to induce development of an adaptive immune response that will protect the individual against a specific pathogen or a toxin.

vaccinomics The application of genomics to vaccine development.

valence The number of antigenic determinant sites on the surface of an antigen or the number of antigen-binding sites possessed by an antibody molecule.

vancomycin A glycopeptide antibiotic obtained from *Nocardia orientalis* that is effective only against Gram-positive bacteria and inhibits peptidoglycan synthesis.

variable region (V_L and V_H) The region at the N-terminal end of immunoglobulin heavy and light chains whose amino acid sequence varies between antibodies of different specificity. Variable regions form the antigen-binding site.

vector (1) In genetic engineering, a DNA molecule that can replicate and transport a piece of inserted foreign DNA, such as a gene, into a recipient cell. It may be a plasmid, phage, cosmid or artificial chromosome. (2) In epidemiology, it is a living organism, usually an arthropod or other animal, that transfers an infective agent between hosts.

vector-borne transmission The transmission of an infectious pathogen between hosts by means of a vector.

vehicle An inanimate substance or medium that transmits a pathogen.

vertical gene transfer The transfer of genes from a parent organism to its offspring.

vertical transmission Pathogen transfer from mother to unborn child (in utero).

vesicular transport The movement of materials in small membrane-bound vesicles between the endoplasmic reticulum, Golgi apparatus, lysosomes, plasma membrane, and other organelles of the endocytic and secretory pathways in eukaryotic cells.

viable but nonculturable (VBNC) microorganisms Microbes known to be growing in a specific environment but that cannot be cultured under standard laboratory conditions.

viable counting methods Methods for determining population size that depend on a microbe's ability to reproduce when cultured. Also called standard plate counts.

vibrio (vib′re-o) A rod-shaped bacterial cell that is curved to form a commalike shape.

viral hemagglutination The clumping of red blood cells caused by the attachment of some viruses.

viral neutralization An antibody-mediated process in which IgG, IgM, and IgA antibodies bind to some viruses during their extracellular phase and inactivate or neutralize them.

viricide (vir′i-sīd) An agent that inactivates viruses so that they cannot reproduce within host cells.

virion A complete virus particle; at the simplest, it consists of a protein capsid surrounding a single nucleic acid molecule.

virioplankton Viruses that occur in waters; high levels are found in marine and freshwater environments.

viroid An infectious agent that is a single-stranded RNA not associated with any protein; the RNA does not code for any proteins and is not translated.

virology The branch of microbiology that is concerned with viruses and viral diseases.

virulence The degree or intensity of pathogenicity of an organism as indicated by case fatality rates and/or ability to invade host tissues and cause disease.

virulence factor A product, usually a protein or carbohydrate, that contributes to virulence or pathogenicity.

virulent (bacteriophages) viruses Viruses that lyse their host cells at the end of the viral life cycle.

virus An infectious agent having a simple acellular organization with a protein coat and a nucleic acid genome, lacking independent metabolism, and multiplying only within living host cells.

viruslike particles (VLP) Presumptive viruses detected by electron microscopy or fluorescence microscopy; because these approaches do not demonstrate that these entities can infect host cells, they cannot be considered viruses.

W

wastewater treatment The use of physical and biological processes to remove particulate and dissolved material from sewage and to control pathogens.

water activity (a_w) A quantitative measure of water availability in the habitat; the water activity of a solution is one-hundredth its relative humidity.

water molds *See* öomycetes.

white blood cell (WBC) Blood cell having innate or acquired immune function. These cells are named for the white or buffy layer in which they are found when blood is centrifuged.

whole-cell vaccine A vaccine made from complete pathogens, which can be either killed microorganisms or live, attenuated microbes.

whole-genome shotgun sequencing Genome sequencing in which random fragments of a complete genome are individually sequenced. The nucelotide sequences of the fragments are placed in the proper order based on overlapping identical sequences.

wild type Prevalent form of a gene or phenotype.

Winogradsky column A glass column with an anoxic lower zone and an oxic upper zone, which allows growth of microorganisms under conditions similar to those found in a nutrient-rich lake.

wobble The loose base pairing between an anticodon and a codon at the third position of the codon.

World Health Organization An international health agency located in Geneva, Switzerland.

wort The filtrate of malted grains used as the substrate for the production of beer and ale by fermentation.

X

xenograft (zen″o-graft) A tissue graft between animals of different species.

xerophiles Microorganisms that grow best under low water activity (a_w) conditions, and may not be able to grow at high a_w values.

Y

yeast A unicellular, uninuclear fungus that reproduces either asexually by budding or fission, or sexually through spore formation.

yeast artificial chromosome (YAC) Engineered DNA that contains all the elements required to propagate a chromosome in yeast and is used to clone foreign DNA fragments in yeast cells.

Z

zoonosis (zo″o-no′sis; pl., **zoonoses**) A disease that can be transmitted from animals to humans.

zooxanthella (zo″o-zan-thel′ah) A dinoflagellate found living symbiotically within cnidarians (corals) and other invertebrates.

zygomycetes (zi″go-mi-se′tez) A group of fungi that usually has aspetate hyphae. Sexual reproduction normally involves the formation of zygospores.

zygospore A thick-walled, sexual, resting spore characteristic of the zygomycetous fungi.

Index

Page numbers followed by t and f designate tables and figures, respectively; page numbers in *italics* refer to definitions; page numbers in **boldface** refer to major discussions; pages numbers with A refer to appendix.

A

AAnP (aerobic anoxygenic photosynthesis), *508*
AAnPs (aerobic anoxygenic phototrophs), 658
Abbé, Ernst, 24
Abbé equation, 24–25
ABC (ATP-binding cassette) transporters, *51,* 51f
Abiotic methane, 464
ABO blood groups, *762*
AB toxin, *777*
Acanthamoeba keratitis (cornea inflammation), *918*–919
Acarbose (type 2 diabetes drug), from *Actinoplanetes,* 558
Accessory pigments, in photosynthesis, *254,* 255f
Acellular slime molds, *569,* 569f
Acellular vaccines, *821*
Acetyl-coenzyme A, *236*
Acidaminococcaceae, 544
Acid-fast cell walls, *558*
Acid-fast staining, *33,* 34f
Acidianus convivator, 110
Acidianus two-tailed virus (ATV), 110, 110f
Acidimethylosilex fumarolicum, 498–499
Acidithiobacillus ferrooxidans, 519, 631
Acidithiobacillus species, 251
Acid mine drainage, **518–519**
Acidobacteria, 257, 490, 631
Acidophile microorganisms, *144*
Acne vulgaris, 559, 703
Acquired immunity, *708*; *See also* Adaptive immunity
Acridine orange stain, 641
ACT (artemisinin-based combination therapy), for malaria, 438, 910
Actin filaments, *94,* 94f
Actinobacteria, **552–562**
  Actinomycetales, 555
  Bifidobacteriales, 561
  characteristics of, 553t
  Corynebacteriales, 557–558
  Frankiales, 561
  Gram positive bacteria in phylum, 56
  Micrococcales, 555–556
  Micromonosporales, 558
  as monoderms, 54
  overview, 554–555
  Propionibacteriales, 558–559
  Streptomycetales, 559–560
  Streptosporangiales, 560–561
Actinomycetales, 555
Actinomycetes, 553, 555f
Actinomycetoma disease, 560
Actinoplanetes, diabetes drug from, 558
Actinorhizae, *679*–680
Actin tails, of intracellular bacterial pathogens, 781f
Activated sludge, in wastewater treatment, *971,* 971f
Activation energy for reactions, *219,* 220f
Activator proteins, *324–325,* **363–366**
Active sites, for reactions, *220*
Active transport
  in archaea, 83
  in eukaryotic cells, 92–93
  primary and secondary, *51*–52, 51f
Acute bacterial diarrhea and food poisoning, 886t–887t
Acute inflammatory response, *732,* 732f
Acute-phase proteins, *717*
Acute viral gastroenteritis, *851*–852, 852t
Acyclovir antiviral drug, 202, 828, 844
Acylhomoserine lactones (AHLs), 172
Adaptive immunity, **736–769,** 737f; *See also* Host resistance, innate
  antibodies, **749–757**
    binding to targets, 757–760
    clonal selection, 757
    diversity of, 755–757
    immunoglobulin classes, 752–753
    immunoglobulin function, 751–752
    immunoglobulin structure, 750–751
    kinetics of, 753–755
  antigens to elicit, 738–739
  autoimmunity and autoimmune diseases, 765–766
  B cells in, 747–749
  earned or borrowed, 739–740, 739f
  foreignness, recognition of, 740–742
  hypersensitivities, 760–765
  not responding as part of, 760
  recognition and memory in, 736–738
  T cells in, 743–747
  transplantation (tissue) rejection, 766–767
Adaptive mutations, *459*
ADCC (antibody-dependent cell-mediated cytotoxicity), 723–724, 723f, 752
Adenine, *276*
Adenine arabinoside antiviral drug, 202
Adenoids, 726
Adenosine 5'-phosphosulfate (APS), 251
Adenosine diphosphate (ADP), *212*
Adenosine monophosphate, 277f
Adenovirus, 113f
Adherence and colonization factors, in pathogenicity, 774–775, 775f, 775t
Adhesion molecules, in *Caulobacter crescentus,* 510
Adipokines, 707
Adjuvants, in vaccines, *818*
ADP (adenosine diphosphate), *212*
Aerial mycelium (hyphal mat), *554*
Aerobes, 147, 157–158
Aerobic anoxygenic photosynthesis (AAnP), *508*
Aerobic anoxygenic phototrophs (AAnPs), 658
Aerobic respiration, **232–243**
  electron transport to oxidative phosphorylation, 236–243
    ATP yield, 241–243
    electron transport chains, 238–240, 239f
    overview, 236–237
    oxidative phosphorylation process, 240–241
  glucose to pyruvate, 232–235
  overview, *232*
  pyruvate to carbon dioxide, 236

Aerobic secondary wastewater treatment, 972f
Aerotolerant anaerobes, 147, *147*
Aeschynomene sensitiva, 679
A-factor, in streptomycin production, 552
Aflatoxins, 592, 779, *935,* 935f
African sleeping sickness, 189, 568, 912
Agar
  agar dilution method for antimicrobial susceptibility, 793
  for cultures, 15, *156*
  Mueller-Hinton, 192
Agaricus campestris mushrooms, 593
Agglutination reaction, *760, 798,* 798–799, 799f
Agriculture
  biotechnology in, 959, 960f
  microbiology in, 18–19
  runoff from, 663
Agrobacterium, 510–511, 511f, 680–681, 680f, 681f
Agrobacterium tumefaciens, 959, 961f
AHFCA (2-alkyl-4-hydroxymethylfuran-3-carboxylic acids), 552
AHL (*N*-acylhomoserine lactone), *152*–153, 172, *342*
AIDS; *See* HIV/AIDS
Aigarchaeota (proposed archaea phylum), 465
Airborne transmission of disease
  of bacteria, **859–868**
    chlamydial pneumonia, *859*–860
    diphtheria, *860*
    Legionnaires' disease, *860*–862
    meningitis, *862*–863
    mycobacterium infections, 863–866
    mycoplasmal pneumonia, 866
    pertussis (whooping cough), *866*–867
    streptococcal diseases, *867*–868
  of fungi and protists, **904–907**
  overview, *783*
  of viruses, **827–836**
    chickenpox (varicella) and shingles (herpes zoster), 827–829
    measles (rubeola), 831–833
    mumps, 833
    respiratory syndromes and viral pneumonia, 833–834
    rubella (German measles), 834–835
    smallpox (variola), 835–836
Air conditioning systems, bacterial biofilms in, 880
Akinetes, *494,* 494f
Akkermansia muciniphila, 499, 694
Alanine, stereoisomers of, A.5f
Alcaligenaceae, 516
Alcoholic fermentation, *246,* 941–943
Alcohols for microbe control, 180, 183f
Aldehydes for microbe control, 182, 183f
Ales and beers, 927, 942–943, 942f
Alexandrium dinoflagellates, 653
Algae
  blooms of, 495, 495f
  overview, *4*
  peptidoglycan in chloroplasts of, 10
  as photosynthetic protists, *563*
Algicides, 181
Alignment, in genome sequencing, *429*
Alkaliphile microorganisms, *144*
Alleles, of genes, *380*
Allergies; *See also* Hypersensitivities
  allergic-type aspergillosis, 922
  contact dermatitis, 763–765, 765f
  eosinophils and, *720*
  overview, ***760–761,*** 761f, 815t
Allografts, *766*

Classification
  of enzymes, 219t
  of fungi *(Eumycota),* 585t
  Gell-Coombs, *760*
  genotypic, *444*–445
  Gram-staining in phylogenetic, 461
  Linnaeus system of, 11, *446*
  natural, *444*
  of organisms, 2
  phyletic, *445*
  of probiotics, *944*–945
Classification of the Protists (International Society of Protistologists), 566
Class I MHC molecules, *740*–742, 741f
Class lI MHC molecules, *740*–742, 741f, 744
Clathrin-dependent endocytosis, *97*
Claviceps purpurea, 592, 779
Climate change, biogeochemical cycling and, **623–636**
  carbon cycle, 625–627
  carbon fixation by phytoplankton, 655
  elements important in, 624t
  harmful algal blooms and, *653*
  interaction between cycles, 632–633, 632f
  iron cycle, 629–631
  manganese and mercury cycles, 631–632
  nitrogen cycle, 627–628
  out of balance, 633–635
  phosphorus cycle, 628–629
  sulfur cycle, 629
Clinical laboratory scientist (CLS), 790
Clinical microbiology, **786–805,** *787*
  biosafety practices, 787–789
  laboratory detection of infectious diseases, 786–787
  measurement or exploitation of immune responses, 797–804
    agglutination, 798–799
    complement fixation, 799–800
    flow cytometry, 803
    immunoblotting (Western blotting), 799–800
    immunoelectrophoresis, 801–803
    immunoprecipitation, 800–801
    overview, 797–798
    radioimmunoassay, 804
    serotyping, 798
  specimens for microorganism identification, 790–797
    clinical specimens, 790
    culture-based methods, 791–793
    direct identification, 790–796
    indirect identification, 796–797
    microscopy, 793–796
    molecular methods, 796
Clinical specimens for identification of microorganisms, 787f, 790, 790f
ClO_2 (chlorine dioxide) sterilizing gas, 183
Cloning
  cDNA synthesis and, 402
  clonal selection, 757, 757f
  genes, 400f
  vectors for recombinant DNA, 408–411, 408t, 409f
Clostridia, 540–543, 541f, 541t
Clostridial myonecrosis, 872
Clostridium botulinum, 75, 542, 934
Clostridium difficile, 685, 699, 897
Clostridium perfringens, 934
Clostridium tetani, 541f, 542–543, 542f
CLR-MAMP binding, 727
CLRs (C-type lectin receptors), 727, 728f
CLS (clinical laboratory scientist), 790
Club fungi, *592*–595
CLUSTAL software, *452*
Cluster analysis, for phylogenetic trees, 453
Clustered, regularly interspaced short palindromic repeats (CRISPR/Cas system) viruses, 606–607, 606f, 939
Cluster of differentiation (CDs) molecules or antigens, *742,* 742t
CMV (cytomegalovirus); *See* Cytomegalovirus (CMV)
CO_2 fixation
  in anabolism, 264–267
  in archaea, 466–469
  prochlorophyte cyanobacteria affect on, 494–495
Coagulation, in water purification, *965*
Coastal ecosystems, microorganisms in, 652–654
Cocci, *43,* 43f, *80,* 81f
Coccidioidomycosis, *905,* 905f
Coccolithophore *Emiliania hyxleyi,* 659
Coccolithophores, *579,* 652f
Code degeneracy, *305*
Coding region of gene, *299,* 300
Coding regions, bacterial, 298–301
Coding sequences (CDS), *429,* 429f
Codons, DNA nucleotides as, *305*
COD (chemical oxygen demand) test, as water quality measure, *973*
Coenocytic hyphae, *586,* 588–589
Coenzyme Q, 238, *240*
Coenzymes, *219,* 219f, 476f
Coevolution, *688*
Cofactors, *218*–219, *263*
Cohn, Ferdinand, 14
Cold, common, 844–845
Cold sores, 607, 843–844, 843f
Coliforms, in water purification, *966*
Colilert defined substrate test, *968,* 968f
Colitis, 685, *897*
Colon, microbiota of, 705
Colonies
  on membrane filter, 167f
  of microorganisms, *158,* 160f
Colonization factors, in pathogenicity, 774–775
Colony forming units (CFU), *166*
Colony-stimulating factors (CSFs), in bone marrow, *717*
Colorado State University, 827
Colorless sulfur bacteria, *516*–518, 517t
Columbus, Christopher, 879
Combinatorial joining, *755*–756, 755t
Comentabolism, *978*
Commensalism, as microbial interaction, *695*
Common cold, *844,* 844–845
Common-source epidemic, 812, 812f
Communicable diseases, 812
Communication
  cell-cell, 151–152
  interdomain, 153–154
Community activity assessment, in microbial ecology, 645–648
Community state types (CSTs), 712
Comparative genomics, *438*–441, 441f, 497
Compartmentalization, as metabolic channeling, *222*–223
Compartmentation of anabolism and catabolism, 263

Compatible solutes, *143*
Compatible solutes, to increase osmolarity, *478*
Competent cell, in transformation, *390*
Competition, as microbial interaction, *698*
Competitive exclusion principle, *698*
Competitive inhibitor of enzymes, *221,* 221f
Complementary DNA (cDNA), *402,* 403f, 432
Complementary DNA double helix, *288*
Complement fixation, 799–800, 800f
Complement system of cascading enzymes, *713*–716, 714f, 715t
Complex culture media, *155,* 156t
Compromised host, *699*–700
Concatemers, in T4 bacteriophages, *601*–602
Condenser, in microscopes, *23*
Conditional mutations, *374*
C1 compounds, 511–512, 512f, 522, 524f
Confocal microscopy, 30–*31,* 30f, 31f
Congenital disease, 784
Congenital (neonatal) herpes, *846*
Congenital rubella syndrome, *834*
Congenital syphilis, *877*
Conidia, in fungi, *591*
Conidiospores, *587*
Coniophora, 669
Conjugate redox pair, *213*
Conjugation, *384,* 385f, *565,* 574f
Conjugative plasmids, *384*
Conjugative transposons, *383*
Conjunctivitis of newborns, *877*
Consensus sequences, *303*
Conserved hypothetical proteins, *430*
Constant (C) regions, *750*
Constitutive genes, *323*
Contact dermatitis, 765f
Contact lenses, microbe growth on, 880, 918
Contact time, of antimicrobial exposure, 185
Contact transmission of disease, *783*; *See also* Direct contact diseases
Containment, to prevent contamination, 788
Contigs (contiguous nucleotide sequences), *424*
Continuous culture system, *168*
Continuous feed, in industrial microbiology, *952*
Contractile vacuoles, in protists, *564*
Control of microorganisms, **172–187**; *See also* Chemotherapy; Microbial growth
  by alterations leading to nonviability, 177–179
  biological methods of, 185–186
  chemical agents for, 180–184
  death and growth patterns, 174–175
  evaluation of effectiveness, 184–185
  mechanical removal, 175–177
  targets for, 172–174
Convalescent period, of disease, *772*
Coombs, Robert, 760
Cooperation, as microbial interaction, *694*–695
Copper sulfate, 181
CoQ (coenzyme Q), *215,* 216f
Coral bleaching, *688,* 690
Corals, hermatypic, 688–690, 689f
Core enzyme, of RNA polymerases, *301*
Core genome, *454,* 455f
Core polysaccharide, *58*
Corepressor proteins, *325*
Corkscrew morphology of *Spirochaetes,* 499–500
Corneal inflammation (keratitis), *843, 918*
Coronary artery disease, 860
Coronaviruses, *832,* 832f
Corrosion, sulfate- or sulfur-reducing bacteria (SRB) in, 531
Corynebacterales Order, 54
Corynebacteriales, 557–558, 557f
Corynebacterium diphtheriae, 123
Cosmetics, allergic reaction to, 765
Cosmids, 410
Cotranslocational movement of proteins, 317, 317f
Cotransporters, primary active transporters as, 51f
Coughing reflexes, 711
Coulter counter, for measuring cell number, 165
Counting chamber, for measuring cell number, 165
Covalent chemical bonds, A.3, A.3f
Coverage, in genomic sequencing, *426*
Cowpox, 820, 835
Coxiella burnetii, 896, 896f
Coxsackie virus, 821
CPEs (cytopathic effects), *123*
CRE (carbapenem-resistant *Enterobacteriaceae*), 394
C-reactive protein (CRP), 707, 717
Crenarchaeota archaeal species, 85, 465, 471–473, 631
Cresentin polymerization, cell shape and, 139
Creutzfeldt-Jakob disease (CJD), 18, 129, 815, 856
CRISPR/Cas system viruses, 606–607, 606f, 939
Cristae, in mitochondria, *101*
Crithidia fasciculata, 145
Crocospher watsonii, 657
Crohn's disease, monoclonal antibody therapy for, 758
Cross-linking, in peptidoglycan sacculus, 55–56, 55f, 56f
Crown gall disease, 511, 511f, 680
CRP (C-reactive protein), 707, 717
Cryophiles, *146*
Cryptococcal pneumonia, 841
Cryptococcosis, 594, *905*–906, 906f
Cryptococcosis meningitis, 906
Cryptosporidiosis, 576, 919
Cryptosporidium, food and water contamination by, 904
Crystallizable fragment (F_c), *750*
CSF (cerebral spinal fluid), 22, 862
CSFs (colony-stimulating factors), in bone marrow, *717*
CSTs (community state types), 712
C-terminal repressor domain (RD), 729
CTP synthase, 139
C-type lectin receptors (CLRs), 727, 728f
Culture-based methods, **11–17**
  developments in, 12f
  disease and, 14–15
  immunology, 16–17
  Koch's postulates, 15
  microbial ecology, 17
  in microbial ecology studies, 638–641
  for microorganism identification, 791–793, 791t, 792t, 793f–794f
  pure, 15–16
  from soils, 671t
  spontaneous generation theories, 13–14
Culture media, ***154*–157,** 155t
Culturomics, *640*
Curing, of plasmids, *68*
Cut-and-paste transpositions, *383*
Cutaneous anthrax, *894*
Cutaneous mycosis, *914,* 915f
Cyanobacteria
  for biodiesel fuels, 483
  dissimilatory sulfate reduction by, 629
  evolution of, 455

in fossilized stromatolites, 8, 8f
multiple fission of, 133, 134f
Prochloron, 10
Cyanobacteria (oxygenic photosynthetic bacteria), **491–495,** 492f, 492t, 493t
Cyanophycin granules, *491*
Cyclic adenosine monophosphate (cAMP), 335f
Cyclic AMP receptor protein (CRP), *337*
Cyclic dimeric GMP (c-di-GMP), *335*–336
Cyclic photophosphorylation, *256,* 258f
Cyclospora, food and water contamination by, 904
Cyclosporiasis, *919*–920, 919f
Cyclosprine, 586
Cyclotella meneghiniana, 577f
Cysteine, 274
Cyst formation, *508,* 567
Cystic fibrosis, 524, 880
Cytidine 5'-triphosphate (CTP), 212
Cytochromes, *215*–216, 238
Cytocidal infection, 123
Cytocine, *276*
Cytokines
from $CD4^+$ T cells, 747
as cellular chemical messages, *716*–717
functions of, 718t
pro-inflammatory, 707
T cells releasing, 738
Cytokinesis, in bacterial cell cycle, *136*–137
"Cytokine storm," 777
Cytolytic or cytotoxic reactions, 762
Cytomegalovirus (CMV)
cytomegalovirus-induced mononucleosis, 847, *847*
fusion of host cells from, 780
as herpes virus, 607
in HIV/AIDS complications, 841
inclusion disease, *845,* 845f
size of, 438
Cytopathic effects (CPEs), *123*
Cytophaga spp., 669
Cytoplasm
archael, 85–86
bacterial, 62–68
eukaryotic, *93*–95, 94f
peptidoglycan synthesis in, 268–270
Cytoproct, *564*
Cytoskeleton
archaeal, *85*
bacterial, *62*–64, 63f, 63t
eukaryotic, *94,* 94f
Cytosol, in cytoplasm, *62, 93*
Cytosomes (protist cell mouth), *564,* 566
Cytotoxic T lymphocytes (CTLs), *745*

D

DAEC (diffusely adhering *Escherichia coli*), *892*
Damage inducible polymerase (DinB), 380
Damage- or danger-associated molecular patterns (DAMPs), 707, 727
DAPI (4',6-diamido-2-phenylindole) stain, 641, 641f
Dapsone, to treat toxoplasmosis, 204
Daptobacter, 695, 695f
Dark-field microscopes, 11, *26,* 26f
Dark reactions, in photosynthesis, *253*
Darwin, Charles, 445, 736
Davis, Bernard, 385
DBPs (disinfection by-products), in water purification, *965*
DC/HB (dicarboxylate/4-hydroxybutyrate) cycle, 266, 467–469, 468f
ddATP (dideoxyadenosine triphosphate), 420f
DDT, resistance to, 907
Dead zones, in oceans, 650–651, 663
Deamination, *249*
Death and growth patterns, in microbes, 174–175, 175f
"Death angel" mushroom, 593
Death of microbes, 810t; *See also* Control of microorganisms
Death phase, in microbial growth curve, *162*
Dechlorosoma suillum, 631
Decimal reduction time (D value), *174*–175
Decomposition, 626t, 902
Decontamination, natural, 964
"Deep hot biosphere," 637, 683
Deep-ocean sediments, microbial activity in, 661
Deep sequencing, 426
Deepwater Horizon oil rig, 964
Defensin peptides, *713*
Defensins, 730
Deferribacteraceae, dissimilatory iron reduction by, 631
Defined culture media, *155,* 155t
Deforestation, 634
Degradation, 626t
Degradation products, 977f
Degranulation, 753, *753,* 761
Dehydration, fatal, 851
Deinococci, mollicutes, and nonproteobacterial Gram-negative bacteria, **483–503**
Aquificae and *Thermotogae* lineages, 484
cell walls lacking in *Mollicutes Tenericutes,* 485–487
corkscrew morphology in *Spirochaetes,* 499–500
in human gut microbiota, 501–502
human symbiotes and methylotrophs *(Verrucomicrobia),* 497–499
intracelluar compartments of *Plactomycetes,* 495–496
obligate intracelluar parasites *(Chlamydiae),* 497
photosynthetic bacteria, **488–495**
Gram-negative, 489t
green nonsulfur, 491
green sulfur, 490
overview, 488–490
oxygenic, 491–495
Deinococcus genus, 54
Deinococcus radiodurans, 149, 377, 433, 433f
Deinococcus radiodurans tetracoccus, 485f
Delbrück, Mas, 116
Deletion mutations, 371f
Delsulfovibrionales, Desulfobacteriales, and Desulfuromonadales, 530–531
Delta agent (hepatitis D virus), *849*
*Deltaproteobacteria, **529–535***
Bdellovibrionales, 532–533
characteristics of, 532t
Delsulfovibrionales, Desulfobacteriales, and Desulfuromonadales, 530–531
in iron cycle, 631
Myxococcales, 533–535
phylogenetic relationships among, 529f
de' Mussi, Gabriele, 823
Denaturation of enzymes, 220–221, 220–*221*
Denaturing gradient gel electrophoresis (DGGE), *643,* 644f
Dendritic cells (DCs), *721,* 721f
Dendritic cells, in spleen, 725
Dengue fever, 623, 827

Denitrification, *245, 518, 628,* 657
Dental decay (caries), 704, 898–899, 898f
Dental plaque, 704, *898,* 898f
Deoxyribonucleic acid (DNA); *See* DNA (deoxyribonucleic acid)
Deoxyribonucleoside triphosphates (dNTPs), 407
Deoxythymidine monophosphate synthesis, 278f
Depth filters, as barrier to microorganisms, *175*
Dermatomycoses, *914*
Desert rheumatism, *905*
Destructive interference, in microscopy, 28
Desulfonema species, 629
Desulfotomaculum, 543, 543f
Desulfovibrio species, 532f, 628, 629
Desulfurococcaceae, 472
Desulfuromonales, 531–532, 629
Detergents to control microbes, *182*
DFA (direct immunofluorescent antibody) diagnosis, 856
DGCs (diguanylate cyclases), 335
DGGE (denaturing gradient gel electrophoresis), *643,* 644f
d'Herelle, Felix, 186, 206
DHFR (dihydrofolate reductatase), 198, 199f
Diabetes
  acarbose to treat type 2, 558
  type 1, 699, 765
  type 2, 699–700
Diarrhea
  bacteria causing, 934t
  Dientamoeba fragilis as cause of, 567
  Enterocytozoon bieneusi as cause of, 595
  rotaviruses as cause of, 612, 851
Diatoms
  in algal blooms, 653
  description of, *577*
  life cycle of, 578f
  in nanotechnology, 961, 961f
Diauxic growth of *Escherichia coli, 337,* 337f
Dicarboxylate/4-hydroxybutyrate (DC/HB) cycle, 266, 467–469, 468f
DIC (differential interference contrast) microscopy, *28,* 28f
Dictyostelium discoideum, 563, 570, 570f
Dideoxyadenosine triphosphate (ddATP), 420f
Dientamoeba fragilis, 567
Differential interference contrast (DIC) microscopy, *28,* 28f
Differential media, *156,* 157t
Differential staining, ***33–34***
Diffusely adhering *Escherichia coli* (DAEC), *892*
Diglycerol tetraether lipids, *82*
Diguanylate cyclases (DGCs), 335
Dihydrofolate reductatase (DHFR), 198, 199f
Dikaryotic stage, in fungal reproduction, *587*
Dilution susceptibility tests, to determine MIC and MLC, 192
Dimerized chromosomes, 296, 297f
Dimethylsulfoniopropionate (DMSP), 629
DinB (damage inducible polymerase), 380
Dinoflagellates
  Alexandrium, 653
  *Alveolata, 572–*573, 573f
  photosynthetic, 103
  Symbiodinium, 688–690
Diphtheria, 17, 557, *860,* 861f
Diplococci, as bacterial shape, *43*
Direct contact diseases
  of bacteria, **872–885**
    gas gangrene, *872*
    group B streptococcal disease, *872–*873
    leprosy, *873–*874
    peptic ulcer disease and gastritis, *874–*875
    sexually transmitted diseases, 875–879
    staphylococcal diseases, 879–883
    streptococcal diseases, 883–884
    tattoo-associated myobacterial infections, 874
    tetanus, 884–885
  of fungi and protists, **914–917**
  of viruses, **838–851**
    cold sores, 843–844
    common cold, 844–845
    cytomegalovirus inclusion disease, *845*
    genital herpes, *845–*846
    HIV/AIDs, *838–*843
    human herpesvirus 6 infection, *846*
    human parvovirus B19 infection, *846–*847
    mononucleosis, *847*
    viral hepatitides, *847–*849
    warts, *849–*851
Direct counts, *165*
Directed evolution, ***953–956,*** 955t, 956f
Direct identification of microorganisms
  clinical specimens for, 790
  culture-based methods for, 791–793
  microscopy for, 793–796
  molecular methods of, 796
Direct immunofluorescence, *795,* 795f
Direct immunofluorescent antibody (DFA) diagnosis, 856
Directly observed treatment short course (DOTS), 864
Direct repair, *379*
Direct staining, viability assessment by, 639f
Disaccharide structure, A.5f
Discriminatory ability, in adaptive immunity, *737*
Disease feature
  biofilms, 880
  malaria, history of, 907
  microorganisms as cause of disease, 14–15
  white-nose syndrome in bats, 593
Disease syndrome, *772*
Disinfection, *173,* 173f, 182t, 183f, *185*
Disinfection by-products (DBPs), in water purification, *965*
Disk diffusion tests, for rapidly growing microbes, 192–193
Dissimilatory iron reduction, 631
Dissimilatory nitrate reduction, *245, 628*
Dissimilatory sulfate reduction, 532f, *629*
Dissolved organic carbon (DOC), 663
Dissolved organic matter (DOM), *654*
Dissolved oxygen sag curve, 664, 664f
Distance method, for phylogenetic tree construction, 9f, 453, 453f
Distilled spirits, 943
Diversity, 458f, *737*; *See also* Microbial taxonomy and evolution of diversity
Division of Vector Borne Diseases, of Centers for Disease Control and Prevention (CDC), 827
Divisome, in septation, *137,* 137f, 137t
DMSP (dimethylsulfoniopropionate), 629
DNA (deoxyribonucleic acid); *See also* Bacterial genome replication and expression; Genomic methods; Recombinant DNA technology
  archaeal, *85*
  as bacterial genetic material, 285–286

in bacterial nucleoid, *67*
in base composition, 448
as dexoyribonucleotide polymer, *288*–290, 289f
Hfr conjugation transfer of chromosomal, *388*–389
mitochondrial, 102
protein interactions with, 437
repair of, 377–380
replication of, **291–298**
daughter chromosome separation for termination, 296–297
linear chromosome end protection, 297–298
origin of replication, 291
replication fork, 294–296
replisomes for, 291–294
replication of in eukaryotic and archaeal cells, 350–354
replisome synthesizing machinery for, *134*–135
RNA, protein and, 7f
DNA amplification, *407*
DNA-binding proteins, 323, 334

DNA-modifying agents, *372*
DNA polymerases, *291*–292, 293f, 296f, 352, 352t
DNA sequencing
next-generation methods of, 421–424
overview, 419–420
Sanger method of, 420–421
DNA vaccines, *821*–822, 822f
DNA viruses
bacterial transformation from free, 389–391
double-stranded, 599–609
archaeal, 605–606
bacteriophage lambda, 602–605
bacteriophage T4, 599–602
CRISPR/Cas system, 606–607
herpesviruses, 607–609
multiplication strategy of, 599f
nucleocytoplasmic large DNA, 609
minus-strand, *611*
negative-strand, *611*
plus-strand, *610*
reverse transcribing, 619–620
single-strand, 610–611
transduction for virus-mediated transfer of, 391–394
dNTPs (deoxyribonucleoside triphosphates), 407
DOC (dissolved organic carbon), 663
"Docking" in adherence, 775
Doctors without Borders, 809
Döderlein's bacillus, 705
DOM (dissolved organic matter), *654*
Domains of life, 8–11, 455–458
Dornagk, Gerhard, 189
DOTS (directly observed treatment short course), 864
Double diffusion agar assay, *802*
Double-stranded DNA viruses; *See* DNA viruses
Double-stranded RNA viruses, 611–613, 612f
Drinking water, safety of, 964–968, 966f
Droplet nuclei, *783*
Drug cocktails, 205
Drug resistance; *See also* Antibiotic resistance
bacteria with, *395*
gene expression systems for detecting, 193–194
overcoming, 205–206
Drugs, fungi for, 586
Drugs for microbe control; *See* Chemotherapy
Dry heat incineration, for microbe control, 179, 179f
DrySlide Nitrocefin, 194
Duchesne, Ernest, 189
Dunaliella viridis, 143
Duncan, Thomas Eric, 809
Dusch, Theodor von, 13
Dutch elm disease, 590, 667
Dyes
fluorescent, 29f
ionizable, 32t
for staining, *31*
Dysbiosis, 699, 765
Dysentery
amebic, 204, *917*–918, 918f
ampicillin effective against, 195
bacillary, *893*
bacteriophage therapies for, 186
Balantidium coli as cause of, 575
Entamoebida histolytica as cause of, 569
Shigella in, 529

E

Early life, RNA basis of, 5–8
Ears, microbiota adaptations in, 705
East Coast fever, in cattle, 576
Eastern equine encephalitis (EEE), 837
"Eating rocks" (chemolithotrophy), 250–252
EB (elementary body), in Chlamydial reproduction, *497*
Ebola virus disease (EVD)
epidemic of, 809
epidemiology of, 816
global climate change and, 623
overview, *854,* 854f
receptors for, 118
EBV (Epstein-Barr virus), 607, 847, 847f
ECF-A (eosinophil chemotactic factor of anaphylaxis), 761
ECF (extracytoplasmic function) sigmas, *336*
ECM (extracellular matrix), 151
Ecological characteristics, in microbial taxonomy, 448
Ecological studies, fluorescence microscopy in, 29
Ecotype model of microbial evolution, *459*
Ectomycorrhizae (ECM), *673*–674, 674f
Ectoplasm, *564*
Editing, in genome sequencing, *424*
ED (Entner-Doudoroff) pathway; *See* Entner-Doudoroff (ED) pathway
EEE (eastern equine encephalitis), 837
Eelgrass, wasting disease of, 579
EF (elongation factors), *311*
Effector cells, *744*
Effector response, *737*
Efflux pumps, *395*–396
EHEC (enterohemorrhagic *Escherichia coli*), 891f
Ehrlich, Paul, 188, 879
EIEC (enteroinvasive *Escherichia coli*), 891
Eimera, 576
Eldredge, Niles, 459
Electrokinesis, 526
Electromagnetic spectrum, 149f

Electron acceptors, 244t, 525f
Electron cryotomography, *38*–39, 39f, 92f, 838
Electron donor to electron acceptor reactions (redox), *213*–214, 214f
Electron microscopy, **34–39**
  electron cryotomography, 38–39
  light microscopy *versus,* 35f
  scanning, 38
  transmission, 34–37
Electron orbitals, chemical bonds and, A.2, A.2f
Electron shuttles, *525*
Electron sources, 228–229, 228t
Electron tower, 238f
Electron transfer, in *Heliobacterium modesticaldum,* 543f
Electron transport chains (ETC)
  in aerobic respiration, *238*–240, 238f, 239f, 240f
  in bacteria, 73
  bacterial, 242
  membrane-associated, 147, 215
  in metabolism, *214*–217, 215f
  to oxidative phosphorylation, 236–243
  of paracoccus denitrificans, 245f
Electrophoresis, 801–803; *See also* Gel electrophoresis
Electrophoretic mobility shift assays (EMSA), 437
Electroporation, *412*
Electrospray ionization-mass spectroscopy, 791
Elementary body (EB), in Chlamydial reproduction, *497*
ELISA (enzyme-linked immunosorbent assay); *See* Enzyme-linked immunosorbent assay (ELISA)
Ellis, Emory, 116
Elongation factors (EF), *311,* 312f
Embden-Meyerhof (EM) pathway
  as amphibolic pathway, 231f
  Borrelia burgdorferi use of, 500
  Calvin-Benson cycle connection to, 265–266
  carbohydrates catabolized by, 248
  in chemoorganotrophic archaea, 469–470, 470f
  diagram of, A.9f
  enteric bacteria use of, *527*
  Gammaproteobacteria use of, 519
  gluconeogenic pathway connection to, 267
  glucose to pyruvate catabolized in, *232*–233, 233f
  homolactic fermentation in, 246, *548*
  lipids catabolized by, 249
  mycoplasmas use of, 486
  in *Plasmodium,* 576
  reversed, in *Candidatatus,* 514
  reversible enzymes in, 231
Emiliania huxleyi, in *Haptophyta,* 579f
Emiliania hyxleyi, 659
EMSA (electrophoretic mobility shift assays), 437
Encephalitis
  amebic meningoencephalitis, 918–919
  as Chikungunya virus complication, *836*
  Encephalitozoon cuniculi as cause of, 595
  equine, *836*–837
  from rabies virus, 855
  West Nile fever, *837*
Encephalitozoon cuniculi, 439, 595, 696
Encrypting data in biostorage, 284
Encystment, *565*
Endemic diseases, *808*
Endergonic reactions, *211*
Enders, John, 853
Endocytic and secretory pathways, **95–98,** *96,* 98f, 118
Endogenous antigen processing, *742*
Endomycorrhizae, *673*
Endophytes, *672*
Endoplasm, *564*
Endoplasmic reticulum (ER), *95,* 100
Endosomes, *97,* 140
Endospores
  from *Bacilli,* 544–550
  as bacterial survival strategy, 75–77
  formation of, 77f
  schematic of, 76f
  staining of, *33,* 34f
Endosymbiosis, 688, 692f
Endosymbiotic hypothesis, **9–10,** 457, *457,* 457f
Endotoxins, *778,* 778–779
End product inhibition, to regulate enzymes, *224*
"End replication problem," 297, 298f, 352
Energy; *See also* Catabolism; Metabolism
  anabolism consumption of, *263*
  chemolithotropic yield of, 251–252, 251f, 251t
  conservation in eukaryotic cells, 100–104
  cycle of, in cells, 212f
  definition of, *209*
  in endosymbiosis, 692f
  sources of, 228–229, 228t
Enerococcus, Vancomycin resistance of, 195
Enhancers, as transcription activator bindings sites, *363,* 364f
Enology, *941*
Enriched media, *156,* 156f
Enrichment culture, *638*
Entamoebida, 569
Entercoccus faecalis, 389
Enteritis, campylobacters in, 535
Enteroaggregative *Escherichia coli* (ETEC), 891f, 892, *892*
Enterobacteria, 528f, 530t–531t, *817*
Enterobacteriales, 527–529
Enterobactin siderophore, 52f
Enterococcaceae, 43, 548, 549t
Enterococcus faecalis, 153, 705
Enterocytozoon bieneusi, 595
Enterohemorrhagic *Escherichia coli* (EHEC), 891f, *892*
Enteroinvasive *Escherichia coli* (EIEC), 891, *891,* 891f
Enteropathogenic *Escherichia coli* (EPEC), *891*–892, 891f
Enterotoxic *Escherichia coli* (ETEC), *890*–891, 891f
Enterotoxins, *885*
Enthalpy, *210*
Entner-Doudoroff (ED) pathway
  in chemoorganotrophic archaea, 469–470, 470f, 472–473
  diagram of, A.9f
  Gammaproteobacteria use of, 519
  glucose to pyruvate catabolized in, 232–234, 234f
  modified, in *Candidatatus,* 514
Entomopathogenic fungi, 583
Entropy, in thermodynamics, *210*
Entry into host, in life cycle of viruses, 118, 119f
Enveloped viruses, *112,* 113f, *115*
Environmental microbiology, 623, **964–980**
  biodegradation and bioremediation, ***976–979***
  drinking water safety, **964–968,** 966f–968
  microbially powered fuel cells, 975–976
  wastewater treatment, **968–975**
    challenges of, 974–975

home treatment systems, 974
processes, 969–972
quality measurement, 972–973
Enzyme-linked immunosorbent assay (ELISA), *799*–800, 801f, 837, 844, 936
Enzymes
activation energy lowered by, 220f
amphibolic, *263*
autolysin, *269*
β-lactamases (penicillin-destroying enzymes), 369
catalase, *148,* 148f
catalytic proteins as, 5
chromatin remodeling and modifying, 355
classification of, 219t
in complement system, *713*–716
core, of RNA polymerases, *301*
DNA polymerases, *291*–292, 293f
exoenzymes, *57*
induced fit model of function of, 220f
induction and repression of synthesis of, 323
lysozyme, *60*
in metabolism, 217–222
proteolytic, 761
restriction, 17
reverse transcriptase (RT), *402*
staphylococci, 881t
substrate concentration and, 221f
superoxide dismutase (SOD), *148,* 148f
transaminase, *270*
Eosin methylene blue agar, 156
Eosinophil chemotactic factor of anaphylaxis (ECF-A), 761
Eosinophils, *720,* 753, 761
EPA (U.S. Environmental Protection Agency), 184, 965, 965t
EPEC (enteropathogenic *Escherichia coli*), *891*–892
Epidemics
common-source, *812,* 812f
control and prevention of, 818–822
examples of, *808*–809
propagated, *812,* 814f
Epidemiologic Intelligence Program, Centers for Disease Control and Prevention (CDC), 808
Epidemiology, ***806*–826,** 807f
bioterrorism readiness, 822–824
data example of, 813f
emerging and reemerging infectious diseases, 815–816, 815t
epidemic control and prevention, 818–822
evidence basis of, 806–808
health-care facilities, infectious diseases in, 816–818
infectious dose 50% studied by, 770
methods in, 808–812
population patterns of infectious disease, 812–815
Epifluorescence microscopy, 29, 29f, *642*
Epilimnion, *664*
Epiphytes, *672*
Episomes, plasmids as, *68, 384*
Epitopes (antigenic determinant sites), *738*
Epothilones C and D (anticancer drugs), 955, 956f
EPS (extracellular polymeric substances), 151
Epsilonproteobacteria, 535–537, 536t
Epstein-Barr virus (EBV), 607, 847, 847f
Epulopiscium fishelsoni, 44–45, 45f
Equilibrium, reactions at, *210,* 211f
Equilibrium constant (K_{eq}), *210,* 213
Equine encephalitis, *836*–837
ER (endoplasmic reticulum), *95,* 100
Ergotism, 592, 592f, 779
ERIC (124–127 bp enterobacterial repetitive intergenic consensus) sequence, in microbial identification, 451
Erysipelas, *883*
Erythema infectiosum, *846,* 846f
Erythema migrans, 869
Erythroblastosis fetalis, *762*

Erythromonas, 508
Erythromycin antibiotic, 197, 197f
Escherichia coli
acidic tolerance response of, 145
average bacterial size of, 44
bacteriocin produced by, 713
bidirectional replication of chromosome of, 292f, 293t
in biological control of microorganisms, 172
biosynthesis in, 263t
catabolite repression in, 337–339
cell cycle of, 133, 134f
chemical concentrations and movement of, 75
chemotaxis in, 339–341
diauxic growth of, 337f
divisome of, 137f, 137t
electron transport chains of, 238–239, 240f
fecal contamination of water and, 529
food-borne diseases caused by, 19
food intoxication by, 933–934
gastroenteritis from, 890–892
glutamine synthetase regulatory enzyme of, 223–224, 223f
irradiation to control, 179
metabolism of pyruvate and formate by, 528f
methyl-directed mismatch repair in, 378f
mixed acid fermentation products of, 246t
nucleoid and chromosomes of, 68f
nutrient transport systems of, 51–52
phage fd, 610, 610f
sigma factors and sequences, 304t, 336t
specialized transduction in phage lambda of, 393
stringent response in, 344–345
T4 phage of, 114–117, 114f
2011 food-borne illness outbreak in Germany from, 937
as water purification indicator organism, 966
ESCRT proteins, 140, 140f
Estuaries, 652–653
ETC (electron transport chains); *See* Electron transport chains (ETC)
ETEC (enteroaggregative *Escherichia coli*), 891f, *892*
ETEC (enterotoxic *Escherichia coli*), *890*–891
Etest for sensitivity testing, *193,* 194f, 793
Ethylene oxide (EtO) to control microbes, 182–183, 184f, 929
E (exit) tRNA binding site, *310*
Euglenozoa, 567–568, 567f
Eukarya domain, protists and fungi in, **3–4**
Eukaryotes; *See also* Microbial growth
archaea cell cycle similarities to, 140–141
bacteria and archaea *versus,* 456t
ESCRT proteins of, 140, 140f
infection of, 123, 124f
replisomes in, 351t

Eukaryotic and archaeal genome replication and expression, **349–368**
cellular process regulation, 364–367
commonalities, 350
DNA replications, 350–354
transcriptions, 354–358
translation and protein maturation and localization, 358–364
in archaea, 363–364
bacteria protein folding similar to, 361
bacteria translation similar to, 360–361
localization and secretion, 361–363
overview, 358–360

  in filamentous Ascomycetes, 591f

in fungi, 586–587, 587f
mutualism necessary for, 694
in protists, 565
in *Saccharomyces cerevisiae* yeast, 590f
REP (35–40 bp repetitive extragenic palindromic) sequences, in microbial identification, 451
RER (rough endoplasmic reticulum), *95*–96
Reservoir, for pathogens, *771*
Reservoir host, *808*
Residual body, lysosomes as, *98*
Resolution of microscopes, *24*–26, 35f
Respiration
aerobic
electron transport to oxidative phosphorylation, **236–243**
ATP yield, 241–243
electron transport chains, 238–240
overview, 236–237
oxidative phosphorylation process, 240–241
glucose to pyruvate, 232–235
pyruvate to carbon dioxide, 236
anaerobic, 244–245
electron acceptors in, 244t
overview, *230*
Respiratory system
as immune barrier, 711–712, 711f
microbiota adaptations in, 705
syndromes of, 833–834
Response regulator, DNA-binding proteins as, *334*
Restriction enzymes, 17, *401*–402, 401f, 402t, *601*
Restriction fragment length polymorphism (RFLP) analysis, *450,* 451f, 936
Reticulate body (RB), in Chlamydial reproduction, *497*
Reticulopodia, *568*
Retinal Schiff base, 478–479, 479f
Retinoic-acid-inducible gene I (RIG-I)-like receptors (RLRs), *727*–729
Retroviruses, 402, 618–619, 618f
Revenue Marine Division, U.S. Treasury Department, 807
Reverse DNA gyrase, in hyperthermophiles, 147
Reverse electron flow, *252*
Reverse transcribing DNA viruses, 619–620
Reverse transcriptase (RT), *402, 618*–619
Reverse vaccinology, *950*
Reversible chain termination sequencing, *421,* 422f–423f, 424, 424f
Reversible covalent modification of enzymes, *223*–224, 223f
Reversion, 374
Reye's syndrome, 831
Reynman, Richard, 419
RFLP (restriction fragment length polymorphism) analysis, *450,* 451f, 936
RFs (replicative forms), 523, *610*
RGM (rapidly growing mycobacteria), 874
RGs (risk groups), of pathogens, 788
Rhesus (Rh) factor, in blood, 762, 764f
Rheumatic fever, 549, *868*
Rheumatoid arthritis, 699, 758, 765
Rhizaria protists, 571–572
Rhizobia
leguminous plants and, *677*–678
for nitrogen fixing, 510–512
stem-nodulating, 678–680, 678f, 679f
Rhizobium, 511f
Rhizomorphs, *674*
Rhizoplane and rhizosphere, *672*–676
Rhizopus stolonifer, 588, 589f
Rhodesiense HAT, 912
Rhodobacter sphaeroides, 72f
Rhodococcus, 558
Rhodopseudomonas palustris, 626–627
Rhodopsin-based phototrophy, 88, 258–259
Rhodopsin proteins, 478–479
Rhodospirillum centenum, 508f
Rhodospirillum rubrum purple nonsulfur bacterium, 507f
Rho termination factor, 304–305, 305f
Ribonucleic acid (RNA); *See* RNA (ribonucleic acid)
Ribosomal frameshifting, *619*
Ribosome-binding site (RBS), 310
Ribosomes
archaeal, *85*
bacterial, *66*–67, 67f, 310f
cellular pool of RNA in, 7
discovery of, *5*
eukaryotic, 98–100
eukaryotic *versus* bacterial and archaeal, 100f
nucleolus in synthesis of, 99
Riboswitches (sensory RNAs)
for cellular regulation, 329–332, *330,* 331f, 331t
translation controlled by, 332–333
translation inhibited by, 332f
Ribotyping, *450, 796*
Ribozymes, 217–*222,* 222t
Ribulose monophosphate pathway, got C1 compound assimilation, 524f
Ribulose 1, 5-bisphosphate carboxylase/oxygenase (RuBisCO), *265*
Rice University, 563
Rickettsia
parasitic or mutualistic, 508–509
Rocky Mountain spotted fever caused by, 508f, 509, 773, 871
Wolbachia pipientis, 687
Rickettsia rickettsii, 508f
Ricord, Philippe, 879
RID (radial immunodiffusion) assay, *801*–802
Riftia (tube) worms, at hydrothermal vents in ocean, 691
RIG-I (retinoic-acid-inducible gene I)-like receptors (RLRs), *727*–729
Ringworms, *914*
Rinovirus virion, 844, 844f
RISC (RNA-induced silencing complex), 366
Risk groups (RGs), of pathogens, 788, 789f
Risus sardonicus, 884
River blindness, 687
Rivers, microbial communities in, 662–663
RNA (ribonucleic acid)
as basis of early life, 5–8
catalytic, 222
catalytic (ribosomes), *5*
DNA, protein and, 7f
engineered (aptamers), 955
protocell formation with, 7
as ribonucleotide polymer, *290*
small RNAs to control translation, *332*–333
subgenomic, *614*
in viroids, 4
RNA-dependent DNA polymerase, *618*
RNA-dependent RNA polymerase, *612,* 616–618
RNA helicase domains, 729
RNA-induced silencing complex (RISC), 366
RNA-induced transcriptional silencing complex (RITS), 366
RNAPII promoter, *356,* 356f
RNA polymerase holoenzyme, 150, *301,* 303
RNA polymerases (RNAP), *301*–302, 302f, 355, 355t, 359f

RNA-Seq, 432, *434,* 434f
RNA silencing, *128*
RNA viruses
  double-stranded, 611–613, 612f
  minus-strand, *598,* 616–618, 616f
  negative-strand, 598f
  plus-strand, *598,* 598f, 613–616, 614f
RNA world hypothesis, *5,* 7f, 8
RNS (reactive nitrogen species), *729*
Robbins, Frederick, 853
Robotic automation of biochemical tests, 791
Rocky Mountain spotted fever, 508–509, 773, *871*–872, 872f
Rods, as microbe cell shape, 43f, *80,* 81f
Rohrer, Heinrich, 39
Rolling-circle replication, *387,* 387f
Rolling-hairpin replication by parvoviruses, 611, 611f
Roosevelt, Franklin D., 853
Root colonization, 675f
Rooted phylogenetic trees, 453

Saccharomyces rouxii, 143
Sac fungi, *590*
SAGA co-activator, *356*
Salem witchcraft trials, ergotism and, 592
Salivation, 711
Salk, Jonas, 853
Salk vaccine for polio, 853
Salmonella enterica serovar Typhimurium
  acidic tolerance response of, 145
  in Ames test, 376
  as bioterrorism agent, 822
  DNA fingerprinting to track, 806
Salmonella gastroenteritis, 892–893
Salmonella species
  ampicillin effective against, 195
  food-borne disease outbreaks, 19, 815
  in infections in 2010–2014, 788
  lysogenic conversion in, *123*
Salmonellosis, 892–893
SALT (skin-associated lymphoid tissue), *725,* 725f
Salt marshes, 654
Salvarsan, 879
Salvarsan arsphenamine, 189
SAM (sorting and assembly machinery) complex, 363
Sanger, Frederick, 17, 420
Sanger method of DNA sequencing, 420–421, 420f, 421f, 424f
Sanitation measures, 818
Sanitization, *173*
San Joaquin fever, *905*
Saprophytes, fungi as, *564, 586*
SAR11 (Sargasso Sea) clade, 514, 657–658
SARS-CoV (severe acute respiratory syndrome coronavirus) virus, 109, 120f, 788, 832f, 833
SAR supergroup, of protists, **570–579**
  Alveolata, 572–576
  Rhizaria, 571–572
  Stramenopila, 577–579
Satellite viruses, *4, 129*
Satratoxins, 779
Sauerkraut (fermented cabbage), 943
SBV (Schmallenberg virus), 597
Scaffolding proteins, in virus assembly, 120
Scale-up, in industrial microbiology, *952*
Scanning electron microscopy (SEM), *38,* 38f, 44f, 770
Scanning probe microscopy (SPM), *39*–40
Scanning tunneling microscopy, *39,* 39f
Scarlet fever, 539
Schaudinn, Fritz, 879
Schiff's reagent, 32
Schizosaccharomyces pombe, 92f
Schmallenberg virus (SBV), 597
Schroder, Georg Friedrich, 13
Schwann, Theodore, 13
Science magazine, 736
Scientific method, 4
Sclerotia, in fungi, *592*
Sclerotinia sclerotiorum, 682
Scrapie, prions as infectious agents of, 4, 129, 856
SCV (small cell variant), 523
SDS polyacrylamide gel electrophoresis (SDS-PAGE), 435
Secondary active transport, *51*–52, 83, 93
Secondary antibody response, 754–755
Secondary metabolites, *554, 952*
Secondary treatment of wastewater, 969t, *971,* 972f
Second law of thermodynamics, *210*
Second messengers, in global control systems, *335*
Secretory and endocytic pathways, eukaryotic, 95–98, *96*

Secretory IgA (sIgA) immunoglobulin, *752*–753, 758
Secretory pathway, *96*
Sec system, for protein secretion, *316*–318, 317f, *362,* 362f, 363t
Sedimentation basins, in water purification, *965*
Seedling blight, in rice, 589
Segmented genomes, *116, 612*
Selectins (cell adhesion molecules), *732*
Selective markers, in recombinant DNA technology, 408–*409*
Selective media, 156, *156,* 157t
Selective toxicity of chemotherapy, *189*–191
Selenocysteine, 307, 307f, 314
SELEX (systematic evolution of ligands by exponential enrichment), 955, 957f
Self-assembly, *70, 264*
Self-antigens, autoimmunity against, *760*
Self-reactive T-cells, 744
SEM (scanning electron microscopy), *38,* 38f, 44f, 770
Semmelweis, Ignaz Phillip, 783
Sense codons, *305,* 307
Sense strand of DNA, 299
Sensor kinase, *334*
Sensory rhodopsins, *479*
Sentinel cells, 570
Sepsis, 758, *892*
Septa, in fungal hyphae, *586*
Septate hyphae, *586*
Septation, in cytokinesis, *135*
Septicemia, 535, *776*
Septic shock, *778*–779, 780f, 862, *892*
Septic tanks, *974,* 974f
Sequencing by synthesis, *421*–422
SER (smooth endoplasmic reticulum), *95*
Serine pathway for C1 compounds, *512f*
Serology, *796*–797
Serotyping, 798
Serovars, definition of, *445*
Settling basins, in water purification, *965*
70S initiation complex for protein synthesis, 310–311
Severe acute respiratory syndrome (SARS), *833*
Sewage treatment plants, 969f
Sex pili, in bacteria, *69*
Sexually transmitted diseases (STDs), 875–879, **875–879**
  chlamydial, 875–876
  gonorrhea, *876*–877
  overview, 875
  summary of, 876t
  syphilis, *877*–879
  trichomoniasis, 917
Sexual reproduction, 380
Sheaths, in *Burkholderiales, 516*
Shewanella genus, 631–632
Shewanella oneidensis, 525, 525f
Shiga toxin-producing *Escherichia coli* (STEC), *892*
Shigella dysenteriae, 195, 822
Shigellosis, *893*
Shimomura, Osamu, 30
Shine-Delgarno sequence, *299,* 310–311, 332, 358, 363
Shingles, 607, 827–829, *828*
Shuttle vectors, plasmids as, *408*
"Sick building syndrome," fungi as cause of, 592, 592f
Sickle cell disease, 847
Siderophores, *52,* 52f, 631
Sigma factor (σ), of RNA polymerases, *301,* 303, 303f, 304t, 336t
Signal 1, in T-cell activation, *743*–744
Signal peptide, *316*–317, *362*
Signal recognition particle (SRP), *317*
Signal 2, in T-cell activation, *744*
Signature sequences, oligonucleotide, *449*
Signs of infectious disease, *772*
Silage, *945*
Silencer DNA sites, *363,* 364f
Silent mutations, *374*
Silver nitrate, 181
Silver sulfadiazine, 181
Simple staining, *32,* 32f
Simple transpositions, *383,* 383f, 384f
Sinclair, Upton, 936
Single-cell sequencing, *426*–427, 426f, 686
Single nucleotide polymorphisms (SNP), *452*
Single radial immunodiffusion (RID) assay, *801*–802
Single-stranded DNA binding proteins (SSB), *294,* 294f
Single-stranded DNA viruses, 610–611
Sin Nombre virus, 811
Sinorhizobium meliloti, 137
Sinusitis, *Haemophilus influenzae* in, 529
siRNAs (small interfering RNAs), *366*
Site-directed mutagenesis, *954,* 954f
Site-specific recombination, of genes, *382*
Sixth disease, roseola infantum as, 846f
Sizes of microbial genomes, 439f
Skin
  Erysipelas, *883*
  as immune barrier, 709–710, 710f
  microbiota adaptations on, 702–703
  mycobacterial infections of, 873–874
  staphylococcal infections of, 882f
  streptococcal diseases of, 883–884
Skin-associated lymphoid tissue (SALT), *725,* 725f
"Slapped face syndrome," erythema infectiosum as, 846f
S-layer, *61*–62, 62f, *84*
Slime
  as archaea cell envelope, 84
  in bacteria, *61*
  staphylococci as producer of, 880, 880f
Slime molds, *4,* 569f
Slime molds *(Myxogastria), 569*
Slow-reacting substance (SRS), 733
Slow sand filters, in water purification, *966*
Sludge, in wastewater treatment, 971
Small cell variant (SCV), 523
Small interfering RNAs (siRNAs), *366*
Small nuclear ribonucleoproteins (snRNPs), *357*
Smallpox (variola)
  cowpox-based vaccine against, 16
  description of, *835*–836
  rash in, 835f
  unsecured laboratory samples of, 788
  vaccine for, 820
Small RNAs (sRNAs), *332*–333, 333f, 333t
Small subunit (SSU) ribosomal RNA (rRNA)
  comparing, 8–9
  evolutionary relationships assessed by, 445, *449*–450, 450f, 451f
  to identify bacteria, 796
  mitochondria and chloroplasts analysis based on, 10
  in phylogenetic trees, 452
Smith, Hamilton, 17, 401, 424
Smooth endoplasmic reticulum (SER), *95*
Smuts (cereal crop disease), 14, 594
Snapping division, *557,* 557f
Sneezing reflexes, 711
Snow, John, 808
SNP (single nucleotide polymorphisms), *452*
snRNPs (small nuclear ribonucleoproteins), *357*

Social distancing, for infectious disease prevention, 818
SOD (superoxide dismutase), *148,* 148f
Sodium chloride impact on microbial growth, 143f
Sodium motive force in *Clostridium tetani,* 542f
Sofosbuvir, for hepatitis C, 849
Soil-dwelling pseudomonads, 230
Soil organic matter (SOM), *668*
Soils, microorganisms in, 667–671, 668f
Solid media, for laboratory culture of microbes, 159–160
Soluble substances in disease prevention, 17
Solutes, microbial growth affected by, 141–143, 142t
SOM (soil organic matter), *668*
Somatic hypermutation of V regions, *756*
Sorting and assembly machinery (SAM) complex, 363
SOS response, as DNA global control, *380*
Sour mash, in distilled spirits production, 943
Southern, Edwin, 403
Southern blotting, in recombinant DNA technology, 403–406, 404f
Soybeans, zygomycetes used with, 589
Spallanzani, Lazzaro, 13
Spanish influenza virus, 829
Specialized transduction, *393,* 394f
Species
  definition of, 10–11, *445*–446
  microbial, 458
Specific immunity, *708*
Specificity, in adaptive immunity, *737*
Specimens for microorganism identification, **790–797**
  direct identification
    clinical specimens, 790
    culture-based methods, 791–793
    microscopy, 793–796
    molecular methods, 796
  indirect identification, 796–797

University of Pennsylvania, 460
University of Texas, 483
Unrooted phylogenetic trees, 453
Unsaturated fatty acid synthesis, 279
UPC bar code patterns, 451
Upstream activating sequences (UASs), *363*
Uracil, *276*
Ureaplasma urealyticum, 486, 487f
Urediniomycetes, 594
Uridine 5'-triphosphate (UTP), 212
Uridine diphosphate glucose (UDPG), 267–268, 268f
Urinary tract infections (UTIs), 486, 524
U.S. Advisory Committee on Immunization, 850
U.S. causes of death, 810t
U.S. Department of Agriculture (USDA), 933
U.S. Department of Energy, 637, 683, 950
U.S. Department of Health and Human Services, 807, 824
U.S. Department of Homeland Security, 824
U.S. Department of Veterans Affairs, 849
Use dilution test of disinfectant potency, *185*
U.S. Environmental Protection Agency (EPA), 184, 965, 965t
U.S. Food and Drug Administration (FDA), 828
  antiviral drug approvals by, 202
  bacteriophage sprays approved by, 186
  Botox (type-A botulinum toxin) approved by, 889
  "generally recognized as safe" chemical food preservation, 931
  hepatitis C drugs approved by, 849
  irradiated food, approval of, 179
  Listeria monocytogenes prevention methods, 109
  on malaria diagnosis tests, 910
  microbe control agents regulated by, 184
  on *Pseudomonas fluorescens* contamination (2004–2005), 321
  Salmonella outbreaks and, 893
U.S. Marine Hospital Service (MHS), 807, 811
U.S. Public Health Service, 700, 807
Ustilaginomycetes, 594
Ustilago maydis, 594f, 595, 595f
U.S. Treasury Department, 807
UTIs (urinary tract infections), 486, 524
UTP (uridine 5'- triphosphate), 212
UV (ultraviolet) radiation, *149, 179,* 372, 372f

V

Vaccine-derived polio, 821
Vaccines, ***739–740***
  anthrax, 895
  attenuated cultures as, 16
  biotechnology in, 949–950
  diseases preventable by, 815–816
  group B *Streptococcus* (GAB), 950
  hepatitis A (infectious), 852
  human papillomavirus, 850
  influenza, 831
  malaria, strategies in, 910f
  MMR (measles, mumps, and rubella), 832
  Neisseria meningitidis serogroup B (MenB), 950
  pneumoncoccalconjugate, 899
  poliomyelitis, 853
  protective immunity from, 818–822, 819t, 821t
  rabies, 855
  rubella (German measles), 834
Vaccinia virus (VACV), 114f, 121f, 835
Vaccinomics, *818*
Vaginitis, bacterial, 561
Vaginosis, bacterial, 897–898
Valacyclovir antiviral drug, 202, 844
Valence, *738*
Valley fever, *905*
Vampirococcus, 695, 695f
Vancomycin, *195,* 196f
Vancomycin-resistant enterococci (VRE), *394–*395, 817
Vancomycin-resistant *Staphylococcus aureus* (VRSA), 394, 770, 815, 817
Vaporized hydrogen peroxide (VHP) sterilizing gas, 183
Variable (V) regions, *750,* 756
Variant Creutzfeldt-Jakob disease (vCJD), 18, 856, 856f
Varicella (chicken pox), 607, **828–829,** 828f, 829f
Vasoactive mediators, *720*
VBNC (viable but nonculturable cells), *162,* 175, *638,* 638t
vCJD (variant Creutzfeldt-Jakob disease), 18, 856, 856f
Vector-borne transmission of disease, *771, 784*
Vegetative cells, endospores to, 76
Vehicle transmission of disease, ***783–784,*** 784f
Veillonellaceae, 544
Venereal warts (anogenital condylomata), *849–*850
Venter, J. Craig, 419, 424
Verrucae vulgaris, *849*
Verrucomicrobia, as human symbiotes and methylotrophs, 497–499
Vertical gene transfer, *380*
Vertical transmission of disease, *784*
Vesicular transport, *361*
VHF (viral hemorrhagic fever), *854*
VHP (vaporized hydrogen peroxide) sterilizing gas, 183
Viable but nonculturable (VBNC) cells, *162,* 175, *638,* 638t
Viable counting methods, *166*
Vibrio alginolyticus, 72f
Vibrio cholerae, 67, 526, 786, 890f
Vibrio fischeri marine luminescent bacteria, 152
Vibrionales, 43, 44f, 526–527
Vibrio parahaemolyticus, 526
Vibrio species, quorum sensing in, 342–344
Vibroids, cell shape of, 139f
Viili (Finnish fermented milk), 939
Vinegar for microbe control, 181
Viral hemagglutination, *798,* 798f
Viral hemorrhagic fever (VHF), *854*
Viral hepatitides, *847–*849
Viral-mediated lysis of microbes, 186
Viral neutralization, *758*
Viral pneumonia, 833–834
Viral replication complex, 120f
Viricides, *174*
Virions, *111,* 111f, 112f, 114f
Virioplankton, *658*
Viroids, *4, 128,* 128f
Virulence factors, 770–*771,* 774–775, 776t
Virulent bacteriophages, *391,* 599–602
Virulent phages, *122*
Virus-associated pyramids, 606, 606f

Viruses, **109–131, 597–622**; *See also* Bacterial genome replication and expression; Climate change, biogeochemical cycling and; Microbial genomics
acellular organization of, 109–110
antiviral drugs, 200–203
archaeal, 110, 110f
bacteria and viroids *versus,* 128f
bacteria size *versus,* 45f
cancers associated with, 125f
Chamberland's work on, 15
cultivation and enumeration of, 125–127
double-stranded DNA, **599–609**
archaeal, 605–606
bacteriophage lambda, 602–605
bacteriophage T4, 599–602
CRISPR/Cas system, 606–607
herpesviruses, 607–609
nucleocytoplasmic large DNA, 609
double-stranded RNA, 611–613
Ebola, 809
infections from, 122–125
life cycle of, **116–122,** 117f
attachment, 117–118
entry into host, 118, 119f
assembly, 120
synthesis, 118–120
release of virions, 120–122
minus-strand RNA, 616–618
nucleic acid-based subviral agents, 127–129
overview, *4*
phylogeny of, 597–599
plus-strand RNA, 613–616
prions *versus,* 129
retroviruses, 618–619
reverse transcribing DNA, 619–620
single-stranded DNA, 610–611
structure of, 111–115
transduction for DNA transfer in, 391–394
Viruses, human diseases caused by, **827–858**
airborne transmittal of, **827–836**
chickenpox (varicella) and shingles (herpes zoster), 827–829
influenza, 829–831
measles (rubeola), 831–833
mumps, 833
respiratory syndromes and viral pneumonia, 833–834
rubella (German measles), 834–835
smallpox (variola), 835–836
arthropod transmittal of, **836–837**
direct contact diseases, **837–851**
cold sores, 843–844
common cold, 844–845
cytomegalovirus inclusion disease, *845*
genital herpes, *845*–846
HIV/AIDs, *838*–843
human herpesvirus 6 infection, *846*
human parvovirus B19 infection, *846*–847
mononucleosis, *847*
viral hepatitides, *847*–849
warts, *849*–851
food and water vehicles for, **851–854**
prion proteins for disease transmittal, 856–857
zoonotic diseases, **854–856**
Viruslike particles (VLPs), *658*
Vitamin B_{12}, in purine biosynthesis, 277
Voges-Proskauer test, for fermentation, 527
Volta, Alessandro, 474
Vomiting, bacteria causing, 934t
VRE (Vancomycin-resistant enterococci), *394*–395, 817
VRSA (Vancomycin-resistant *Staphylococcus aureus*), 394, 770, 815, 817

W

Waksman, Selman, 189, 262, 559
"Walking pneumonia," 487
Wampler, Inc., 933
War of the Worlds (Wells), 736
Warts, *849*–851
Wassermann, August von, 879
Wasserman test, 799
Waste prevention, metabolism regulated for, 222–224
Wastewater treatment, 208, **968–975**
challenges of, 974–975
common contaminants, 969t
home treatment systems, 974
methods in, 969t–970t
processes, 969–972
quality measurement, 972–973
Water; *See also* Wastewater treatment
